PREFACE

Over four decades ago, a new compendium of medicine was published under the aegis of Association of Physicians of India. This was due to the vision and hard work of the stalwarts at that time. The first edition of the book was edited by an internationally famed physician Dr Rustam Jal Vakil. The book was well accepted all over the country. Enthused by the response of Indian physicians, eight more editions of the book have been published. Each new edition was an attempt to improve and incorporate the changing profile of medicine.

In the last decade, the progress has far outstripped the progress made in the previous decades. It is in this milieu of continuous change that I have the pleasure of presenting to you the 9th edition of the popular, API Textbook of Medicine. The book is completely revised, updated and better illustrated. There are around 2200 pages with nearly 1588 figures and 1384 tables. There has been a marked 20% increase in the number of figures and nearly 100 new tables have been added than the last edition. This has been done so that the information is easily understood and the reading is not a strain. The book has been divided into 28 sections and each section deals with a special set of medical disorders.

An entirely new section has been added, 'Clinical Approach to Key Manifestations'. This section deals with the common symptoms and signs with regard to how to scientifically and systematically analyse the problem to arrive at a definitive diagnosis in a timely and cost-effective manner. New authors have been requested to contribute new chapters so that the book is entirely re-written in most of the parts and some of the chapters have been exhaustively revised by the previous authors. A few chapters and figures have been reproduced from the 8th edition. I, on my own behalf and on behalf of the Editorial Board of the 9th edition, express our thanks to the erstwhile Editor-in-Chief, Dr Siddharth N Shah of the 8th Edition for having given us this permission.

The explosion of knowledge in medicine is phenomenal and fast so it outpaces the printed textbook of medicine. Therefore the 9th edition endeavours to reflect on some of these changes occurring in medicine during the preceding few years. A number of new chapters have been added like Non Invasive Ventilation under Critical Care. Pharmacotherapy of Cardiovascular Diseases has been added in the section of Cardiology. In the Section of Gastrointestinal Disorders, a new chapter on the Gastrointestinal Symptoms due to Systemic Diseases has been added. The Neurology section has been enriched by adding a chapter on Neuroimaging and separate chapters have been written covering Amyotrophic Lateral Sclerosis and Hyperkinetic Movement Disorders. In the field of Rheumatology, Emergencies have been discussed as a separate chapter altogether which reflects the new way of thinking of treatment and diagnosis of various rheumatic emergencies. The section of Medical Genetics has been thoroughly revised and updated. Genetics is better understood and human genome has been completely delineated. This has tremendous potential for change in the way we practice medicine. Vascular Injury to Kidney and Chronic Dialysis under the section of Nephrology have been discussed in separate chapters because of the better understanding and growing importance of various facets of kidney disorders and diagnosis. An entirely new chapter on Nano Technology and Nano Medicine has been added which is going to be a new paradigm in the field of Clinical Pharmacology. The other sections have been duly revised and updated so that they provide contemporary information and clinical thinking.

The expanse of medicine is vast and varied. The presentation of all disorders in a concise and systematic manner in a book of this size has to be a joint collaborative effort. This has been possible due to the support, constructive criticism and useful editorial guidance from all the members of my editorial team for which I am grateful to them. I am especially indebted to Prof. SK Sharma who has been instrumental in guiding and planning this assignment at the cost of his precious time despite his multifarious academic activities. Dr AK Agarwal and Dr RK Singal have been closely associated and have provided useful inputs and suggestions in preparation of this book for which I am grateful to them. Dr Milind Y Nadkar and Dr Sandhya A Kamath provided useful inputs as to how to circumvent some of the key issues while editing a book of this nature because of their past experience of the 8th Edition of the Textbook. Dr Shyam Sundar, Dr Subhash Varma and Dr Pritam Gupta were forthcoming in their help and suggestions for which I owe my thanks to them. Dr Siddharth N Shah, the Emeritus Editor has guided and supported whenever his help was sought for in the production of this book. I am obliged to him for all his help. The Sectional Editors were generous with their time and suggestions while the authors of chapters contributed their chapters in time and as per the common format which was agreed upon. For all this, I convey my sincere thanks to them.

In the era, of information technology, in consonance with the international practice, a new website for the book, 'API Textbook of Medicine', has been created (www.apitextbook.com). It is a novel feature starting from this edition with online access which will be easily available to all those people who purchase the book. Periodically, the website will be upgraded and new information will be added.

During the entire course of past three years of compiling of this book, my wife Dr Rama Munjal, son Dr Akshay Munjal and daughter Er. Jaya Munjal were a source of great strength and motivation. They showed tolerance and forbearance at all times during the preparation of this book. For all their support I wish to place on record my heartfelt thanks. On the completion of this major task, I feel more humble and ever so grateful to the Governing Body of API for having given me this opportunity to carry out this job for and on behalf of our organisation.

Dr Yash Pal Munjal
Editor-in-Chief
API Textbook of Medicine
9th Edition

ACKNOWLEDGEMENTS

The 9th Edition of the API Textbook of Medicine is now available to you. This has been possible due to the collaborative, co-operative and untiring efforts of the Editorial team and many others. On the occasion of the successful completion of this marathon job, it would be appropriate to acknowledge and express my gratitude to all those who have helped in getting this job well done. I am especially grateful to Dr Anupam Prakash and Dr Ghan Shyam Pangtey. They have been associated from the stage of conceptualisation and planning to the final production of this manuscript and have provided unstinted help all through this exercise with dedication and commitment. Dr AP Misra, Dr Anurag Saxena, Dr DG Jain and Dr Sumit Singla have provided useful help at various stages which is duly acknowledged. The task of proof reading and organising the manuscripts was painstakingly and continuously carried out by Mr RK Gupta, Mr DK Sahu, Mr MS Muddur and other members of their team. The efforts of Mr RK Gupta especially stand out and I would like to express my thanks to all of them. I would like to express my thanks to Mr Sanjeev Chaudhry of 'Initials' for having done the initial type setting of the book.

The final production of the book has been possible due to the hard work put in by the staff of Jaypee Brothers Medical Publishers. The good work done deserves our appreciation and gratitude to Shri Jitendar P Vij, Chairman and Managing Director of Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, which is now the second largest Medical Publishers in the world.

Mr Tarun Duneja (Director Publishing) has been instrumental in getting the final shape of the book. The other members of Jaypee Brothers, Ms Shikha Gupta (Editor), Mr Manoj Pahuja and Mr Ankit Kumar (Graphic Designers), Mr Pramod Kumar Rout and Mr Kapil Dev Sharma (DTP Operators), and Mr KK Raman (Production Manager) have done a marvellous job and put in hard work in the production of this book. They were receptive and wore the brunt of this task willingly. They coordinated with the office of editorial board as a team and carried out the instructions diligently. They deserve our appreciation and thanks.

I would like to express my sincere thanks to my Secretary, Ms Pushap Lata, for having taken up the additional responsibility with a smile on her face at all times. Ms Neha Garg, who joined at a later stage in the book production, was enthusiastic and co-ordinated the work very effectively and efficiently both in compiling as well as proof reading in the final stages of the book.

I would be failing in my duty if I do not express my sincere thanks to Shri Autar Krishna, Chairman and Shri Bhuwan Mohan, Secretary of Shri Banarsidas Chandiwala Sewa Smarak Trust Society for providing the office space and allowing the use of infrastructure during the entire course of the publication of this assignment. Not only they provided the infrastructural support but they also encouraged me in my task as the 'Editor-in-Chief' of this book.

The help of Sectional Editors for editing the section diligently and providing editorial inputs which were very useful and timely is highly appreciated. I would like to extend our thanks on behalf of the Editorial Board and the authors who have been provided useful assistance by their colleagues in preparation of their respective manuscripts.

Dr YP Munjal

CONTENTS

Section 1: Introduction

1. **The Practice of Medicine** 2
Yash Pal Munjal

Section 2: Clinical Approach to Key Manifestations

2.1 **Pain—Mechanisms and Management** 10
D. Rama Rao, Niranjan P. Moulik

2.2 **Headache** 12
K. Ravishankar

2.3 **Chest Pain** 16
Sanjay Tyagi, Amit Mittal

2.4 **Acute Abdomen—Non-Surgical Causes** 20
Sumeet Singla, A.K. Agarwal

2.5 **Cough** 25
Suman Kirti

2.6 **Haemoptysis** 29
Randeep Guleria, Jaya Kumar

2.7 **Jaundice** 32
Aparna Agrawal

2.8 **Upper Gastrointestinal Bleeding** 39
J.C. Vij

2.9 **Fever of Unknown Origin** 42
Priscilla Rupali

2.10 **Generalised Lymphadenopathy** 47
S.K. Verma

2.11 **Dizziness and Vertigo** 49
M. Maiya

2.12 **Syncope** 53
Pushpa Yadav, Vivek Arya

2.13 **Coma** 57
B. Vengamma

Section 3: Diagnostic Imaging

3.1 **Conventional Radiology** 64
Ashu Seith Bhalla, Ankur Gadodia

3.2 **Ultrasound in Medicine** 78
B.S. Rama Murthy

3.3 **Computed Tomography** 84
Bhavin Jankharia, Nishigandha Burute

3.4 **MRI in Medicine** 91
Raju Sharma, Ankur Gadodia

3.5 **Nuclear Imaging** 100
B.R. Mittal

3.6 **Positron Emission Tomography** 113
Rakesh Kumar, Varun Shandal

Section 4: Clinical Pharmacology

4.1 **Introduction and Scope of Clinical Pharmacology** 120
Ranjit Roy Choudhury, Urmilla Thatte

4.2 **Rational Use of Drugs** 123
Sangeeta Sharma

4.3 **Adverse Drug Reactions and Pharmacovigilance** 125
M.C. Gupta

4.4 **Prescribing in Special Situations** 128
Uma Tekur

4.5 **New Drug Development** 133
Sadhna Joglekar

4.6 **Pharmacoeconomics** 135
Gurudas Khilnani

Section 5: Immunology

5.1 **An Overview of the Immune System** 138
Sita Naik

5.2 **General Concepts of Immunoinflammatory Disorders** 146
Ramnath Misra

5.3 **Immunology of Infectious Diseases** 149
Sita Naik

5.4 **Primary Immunodeficiency Disorders—A Clinical Approach** 151
Surjit Singh

5.5 **Laboratory Investigations in Immune-Mediated Diseases** 155
Amita Aggarwal

5.6 **Pharmacological Manipulation of the Immune System** 159
Mitali Chatterjee

5.7 **Immunology of Organ and Haematopoietic Stem Cell Transplantation** 164
Narinder K. Mehra, Jamshaid A. Siddiqui

Section 6: Medical Genetics

6.1 **Introduction to Medical Genetics** 170
Shyam Swarup Agarwal

6.2 **Mendel and Beyond** 173
Ratna Dua Puri

6.3 **Clinical and Molecular Cytogenetics** 180
Ashutosh Halder

6.4 **Genetic Tests** 189
Ashwin Dalal

6.5 **Inborn Errors of Metabolism** 193
Madhulika Kabra

6.6 **Molecular Genetics, Human Genome Project and Genomic Medicine** 201
Girisha K.M.

6.7 **Gene Therapy** 206
Rita Mulherkar

6.8 **Genetic Counselling and Prenatal Diagnosis** 209
Shubha R. Phadke

6.9 **Pharmacogenomics and Personalised Medicine** 215
C. Adithan

6.10 **Cancer Genetics** 217
Rajiv Sarin

Section 7: Critical Care Medicine

7.1 **Basic Considerations in Critical Care** 224
R.K. Mani

7.2 **Monitoring of Critically Ill Patients** 227
M. Hanumantha Rao

7.3 **Fluid and Electrolyte Balance in Health and Disease** 232
Sanjay Jain

7.4 **Acid-Base Disorders** 239
Alladi Mohan, Surendra K. Sharma

7.5 **Enteral and Parenteral Nutrition in Critically Ill Patients** 246
Shilpa S. Joshi

7.6 **Acute Respiratory Failure** 251
Ashit M. Bhagwati

7.7 **Sepsis and Acute Respiratory Distress Syndrome** 256
Alladi Mohan, Surendra K. Sharma

7.8 **Mechanical Ventilation** 263
Surender Kashyap, Surinder Singh

7.9 **Non-Invasive Ventilation** 271
Dhruva Chaudhry, Inderpaul Singh

7.10 **Hypotension and Shock** 277
Anil Dhall, Sanjat S. Chiwane

7.11 **Cardiopulmonary Resuscitation** 282
Ashit M. Bhagwati

7.12 **Brain Death and Support of the Brain-Dead Organ Donor** 289
Rajesh Chawla, Guneet Singh

Section 8: Bone Disorders

8.1 **Bone and Mineral Metabolism in Health and Disease** 294
Deepak Khandelwal, Ravinder Goswami

8.2 **Investigations and Diagnosis of Bone Disorders** 299
Sukumar Mukherjee

8.3 **Rickets and Osteomalacia** 305
Bindu Kulshreshtha, Sachin K. Jain

8.4 **Osteoporosis** 309
S.N.A. Rizvi

8.5 **Developmental Disorders of Bone** 313
Rakesh K. Sahay

8.6 **Miscellaneous Bone Disorders** 316
C.V. Harinarayan

Section 9: Diabetes Mellitus

9.1 **Epidemiology and Basic Considerations of Diabetes** 321
A. Ramachandran, C. Snehalatha

9.2 **Pathogenesis of Type 1 Diabetes Mellitus** 324
V. Mohan, Rakesh Parikh

9.3 **Pathogenesis of Type 2 Diabetes Mellitus** 327
Hemraj B. Chandalia

9.4 **Clinical Features and Diagnosis of Diabetes Mellitus** 331
D. Maji

9.5 **Lifestyle Modifications in Management of Diabetes** 336
B.K. Sahay

9.6	**Oral Anti-Diabetic Drugs** *Anil Bhansali, Viral Shah*	339
9.7	**Insulin Therapy** *Rama Walia*	343
9.8	**Newer Modalities of Treatment in Type 2 Diabetes Mellitus** *Anil Bhansali, G. Shanmugasundar*	347
9.9	**In-Hospital Management of Diabetes Mellitus** *Nihal Thomas, Rahul Ramnik Baxi*	350
9.10	**Hypoglycaemia** *Siddharth N. Shah*	354
9.11	**Diabetic Ketoacidosis, Hyperosmolar Hyperglycaemic State and Lactic Acidosis** *Rajesh Rajput*	359
9.12	**Infections in Diabetes Mellitus** *Samar Banerjee*	364
9.13	**Macrovascular Complications of Diabetes** *Murlidhar S. Rao*	368
9.14	**Microvascular Diseases—Pathogenesis of Chronic Complications** *Suman Kirti*	372
9.15	**Diabetes and Kidney Disease** *Jamal Ahmad*	375
9.16	**Diabetic Retinopathy** *Amod Gupta, Reema Bansal*	377
9.17	**Diabetic Neuropathy** *Manish Modi*	382
9.18	**Sexual Dysfunction in Diabetes** *Shashank R. Joshi*	385
9.19	**The Diabetic Foot** *Pendsey Sharad Purushottam*	387
9.20	**Diabetes and Pregnancy** *V. Seshiah*	390
9.21	**Prevention of Diabetes Mellitus** *Yash Pal Munjal*	393

Section 10: Endocrinology

10.1	**Basic Considerations of Endocrinology** *Ashok Kumar Das*	398
10.2	**Endocrine Disorders—A Clinical Approach** *M.S. Seshadri*	403
10.3	**Disorders of Hypothalamus and Pineal Gland** *Abdul Hamid Zargar, Bashir Ahmad Laway*	407
10.4	**Disorders of Anterior Pituitary** *R.V. Jayakumar*	410
10.5	**Disorders of Posterior Pituitary** *G.R. Sridhar*	417
10.6	**Disorders of Thyroid Glands** *Nikhil Tandon, Gunjan Garg*	419
10.7	**Disorders of Parathyroid Glands** *Ambrish Mithal, Beena Bansal*	430
10.8	**Disorders of Adrenal Glands** *Eesh Bhatia, Vijayalakshmi Bhatia*	433
10.9	**Disorders of Puberty** *A.C. Ammini*	442
10.10	**Disorders of Growth and Development** *Nalini S. Shah*	446
10.11.	**Disorders of Gonads** *Shashank R. Joshi*	452

Section 11: Dermatology

11.1	**Introduction and Principles of Diagnosis in Dermatology** *Vibhu Mendiratta*	462
11.2	**Cutaneous Infections** *Vineet Kaur, Gurmohan Singh*	470
11.3	**Infestations and Insect Bites** *Devinder Mohan Thappa, Laxmisha Chandrashekar*	475
11.4	**Eczemas** *Ashok Kumar Bajaj*	480
11.5	**Drug Reactions** *M. Ramam*	487
11.6	**Abnormal Vascular Responses** *A.K. Jaiswal, T.S. Nagesh*	491
11.7	**Papulosquamous Disorders** *K. Pavithran*	494
11.8	**Autoimmune Bullous Disorders** *K.K. Raja Babu*	498
11.9	**Disorders of Pigmentation** *Bhushan Kumar*	501
11.10	**Disorders of Skin Appendages** *Raj Kubba, Tanvi Pal*	507
11.11	**Cutaneous Responses to Physical Factors** *S. Criton*	512
11.12	**Genodermatoses** *Vibhu Mendiratta*	515
11.13	**Skin in Connective Tissue Diseases** *Sandipan Dhar*	520
11.14	**Skin in Systemic Diseases** *Uday Khopkar*	526
11.15	**Leprosy** *B.K. Girdhar*	534
11.16	**Sexually Transmitted Infections** *Vinod K. Sharma, Naresh Jain*	541
11.17	**Premalignant Conditions and Malignant Tumours of the Skin** *Arun C. Inamadar, Aparna Palit*	546
11.18	**Therapy of Dermatological Diseases** *M.K. Singhi*	549

Section 12: Cardiology

12.1	**Basic Considerations in Cardiology** *Upendra Kaul, Aijaz H. Mansoor*	557
12.2	**Cardiovascular Diseases—A Clinical Approach** *G.S. Sainani*	561
12.3	**Electrocardiology** *M.J. Gandhi*	570
12.4	**Exercise Testing** *Yash Pal Munjal*	580
12.5	**Echocardiography** *Satish Kumar Parashar*	585
12.6	**Cardiac Imaging** *Priya Jagia, Sanjiv Sharma*	595
12.7	**Nuclear Cardiology** *Vikram R. Lele, Parag Aland*	605
12.8	**Cardiac Catheterisation and Angiocardiography** *Lekha Adik Pathak, N.O. Bansal*	610

12.9	**Pharmacotherapy of Cardiovascular Disorders** *J.C. Mohan, Vipul Mohan*	615
12.10	**Heart Failure** *Donald Kikta, Veronica Franco*	621
12.11	**Heart Failure Management** *Veronica Franco, Ragavendra Baliga*	624
12.12	**Acute Rheumatic Fever** *R. Krishna Kumar*	629
12.13	**Valvular Heart Disease (I)** *C.N. Manjunath*	637
12.14	**Valvular Heart Disease (II)** *V.K. Bahl, Ishwar Chandra Malav*	643
12.15	**Infective Endocarditis** *Shyam S. Kothari*	652
12.16	**Atherosclerosis** *K.K. Sethi, S. Lahiri*	661
12.17	**Ischaemic Heart Disease** *Inder S. Anand, Shibba Takkar Chhabra*	666
12.18	**Acute Coronary Syndrome** *Gurpreet Singh Wander, Naveen Kumar Gupta*	673
12.19	**Acute Myocardial Infarction** *Gurpreet Singh Wander, Naved Aslam*	677
12.20	**Hypertension** *M. Paul Anand*	685
12.21	**Management of Hypertension** *Sandhya Kamath*	691
12.22	**Secondary Hypertension** *B.B. Thakur, Arohi Kumar*	698
12.23	**Bradyarrythmias** *Yash Y. Lokhandwala, Gopi Krishna Panicker*	702
12.24	**Tachyarrhythmias** *Amit Vora*	707
12.25	**Sudden Cardiac Death** *Ashish K. Thakur*	713
12.26	**Congenital Heart Disease** *Sunita Maheshwari*	716
12.27	**Heart in Systemic Disease** *Aspi R. Billimoria*	724
12.28	**Disorders of Myocardium** *K.K. Talwar, Pawan Poddar*	728
12.29	**Diseases of the Pericardium** *Sanjay Tyagi, Amit Mittal*	737
12.30	**Surgical Management of Heart Disease** *Muhammad Abid Geelani, Nikhil Prakash Patil*	746
12.31	**Diseases of the Aorta** *Manotosh Panja*	750
12.32	**Vascular Disorders of the Extremities** *Gurpreet Singh Wander, Bishav Mohan*	757
12.33	**Pregnancy and Heart Disease** *Amal Kumar Banerjee*	764

Section 13: Gastroenterology

13.1	**Clinical Approach—Gastrointestinal Disorders** *A.C. Anand*	770
13.2	**Investigations—Gastrointestinal Disorders** *Ashok Chacko*	774

13.3	**Endoscopy—Diagnostic and Therapeutic Utility** *Gourdas Choudhuri*	777
13.4	**Diarrhoea and Malabsorption** *B.S. Ramakrishna*	782
13.5	**Constipation—Diagnosis and Management** *Uday Chand Ghoshal*	787
13.6	**Gastrointestinal Bleeding** *Rakesh Kochhar, Mohd. Talha Noor*	791
13.7	**Oesophageal Disorders** *Shobna J. Bhatia, Praveen Mathew*	799
13.8	**Diseases of the Stomach and Duodenum** *Pankaj Dhawan*	806
13.9	**Diseases of the Pancreas** *V. Balakrishnan, G. Rajesh*	813
13.10	**Functional Gastrointestinal Disorders** *Philip Abraham*	819
13.11	**Abdominal Tuberculosis** *Govind K. Makharia*	823
13.12	**Inflammatory Bowel Disease** *Ajit Sood, Vandana Midha*	829
13.13	**Ischaemic Bowel Disorders** *Deepak Kumar Bhasin*	834
13.14	**Gastrointestinal Symptoms in Systemic Diseases** *Rakesh Tandon, Sudeep Khanna*	837

Section 14: Hepatology

14.1	**Basic Considerations of Hepatobiliary Disorders** *Vivek Anand Saraswat*	842
14.2	**Hepatobiliary Disorders—A Clinical Approach** *Nagaraja Rao Padaki*	846
14.3	**Hepatobiliary Disorders—Investigations** *Radha K. Dhiman*	851
14.4	**Hepatobiliary Disorders—Imaging** *Shrinivas B. Desai*	855
14.5	**Acute Viral Hepatitis** *Deepak Amarapurkar*	862
14.6	**Chronic Viral Hepatitis** *Rajesh Upadhyay, Nitin Gupta*	867
14.7	**Chronic Non-Viral Hepatitis** *C.E. Eapen*	870
14.8	**Alcoholic Liver Disease** *Nitin Gupta, Rajesh Upadhyay*	873
14.9	**Cirrhosis of the Liver** *Philip Abraham*	878
14.10	**Extra-Hepatic Portal Venous Obstruction** *Sharad Shah*	883
14.11	**Non-Alcoholic Fatty Liver Disease** *Yogesh K. Chawla, Sunil Taneja*	885
14.12	**Acute Liver Failure** *S.K. Acharya, Shalimar*	888
14.13	**Inherited Metabolic Disorders of the Liver** *P. Advaitham*	892
14.14	**Parasitic Diseases of the Liver** *Samir R. Shah*	895
14.15	**Toxic and Drug Induced Liver Injury** *Abraham Koshy*	898

14.16	**Liver Transplantation** *Subash Gupta, Ajay Kumar*	899
14.17	**Pregnancy and Liver Disease** *Ramesh Roop Rai*	901
14.18	**Liver in Systemic Disease** *Premashis Kar, Rajiv Singla*	905
14.19	**Tumours of the Liver** *Kaushal Madan, Pankaj Tyagi*	908
14.20	**Diseases of Gall Bladder and Biliary Tract** *Rakesh Tandon*	911

Section 15: Haematology

15.1	**Haematopoiesis** *Shaji V. Ramachandran, Vikram Mathews*	916
15.2	**Anaemia—A Clinical Approach** *Renu Saxena, M. Mahapatra*	922
15.3	**Splenomegaly—A Clinical Approach** *Lalit Kumar, Anuj Kumar Bansal*	926
15.4	**Iron Deficiency Anaemia** *Subhash Varma*	928
15.5	**Megaloblastic Anaemia** *Tarun Kumar Dutta*	933
15.6	**Hereditary Haemolytic Anaemia** *M.B. Agarwal*	938
15.7	**Acquired Haemolytic Anaemia** *Farah F. Jijina*	947
15.8	**Aplastic Anaemia** *Dharma R. Choudhary, Tuphan Kanti Dolai*	952
15.9	**Acute Leukaemia** *S.H. Advani*	956
15.10	**Chronic Myeloid Leukaemia and Other Myeloproliferative Disorders** *Tapan Kumar Saikia*	963
15.11	**Myelodysplastic Syndromes** *Rajat Kumar, Seema Tyagi*	966
15.12	**Chronic Lymphocytic Leukaemia** *M. Mahapatra, Renu Saxena*	970
15.13	**Lymphoid Neoplasms** *Bharath Rangarajan, Purvish M. Parikh*	974
15.14	**Plasma Cell Dyscrasias** *Pankaj Manubhai Shah*	979
15.15	**Bleeding Disorders** *Kanjaksha Ghosh*	984
15.16	**Platelet Disorders** *S.K. Bichile*	987
15.17	**Disorders of Coagulation** *Jina Bhattacharyya*	990
15.18	**Hypercoagulable Disorders** *Mammen Chandy*	996
15.19	**Transfusion Medicine** *Neelam Marwaha*	1000
15.20	**Haematopoietic Stem Cell Transplantation** *Velu Nair*	1004

Section 16: HIV and AIDS

16.1 **Epidemiology** 1012
O.C. Abraham, Susanne A. Pulimood

16.2 **Virology, Immunology and Diagnosis** 1014
V. Ravi, Anita Desai

16.3 **Pathophysiology and Clinical Features** 1017
U.L. Wagholikar

16.4 **Antiretroviral Therapy** 1023
B.B. Rewari, Sanjeev Sinha

16.5 **Drug Resistance** 1026
Alaka Deshpande

16.6 **Non-Opportunistic Infections** 1029
Anil Kumar Tripathi, Shailendra P. Verma

16.7 **Opportunistic Infections** 1032
Natasha Edwin, Dilip Mathai

16.8 **Non-Pharmacologic Interventions and Prevention** 1036
R. Sajithkumar

Section 17: Infectious Diseases

A. General Considerations

17.1 **Basic Considerations of Infections** 1042
Subhasish Kamal Guha

17.2 **Laboratory Diagnosis of Infections** 1044
Camilla Rodrigues

17.3 **Syndromic Approach to Infectious Diseases** 1048
Rajeev Soman

17.4 **Anti-Microbial Therapy—An Overview** 1051
Jagriti Bhatia, Dharamvir Singh Arya

17.5 **Infections in the Immunocompromised Host** 1058
Ghan Shyam Pangtey, Anupam Prakash

17.6 **Hospital Acquired Infections/Nosocomial Infections** 1060
A. Shobhana

17.7 **Prevention of Health Care Associated Infections** 1063
B.B. Rewari, Usha K. Baveja

17.8 **Hospital Infection Control** 1067
Rohini Kelkar

B. Bacterial Infections

17.9 **Staphylococcal Infections** 1069
Rita Sood

17.10 **Streptococcal Infections** 1072
Abhay Narain Rai

17.11 **Pneumococcal Infections** 1074
D.P. Bhadoria, Koushik Dutta

17.12 **Meningococcal Infections** 1077
R.K. Singal, Vivek Pal Singh

17.13 **Gonococcal Infections** 1080
Chander Grover

17.14 **Typhoid Fever (Enteric Fever)** 1083
Swapan Kumar Niyogi

17.15 **Bacillary Dysentery** 1086
Pankaj Tyagi, Jyotsana

17.16 **Cholera** 1088
S.K. Bhattacharya, Dipika Sur

17.17 **Diseases Caused by Gram-Negative Enteric Bacilli** 1090
Richa Dewan, Vivek Kumar
17.18 ***Haemophilus Influenzae* Infections** 1094
M. Sabir, Mansoor Ahmed
17.19 **Legionnaires' Disease** 1097
P.S. Shankar
17.20 **Plague and Other Yersinia Infections** 1099
Veena Mittal
17.21 **Clostridial Infections** 1102
M.K. Daga, Rakshit Kumar
17.22 **Diphtheria** 1107
Sandeep B. Bavdekar
17.23 **Pertusis—Whooping Cough** 1109
Y.K. Amdekar

C. Miscellaneous Bacterial Infections

17.24 **Syphilis** 1111
Debabrata Bandyopadhyay
17.25 **Non-Syphilitic Treponematoses** 1115
Taru Garg
17.26 **Leptospirosis** 1117
A.P. Sugunan
17.27 **Lyme Disease, Rat Bite Fever, and Other Spirochaetal Infections** 1120
Kamlesh Tewary
17.28 **Anaerobic Infections** 1122
R. Sajithkumar
17.29 **Atypical Mycobacteria** 1124
P.D. Khandelwal
17.30 **Brucellosis** 1125
B.G. Mantur
17.31 **Donovanosis** 1127
Dwijendra Nath Gangopadhyay
17.32 **Actinomycosis and Nocardiosis** 1129
A. Muruganathan
17.33 **Bartonella Infections** 1132
Pallavi Bhargava
17.34 **Melioidosis** 1134
Kavitha Saravu

D. Rickettsial, Chlamydial and Mycoplasma Infections

17.35 **Rickettsial Infections** 1135
Raminder Singh
17.36 **Chlamydial Infections** 1138
T.K. Suma
17.37 **Mycoplasma Infections** 1141
Dilip Mathai

E. Viral Infections

17.38 **Basic Considerations of Viral Diseases** 1143
Usha K. Baveja
17.39 **Herpes Virus Infections** 1148
Aditya Prakash Misra
17.40 **Human Papilloma Virus and Parvovirus Infections** 1151
Neerja Bhatla, Biswa B. Dash
17.41 **Bird Flu and Swine Flu** 1155
Sandhya Kamath
17.42 **Dengue** 1158
M.E. Yeolekar
17.43 **Ebola and Marburg Infections** 1161
Partha Pratim Chakraborty

17.44 **Japanese Encephalitis** 1163
U.K. Misra, J. Kalita

17.45 **Rabies** 1166
Tarun Kumar Dutta, Ashish Kumar Panigrahi

17.46 **Viral Gastroenteritis** 1170
Prabhash Chandra Bhattacharyya, Rupjyoti Talukdar

17.47 **Mumps** 1171
Falguni S. Parikh

17.48 **Measles (Rubeola)** 1172
R.K. Goyal, Prashant Mathur

17.49 **Smallpox** 1174
Ramesh Balwant Pandit

17.50 **Lymphocytic Choriomeningitis and Other Arena Virus Infections** 1175
Deepti Vibha, Garima Shukla

17.51 **Prion Diseases** 1176
P.K. Maheshwari, A. Pandey

F. Protozoal Diseases

17.52 **Malaria** 1177
A.K. Agarwal, Sarit Chatterjee

17.53 **Amoebiasis and Giardiasis** 1185
M.P. Sharma, Vaibhav Gupta

17.54 **Leishmaniasis** 1188
Shyam Sundar

17.55 **Toxoplasmosis** 1192
Madhukar Rai

17.56 **Trypanosomiasis** 1195
Prashant P. Joshi

17.57 **Cryptosporidiosis, Trichomoniasis, Balantidiasis and Isosporiasis** 1198
Atul Bhasin

G. Helminthic Diseases

17.58 **Ankylostomiasis, Ascariasis and Other Nematodal Infestations** 1200
Narender Pal Jain

17.59 **Tapeworm and Hydatid Diseases** 1207
Anurag Saxena

17.60 **Filariasis and Other Related Infestations** 1211
Sanjay Zachariah

17.61 **Schistosomiasis/Bilharziasis** 1216
Kirti C. Patel

H. Fungal Infections

17.62 **Systemic Fungal Infections** 1218
Shruti Prem, Rajat Kumar

17.63 ***Pneumocystis Jirovecii* Infections** 1224
Prasanta Raghab Mohapatra

Section 18: Disorders of Metabolism

18.1 **Basic Considerations of Metabolism** 1228
B.K. Sahay

18.2 **Inborn Errors of Carbohydrate Metabolism** 1229
Siddharth N. Shah

18.3 **Lipids and Lipoprotein Metabolism** 1232
Soneil Guptha

18.4 **Disorders of Purine and Pyrimidine Metabolism** 1240
R.V. Jayakumar

18.5 **Iron Metabolism and Iron Overload Syndrome** 1243
Mukesh Desai

18.6 **The Porphyrias** 1253
Dhanpat Kumar Kochar, Abhishek Kochar

18.7 **Wilson's Disease** 1257
Sanjib Sinha, A.B. Taly

18.8 **Lysosomal Storage Disorders** 1263
Prasanta Kumar Bhattacharya

18.9 **Inherited Disorders of Membrane Transport** 1266
S.K. Singh

18.10 **Amyloidosis** 1271
Manisha Sahay

18.11 **Disorders of Adipose Tissue and Obesity** 1275
Shashank R. Joshi

18.12 **Metabolic Syndrome** 1279
Anoop Misra

Section 19: Nephrology

19.1 **Kidney—Structure and Functions** 1282
Sanjay K. Agarwal

19.2 **Kidney Disease—A Clinical Approach** 1286
Vijay Kher

19.3 **Acute Kidney Injury** 1291
Alan F. Almeida, Jatin P. Kothari

19.4 **Chronic Kidney Disease** 1295
Ashok L. Kirpalani, Hardik Shah

19.5 **Primary Glomerular Diseases** 1302
Vinay Sakhuja, Sanjay D' Cruz

19.6 **Secondary Glomerular Diseases** 1310
O.P. Kalra

19.7 **Urinary Tract Infections** 1316
R. Kasi Visweswaran, Praveen Namboothiri

19.8 **Nephrolithiasis and Urinary Tract Obstruction** 1319
P.D. Gulati

19.9 **Vascular Injury to Kidney** 1323
A.S. Narula, A.K. Hooda

19.10 **Polycystic Kidney Disease and Inherited Tubular Disorders** 1327
P.P. Varma, Ranjith Nair

19.11 **Dialysis for Chronic Renal Failure** 1333
N.K. Hase

Introduction

The Practice of Medicine

Yash Pal Munjal

1.1 The Practice of Medicine

Yash Pal Munjal

INTRODUCTION

The history of practice of medicine is as old as the history of mankind. Over the years, medicine has gradually evolved and the modern medicine in its present form came into existence about 400 years ago. The last century has seen tremendous progress which is phenomenal and a lot more than in the preceding three centuries. Despite this explosion of knowledge, medicine still remains 'an art and science' to be practiced with compassion, empathy, and effective communication with the patient. *In today's practice, the patient is an informed partner in the plan of his management.*

This sea change in the medical practice is due to the emergence of new technologies which facilitate a physician to delve into the disease at its molecular level with the help of various biochemical, immunological, and genetic tests. There has been a marked improvement in the imaging technology. We have travelled a long distance from the time of conventional radiology to an era of PET and SPECT scanning. These have improved our capabilities to look into every nook and corner of the body and its organs. This has helped in arriving at a correct diagnosis and also to evaluate the functional status of the organ system. All these investigations with their sensitivity and specificity have armed the clinician to arrive at a diagnosis, plan effective treatment and prevent disease, if possible. Not only science has made rapid strides in diagnosis but also there has been a very significant improvement in the therapeutic modalities. The growing knowledge of genetics and immunology has enabled the clinician to provide treatment based on the molecular defect and individualising therapy accordingly.

The advent of information technology and internet has changed the way we learn medicine and keep our knowledge up-to-date about the latest innovations in medicine. It has given us the capability of maintaining medical records in a comprehensive manner so that they are more useful to the patient as well as help the doctor to follow the patients very effectively. Difficult clinical problems can be solved easily. Patient's records can be transmitted to other institutions and doctors for information. Telemedicine as a discipline has a great relevance, particularly in the context of developing countries, especially India, where there is a shortage of trained and expert medical manpower. This helps to provide medicare to patients in remote places where trained personnel are not available. Even sitting at one place, a senior surgeon can guide surgical procedures at more than one centre.

In this phenomenal progress of scientific knowledge, the basic goal remains to diagnose and treat the patient effectively and as early as possible. In this exercise, due consideration has to be given to the quality of life achieved and cost benefit ratio. It is the latter part which is the practice of the 'art' of medicine. This is learnt and mastered by practice, experience, and gradual understanding of the diverse human nature over the years.

AMALGAMATING THE ART AND SCIENCE OF MEDICINE

The scientific technology has enabled the physician to arrive at a diagnosis at the molecular level. It is now possible to understand the cause and complex mechanisms involved in the pathogenesis of disease. This constitutes the science of medicine. Once the diagnosis is established, the doctor has to inform the patient about the diagnosis, plan of management, and prognosis. He has to get the concurrence from the patient for the line of management to be followed. It is this communication skill of the clinician which wins confidence, faith and builds a healthy relationship between the doctor and the patient. This is an 'art' to be nurtured.

The task of a physician becomes rather delicate especially in situations which involve management of incurable and terminal stages of diseases. In a situation like this, the scientific knowledge at the command of a doctor is to provide adequate and effective relief from symptoms. The doctor and his team should not be carried away by the life-saving procedures used in the hospitals. In such situations, the doctor has to inform the relatives and the patient about the gravity and prognosis of the terminal diseases in a manner that the patient can understand and discuss with his doctor properly. It is an exercise to prepare the relatives and the patient to face the grave situation with forbearance and equanimity. This exercise has to be carried out by the doctor with all the compassion and empathy at his command so that he is able to communicate to the patient effectively and subtly. The doctor who can handle such delicate situations effectively earns the respect of the patient and the family. This is in true sense of the word an 'art' which a doctor has to imbibe and master over the years.

PRINCIPLES OF MEDICAL PRACTICE

Clinical Evaluation

The art of clinical evaluation has to be learnt and mastered by everyone studying medicine. *This forms the basic foundation on which the future course and technological advancement can be used effectively and rationally in a cost effective manner.* Therefore, it is absolutely essential for every practising doctor not to lose sight of this part of clinical medicine thinking that technological advances can take away the importance of clinical examination. The clinical evaluation of a patient comprises of two major aspects:

1. History of sickness of the patient
2. Comprehensive physical examination

History

The history of illness should include all the facts of medical significance in a chronological order and in a comprehensive way. Eliciting the history of the patient is an art which a doctor develops over a period of time. He should be able to guide the patient and to encourage him to narrate the history of his

illness with all its details in a manner which is useful and easily comprehensible. He guides the patient to give the details rather than getting into trivia which may be irrelevant to the medical problem. He may pose questions which guide the patient to narrate the relevant details. To complete the history, personal, past, and family history have to be recorded. The family history is important as it can provide useful clues to certain genetic disorders as well as certain communicable diseases which may be transmitted from one member of the family to the other. Similarly, the details of history provided by the family members may be helpful especially in dealing with psychological disorders.

The history taking and talking to the patient is the first step towards developing an effective and unique doctor-patient relationship. The patient is encouraged at all times to narrate his condition in detail. This will give him the satisfaction of having communicated to the doctor all about his sickness. The feeling that the doctor was receptive to his condition and sickness helps in building a rapport between the patient and the doctor.

Physical examination

The physical examination should be carried out at a place which is comfortable, ensures privacy and maintains dignity of the patient. It has to be comprehensive and complete from head to toe. The physical examination has to identify the clinical signs of disease and confirm the structural and functional changes. The clues may have been provided by the patient in his history. There are no shortcuts in physical examination as they may lead to major errors in diagnosis. Competence in physical examination comes by knowledge, experience, and following the methods of clinical examination in all its detail. Progress of clinical disease alters the physical signs from time to time and therefore a good clinician must carry out the physical examination repeatedly and periodically. Not only the ethical attributes of the clinician but also an alert mind is absolutely mandatory for getting the best information from the physical examination. The success of a good history and physical examination yields information which prepares the clinician to prescribe diagnostic tests which will clinch his diagnosis rather than unnecessary and multitude of tests which cause unnecessary escalation of cost and add to confusion (**Figure 1**). The clinical examination provides useful input to the clinician about the line of investigation and whether to give credence to some symptom and physical sign or not depends not only on his knowledge but also is an art of medical practice.

Figure 1: Hippocrates (460–380 BC).

Investigations

The investigations have significantly improved in their sensitivity and specificity so as to provide accurate diagnosis. The diagnostic tests help clinicians to:

- Establish the diagnosis
- Assess the degree of malfunction and extent of disease
- Make a rational plan for management which may be medical, surgical, or palliative
- Assess the benefit of therapeutics and interventions.

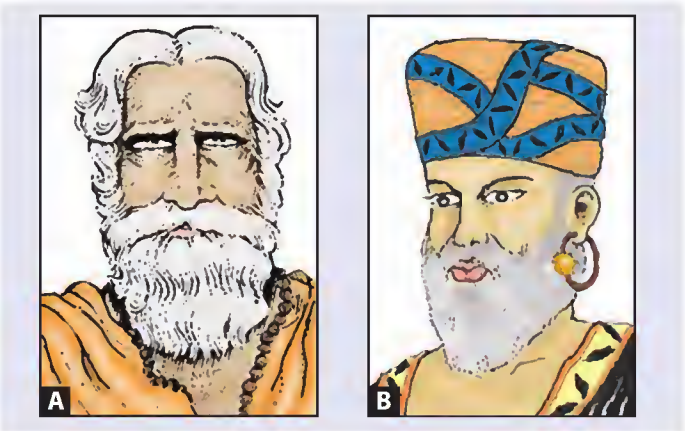
A good clinician is able to plan the investigations which are essential and appropriate in a given clinical situation. After the results of constellation of tests are available he should be able to interpret them in the clinical context. The judicious use of investigations limits the cost and helps to arrive at a diagnosis in an effective and useful manner.

Decision-Making in Clinical Practice

A physician has to take decisions at various stages during the clinical course of sickness. These have to be in consonance with the informed consent of the patient. The first level of decision-making is to arrive at a provisional diagnosis based on the history and physical examination. At this level, he has to plan the investigations as well as start provisional treatment so that there is no further deterioration in the condition of the patient. As soon as the results of investigative procedures are available, his clinical skill is once again called into play to arrive at a definitive diagnosis by following the principle of deductive science and plan a definitive course of treatment. This is the second level of decision-making. After the treatment has been initiated and continued, the response can be an improvement in the condition of the patient or there may be no change in the condition of the patient or it may get worse. This is the next level of decision-making where the doctor has to review his previous diagnosis, order fresh investigations so that missing link is detected. In case the patient shows benefit of treatment then he has to decide how long to continue the treatment so that the patient is restored to his health. Not only the subjective improvement but also an objective assessment has to be made based on the clinical and laboratory parameters which have to be decided by him.

Evidence Based Medicine

This concept means that the clinical decisions to be taken are fully supported by data that is derived from prospectively designed randomised controlled clinical trials over a fairly long period of time. This is in marked distinction to the previous concept of following the treatment based on one's experience and bias towards one form of treatment than the other. It is imperative for today's doctor to take decisions based on hard outcome data from large clinical trials. To get this implemented many National and International Organisations have formulated Practice Guidelines which help the physician and other members of his team in making a diagnosis and taking appropriate therapeutic decisions. These guidelines provide the framework for managing patients with a diagnosis or clinical symptoms and also help to create a standard of medical care so that all patients get the benefit of cost effective and proven therapies. They help to protect the doctors from frivolous charges of medical malpractice and cost overruns due to



unplanned treatment. However, these guidelines have to be used with caution and must be based on the clinical constellation of a particular clinical condition. In case more than one options are available for treatment which is scientifically proven, the physician cannot be faulted for choosing one option for the other option. In planning a treatment, the other factors which have to be taken into consideration are the age and sex of the patient and associated medical conditions, and drug-drug interaction.

Assessment of the Success of Treatment

Previously the assessment of result was based on clinical examination and subjective feelings. Nowadays the evaluation is based on hard outcomes data to judge the success of treatment. This is in the form of prevention of morbidity and mortality. In case of chronic illnesses where cure is not possible, assessment of treatment is based on not only the symptomatic relief but also by finding out that if the progress of the disease has been stalled and complications have been prevented. Another parameter which helps in assessing the benefit of treatment is the quality of life which the patient enjoys after the treatment. Therefore, summing up in today's context, it is predominantly an objective outcome assessment as compared to the olden times. There are certain modifying situations which can change the parameters of assessment like the age and sex of the individual. The delivery of medical care has to be assessed in the context of available resources and infrastructure. It is essential and obligatory for the doctor to provide compassionate care with empathy, understanding and constant dialogue with the patient (this is always possible) even with limited resources and infrastructure.

MEDICAL ETHICS

As soon as the foundation of the modern system of medicine was laid the practice of medicine was 'put into guiding principles' by the famous Hippocratic Oath. If we delve into the ancient Indian literature, similar guidelines were propounded much earlier by Sushruta/Charak Samhita, Aryabhatta Smriti, etc. (**Figures 2A and B**). They have elaborated on various aspects of code of conduct, qualities of physician as well as human aspects of relationship. Among the qualities and characteristics of physician, special emphasis was laid on character (purity, honesty, and integrity), qualification (knowledge, skill, and experience), professional attitude (alert, responsive, communicative, and responsible), and behaviour (friendly, respectful, and compassionate). The basic tenets of these guidelines were to 'provide patients good doctors'. The good doctors are supposed to make patient care their first concern and, therefore, they need to be competent (good medical education). They should keep their knowledge and skills up-to-date (continuing medical education). They should maintain good relationship with the patients and professional colleagues, be honest particularly to themselves and act with integrity (Ethics of Medicine). The various national and international agencies have provided guidelines for the practice of doctors in their respective countries. In India, the Code of Conduct has been framed by the Medical Council of India. This is modified from time to time based on the socio-cultural needs and advancement of medical knowledge. The responsibilities and duties of a doctor formulated by various organisations are based on the following principles enumerated in **Table 1**.

Figures 2A and B: (A) Sushruta (800 BC); (B) Charak (300 BC).

Table 1: Responsibilities and Duties of a Doctor

Patient care should be your first priority
Keep the dignity and privacy of every patient and he should be dealt with politeness and consideration
Do not be judgmental. Listen to the patients and respect their information
Communicate in a manner the patients understand and make patients equal partners in decision-making
Keep your professional knowledge and skills up-to-date
You must practise and manage patients to the level of competence and knowledge acquired by you
Refer patients at appropriate time to a higher centre or a super specialist at the earliest possible occasion, if required
Keep the information given to you confidential and to be divulged only under extremes of circumstances
Do not abuse your position as a doctor
Your dealings with the colleagues and pharmaceutical industry should not raise conflict of interest and your conduct should be in the best interest of the patient
Provide adequate information and take 'informed consent' before any drug trial or 'off label use' of any drug

Implementing Medical Ethics

Medical ethics are also concerned with the standards of care and the ethical issues raised by the practice of medicine. Recent scientific knowledge and their usage have thrown many difficult ethical problems which are still in the process of debate. In these situations the doctor has to decide based on his belief and the sociocultural milieu. Some of the issues under debate are cloning, genetic medicine, abortion, care of the brain dead for organ transplant, and need of live tissues. Another issue which is a matter of concern and debate is the issue of assisted suicide or euthanasia. In clinical practice the ethics come into play in three vital areas. The clinical ethics are concerned with the relationship between the doctor and the patient. Another area is the conduct of research on patients which is guided by the research ethics while public health ethics deal with the health of the community, state, or country as a whole.

CLINICAL ETHICS

In clinical ethics, four principles are important and they can be abbreviated to autonomy, beneficence, non-maleficence, and justice.

Autonomy

The respect and dignity of the patient has to be maintained at all times. Truthful communication with the patient is always a must though it is not essential to inform him of the facts in the first instance especially in critical illnesses or certain disorders (HIV) which have a lot of social stigma attached.

Informed consent

It is the fundamental right of an individual that his body is inviolable. Therefore, a doctor needs to have permission from the individual for his examination, investigations and therapeutic procedures including interventions and surgeries. The patient has to be informed about the method adopted for diagnosis and the line of his management. In case, there are more than one options for treatment then the details of all the options with their pros and cons have to be explained. This communication must be done in a manner that the patient understands and in his language. After this, he should give his consent in writing to carry out that treatment or procedure. Legally and morally, the patient has the absolute right to take a decision about what is right or wrong for him. Sometimes, the choice of the patient may seem irrational and not in accordance with the professional advice. But it should not be construed that he lacks the capacity and mind to take appropriate decision for himself. In situations where he is incapacitated to take a decision on his own, e.g. in children, unconscious patients or insane individuals, the treatment may be planned in consultation with the explicit permission of the relatives. In case the relatives are not available then a group of physicians may take a decision on behalf of the patient depending on the local laws and culture.

Confidentiality

The details of the history, treatment, and prognosis have to be kept confidential. All communications and other records relating to the patient's care are to be treated as confidential documents. This information can be shared between health care professionals if the patient is referred to another institution or a consultant. In other situations, the authorisation in writing by the patient is a must. The confidentiality clause can be rescinded for due process of law and in cases of insurance or a medical claim. This right of confidentiality has been over-ruled in cases where the condition is infectious (e.g. HIV or AIDS) by right to healthy life of the other person who is likely to be in his contact or where the community interest suffers.

Beneficence

This means acting in the best interest of the other person. In clinical ethics, it means the benefit of individual patient based on the patients' point of view as well. In situations where there is a conflict of interest between the benefit of the individual patient over that of the community, the declaration of Geneva by World Medical Association entitles a doctor to follow the dictum "Health of my patient will be my first consideration".

Non-Maleficence

This means do no harm. In traditional medicine, the concept followed is 'primum non nocere'. In the practice of medicine beneficence and non-maleficence have to be balanced (benefit versus risk). Relevant information on the above two grounds must be shared with the patient so that he is able to make an informed decision.

Justice

This means availability and access to the health care by every individual irrespective of caste, creed, social and economic status. It mandates an equitable distribution of health care resources. One associated concept is that of utility, i.e. greatest good for the greatest number must be evaluated for an individual patient. Justice means being fair to him and it involves evaluation of the needs of the patient, respecting his rights as well as the merit.

PUBLIC HEALTH ETHICS

Public health involves the health of the community, state or country as a whole; no direct doctor patient relationship exists. This involves preventive measures like education, mass vaccination, mass screening for diseases and precautions to be taken at the community level. In prevention of certain lifestyle diseases like diabetes, coronary artery disease and obesity, there may be a conflict of interest with the corporates who are dealing with the marketing and advertisement of such substances like alcohol, tobacco, junk food, etc. To resolve these situations of conflict of interest social organisations and medical professionals may have to lobby with the politicians to educate the society to demand action against the sale, marketing and use of these substances if necessary, by laws. In India, a major step has been implemented that all advertisements pertaining to tobacco and its derivatives (e.g. cigarettes, bidis, hookah and chewing tobacco) have been banned and even at the individual level their use at public places is prohibited (by law).

Restrictive measures may at times become a necessity. In an explosion of epidemic to prevent its further spread certain legislations may have to be passed. This was recently amplified and implemented in cases of severe acute respiratory syndrome (SARS) and avian flu. Such interventions are for the good of the general community at large. Another important aspect of public health ethics is the uniform and equitable distribution of funds for various disorders with a view that maximum people may draw benefit.

RESEARCH ETHICS

The conduction of research is a vital component of medical practice. It may provide a sound basis of care for a better and more effective treatment for subsequent patients. The principles of information, beneficence, non-maleficence and justice should be strictly adhered to in all research protocols. The guidelines for conduct of good research have been formulated and must be strictly followed. The patients consenting for trial should be offered due care and they must be compensated both for their time, travel and reimbursement of the other expenditure incurred by them. Such reimbursement should not appear to be an inducement to the patient, health care institutions and the doctors.

END OF LIFE SITUATIONS

A doctor is faced with the dilemma of communicating the diagnosis of certain incurable diseases or a disease in its terminal stage to the patient and/or his relatives. In such situations, the

doctor must be sure about the diagnosis that the disease is incurable, or it has advanced to such an extent that it is in its terminal stage. The doctor is not necessarily bound to divulge the complete information at the time of first contact with the patient, but it is imperative for him that he must confide, educate the patient and the relatives about the gravity of situation and its consequences. This can be done slowly and progressively. The physician should provide this information in a manner that it is easily understood by the patient and other persons attending him so that they can appreciate the gravity of the situation. The doctor should be willing to discuss the details and answer necessary questions of the patient or his family members. This exercise has to be done with compassion, empathy, and it is an art which a physician has to master and practice by knowledge and understanding. The doctor sometimes gets overwhelmed with the prospect and availability of advanced life saving methods (e.g. ventilators, pacemakers, etc.) in an aggressive manner. But it is always important for him to remember the basic fact about the gravity of the sickness and its consequences. Symptomatic and pain relief have to be addressed aggressively to provide comfort to the patient round the clock. During the terminal stages of any disease it is not only the medical treatment which has to be provided but religious, cultural and other supportive measures also have to be used judiciously, and they should be facilitated so that the patient and his relatives are at peace and comfort.

ENVIRONMENTAL MEDICINE

A number of chronic and infectious diseases are emerging and posing a threat to the health of countries. It is believed that due to rapid industrialisation and urbanisation which has led to the degradation of the environment polluting the air, water, and significant lowering of the hygiene. According to WHO estimates, nearly one-fourth (24%) of the global disease burden and 23% of all deaths can be ascribed to environmental factors. This deterioration in the environment can lead to a spurt in the infectious diseases, chronic non-communicable diseases, and trigger certain genetic disorders due to mutation of genes. Due to global warming and increasing carbon dioxide in the atmosphere, it is estimated that the prevalence of vector borne diseases, like malaria and some of the infectious diseases, are likely to increase manifold. The environmental factors that lead to genetic variation concerning the cholesterol synthesis may precipitate increase of coronary artery disease significantly. A physician has to be well-versed with the various environmental pollutants, environment at work place, and have a working knowledge of some of the environmental and occupational diseases.

DISASTER MANAGEMENT

The environment and nature are friendly to the human beings most of the times but at times the ravages of nature can bring death, destruction and disease in a sudden and unexpected manner. Some natural disasters that have struck in the recent times where thousands of lives were lost—Tsunami in South India and Sri Lanka and a few years later we had a very severe Tsunami and earthquake in Japan. These natural disasters led to the outbreak of many infectious diseases and there was an associated increase in vector borne illnesses. The marvel of technological advancement by science is useful to the mankind most of the time but due to an accident it may lead to a disaster. To mention a few examples of technology related disasters are—the Gas leak in Bhopal (MP) in 1984 the so called Union Carbide Gas Leak, the Chernobyl Russian Nuclear Power Plant Explosion in 1986, and the radiation spread by the damage of the Nuclear reactors in the area of Tsunami in Japan in 2011 have led to disastrous consequences. Man himself can unleash disasters like the bombing of Hiroshima and Nagasaki in Japan, chemical and biological warfare. It is the management of such emergencies in which there are mass casualties that it needs courage, presence of mind and a well-planned action so that misery can be minimised. In this situation, the health care professionals have to work in close collaboration with the society. The various phases in which the emergency management has to be carried out are described below.

Mitigation

Mitigations are concerted efforts to prevent hazards from developing into disasters altogether or to reduce the effects of disasters when they occur. The mitigation phase differs from the other phases because it focuses on long-term measures for reducing or eliminating risk. Mitigation is the most cost efficient method for reducing the impact of hazards while it may not always be feasible.

Preparedness

It is to train people to fight the disease and, therefore, it involves planning, organising, training, equipping, exercising, evaluation and improvement over a period of time. It helps to ensure co-ordination and increased capability to deal with disasters, terrorist attacks and man induced disasters.

Response

This phase includes the mobilisation of the necessary emergency services and first responders in the disaster area.

Recovery

The recovery phase aims at restoring the affected area and population to its normal state. The focus of this phase is different from response phase, recovery efforts are started after immediate needs are addressed. In recent years there has been a shift in emphasis from response and recovery to strategic risk management and reduction. There is more emphasis on community participation rather than a Government centred approach. Efforts involve the provision of emergency management training for first responders, the creation of a single emergency telephone number and the establishment of standards for emergency medical staff, equipment and training. The physician therefore has to learn how to handle acute emergencies especially in situations where there are mass casualties.

In India, the Disaster Management Authority of India has been set up by the Government of India to deal with such situations and prepare the infrastructure in the country.

MEDICAL GENETICS

The study of genes and their function in health is called Genetics in Medicine while the understanding of the aberrations in the function and structure of genes is Medical Genetics. The advent of medical genetics has profound

influence on our understanding of the pathophysiology of disease and has opened new vistas of therapy especially the concept of planning and executing individual requirement based therapy. The greatest breakthrough was achieved in the spring of 2003 when complete sequencing of human genome was officially announced and released. This has ushered in an era of immense possibilities of not only cloning of species but repairing of many organ systems. The science of genetics has provided us the speed to understand the pathogenesis of disease epidemics. The discovery of new variant of coronavirus as a causative agent for SARS and the virus of avian flu; this has helped to quickly plan the management of these conditions.

The understanding of genetic disorders and how we can manipulate them has provided a new dimension to the art of genetic counselling in which the patient can be briefed about the likelihood of the genetic disorders which the offspring is likely to suffer. In case it is possible to correct the genetic defect the same may be done by genetic engineering. If it is as yet not correctible then counselling can be done about the consequences of the genetic disorder and its prognosis so that the parents can take appropriate decision at the beginning of the conception.

Another important area of genetics is pharmacogenomics. It deals with pharmacological manipulation of the genes for correction of

(a) Genetic defects or management of certain disease states especially cancer

(b) Choosing the appropriate medicine for a particular disease based on the genetic profile of the individual

(c) Another aspect of this is the use of stem cells. Stem cells are totipotent cells which can grow up into various tissues. These are now being used in many areas of clinical medicine like coronary artery disease, diabetes mellitus, healing of the wounds and rejuvenating organs.

Stem cells are being extracted from the cord blood on the birth of the child. These can be preserved for a number of years and are capable of providing treatment or repair of certain damaged organs at a later stage in life. These stem cells provide the individual with homologous graft.

The interaction between the genes and environmental factors i.e. phenotype can predispose to the common chronic diseases of the 21st century like obesity, diabetes, hypertension, and coronary artery disease which can be partially prevented or ameliorated by modifying the lifestyle factors.

CONTINUING MEDICAL EDUCATION

The science of medicine is galloping at a fast pace and, therefore, it is essential for the practising physician to learn new skills and knowledge so that he can serve the best interest of his patients. A doctor has to keep learning all through the time he is practising. The avenues available for medical education these days consist of learning from the peers in the field, the books and journals which are being brought at a fast pace.

The technological advancement has significantly improved the way one can learn medicine. The availability of internet and video conferencing has added new tools with great potential of learning skills for a clinician who can take the benefit of the same at a place and time of his convenience. Video conferencing provides useful tool for interactive learning and teaching a large number of students at different locations by an expert in the field from a common site. Live case demonstrations and procedures can be learnt by direct telecast. The other advantage is that one can assess his grasp of the subject by taking web based examinations in the privacy of his chamber. The internet has also served the purpose of educating the patients about their sickness and disease.

COMPLEMENTARY AND ALTERNATIVE SYSTEMS OF MEDICINE

Complementary and alternative medicine (CAM) is a diverse group of health care medical systems which does not conform to the commonly practised modern system of medicine. CAM is used and practised globally and in one survey it was found that 36% of people opted for CAM in the year 2002 in USA, while in a recent survey in UK, homoeopathy was used as a method of treatment in approximately 48% of patients. If we include faith, spiritual healing and prayers, then the number goes to approximately 62%. In India, this percentage is much higher and the various commonly used alternative systems of medicine are Ayurveda, Unani, Siddha, Homoeopathy (**Figure 3**), religious, yogic practices, and household remedies. Systems from other countries, such as accupuncture, reflexology, and osteopathy, have also been used quite frequently in recent times.

Figure 3: Christian Friedrich Samuel Hahnemann, Founder of Homoeopathy (1755-1843).

The large acceptance of CAM therapy is due to the perception that it does not have side effects (which may not always be true); it is easily accessible and comparatively cheaper form of therapy. All these therapies are based on perception and individual beliefs. The other major disadvantage and shortcoming of this therapy is that it is not backed by clinical evidence and poor or no standardisation of the medicines is done.

Since this form of therapy is used very widely and frequently, therefore gradually and universally people and politicians are taking it up and certain regulatory bodies are established. In India, also there is a registering body which registers the doctors

who are trained in Homoeopathy, Ayurvedic, or Unani systems of medicine.

The government is making efforts to put these forms of medical management on scientific basis and trying to amalgamate it with the modern system of medicine. This concept of integrated health care is being developed. Therefore, today's physician has to know the good and bad of CAM so that he can keep abreast with the changing times and practice of medicine.

Integrated Health Care

This concept of amalgamated complementary and alternative medicine with modern system of medicine in a manner that it is useful to the patient is gradually evolving itself. How effective and useful will it be to medical profession and patients? The coming few years may answer this question a little more definitively.

The 21st Century Physician

The science based technology has expanded at a very fast pace in the later part of 20th century. The cytomolecular basis of disease is better understood. The progress in imaging modalities has improved the sensitivity and specificity of tests. The complete sequencing of genes, the ease and the cost with which it can be mapped and modified have raised immense possibilities of even managing certain incurable and difficult clinical conditions. It has opened vistas of individualised and highly specific treatment. The use of stem cell therapy has enabled to cure and repair organs. This relentless progress is likely to continue during this century. Therefore a physician has to be well informed and trained in these advances and their rationale use. In this backdrop, the importance of clinical skills to provide a good humane treatment with kindness, justice, and autonomy, to the patient will remain of prime importance for centuries to follow.

2.1 Pain—Mechanisms and Management

D Rama Rao, Niranjan P Moulik

Pain serves to protect the body from harm and promotes healing of damaged tissues. The International Association for the Study of Pain defines pain as 'an unpleasant sensory and emotional experience associated with tissue damage and/or described in terms of such damage'. It is important to recognise that pain is a perception and not a sensation. The perception of pain is believed to be the summation of sensory-discriminative component (e.g. location, intensity, quality), a motivational-affective component (e.g. depression, anxiety), and a cognitive-evaluative component (e.g. thoughts concerning the cause and significance of pain). The patient's account of pain should be evaluated and treated as per the patient's perception of pain. This can be irrespective of the existence and severity of tissue damage. A noxious stimuli is sensed by the body's 'nociceptive' system and generates a physiological and behavioural response. This stimulus can be generated by traumatic, inflammatory, neoplastic or other mechanisms, and sustained by neuroplastic changes even after healing. It is believed that it is this neuroplasticity which maintains chronic pain, although the exact pathophysiology of chronic pain is yet to be elucidated.

Nociceptive stimuli are carried by primary afferent neurons the cell body of which lie in the dorsal root ganglia (**Figure 1**). These are small diameter nerve fibres, type A delta and C fibres and are usually free nerve endings found in the skin, muscle, joints and some visceral tissues/organs. The processes of transduction, transmission, modulation and perception are all involved in the activation of the sensory system. The first order neurons relay to the axons of second order neurons, the cell bodies of which lie in the thalamus and they in turn transmit the sensations to the somatosensory cortex in the post-central gyrus of the cerebrum. However, there are considerable areas of modulation in the central as well as the peripheral components of the pain pathways; and these form the basis for differing action of various pain-alleviating therapies.

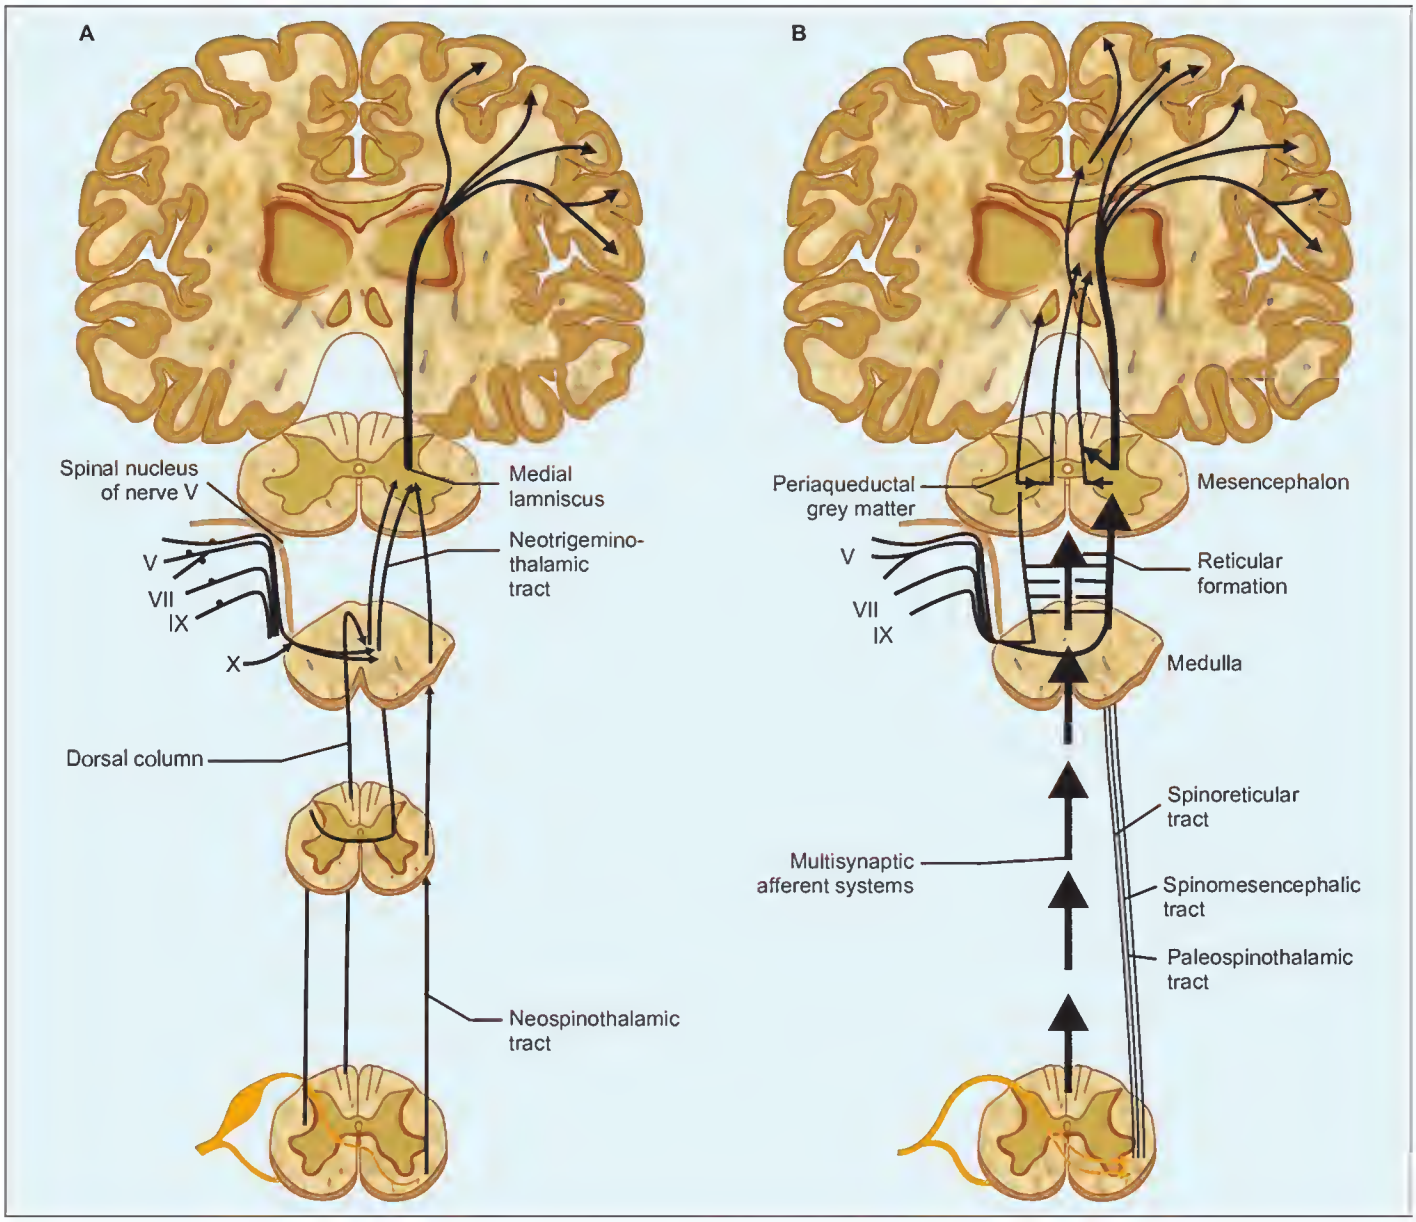
Nociceptive pain primarily involves injury to somatic or visceral tissues. However, neuropathic pain results from direct injury or dysfunction of the nervous system (central or peripheral). Pain is classified usually as acute (short-duration and usually remittent) or chronic (longer duration and persistent).

ASSESSMENT OF PAIN

A comprehensive assessment is required for optimal pain management. The aim is to have a clear understanding of the patient's pain problem, in terms of its aetiology, pathophysiology and syndrome. This requires a detailed history, and systemic examination is carried out to unravel the pain characteristics, impact of pain on multiple domains, relevant pre-morbid conditions, existing co-morbidities, history of substance use, previous investigations carried out and treatment taken.

Although, pain being a subjective phenomenon, is not easy to assess, a variety of validated pain scales are available to assist in the measurement of pain. Pain assessment tools include simple unidimensional scales or multidimensional questionnaires.

Unidimensional scales include the numeric rating scale, the visual analogue scale and the faces pain scale. The former two include pictorial line scales which the patient uses and marks the intensity on a scale of 1 to 10 or no pain at all to worst possible pain. The faces scale has pictures of 6 to 8 different facial expressions depicting a range of emotions again along a 0 to 10 linear scale. It is particularly useful for use in young children, patients with language barriers, or having mild-to-moderate cognitive impairment.



The multidimensional pain scales/questionnaires detail a more comprehensive pain assessment and apart from the intensity of pain also focus on the location and quality and effect of pain on mood and function. They are a bit time-consuming and cognitively-impaired and uneducated may find them difficult. The McGill Pain questionnaire and the Brief Pain Inventory are two such well-validated multidimensional pain measurement tools.

TREATMENT

Pain treatment can be divided into pharmacological, non-pharmacological and alternative medicine approaches. Acute pain effectively responds to nonsteroidal anti-inflammatory drugs (NSAIDs) or to mild-to-moderate efficacy opioids. Acetaminophen and NSAIDs are effective in mild-to-moderate intensity pain while opioids can be used for moderate-to-high intensity pain. A combination of NSAID and opioid can be used for severe intensity pain and has been found to be beneficial in achieving adequate pain relief. Common NSAIDs usually block both cyclooxygenase-1 and -2 enzymes and hence, COX-2 inhibitors were developed. However, use of COX-2 inhibitors has fallen into disrepute and the traditional NSAID like ibuprofen, diclofenac, nimesulide, naproxen, ketorolac, indomethacin continues to be used.

Chronic or persistent pain benefits transiently with these agents. Physiotherapy measures and physical treatments can be offered for chronic pain, while behavioural and psychological therapies do play a significant role as adjuncts in chronically depressed patients. Stimulation therapies like acupuncture and transcutaneous electrical nerve stimulation (TENS) have also been found to be beneficial. Apart from the NSAID and opioids which are also used for chronic pain, other pharmacological agents used include antidepressants (tricyclics, serotonergic uptake inhibitors and selective norepinephrine reuptake inhibitors), membrane stabilising agents like carbamazepine, gabapentin and pregabalin, local lidocaine plasters/patches. The commonly used drugs along with their dosages are listed in **Table 1**.

Despite the availability of numerous analgesic drugs, the clinical relief to patients for chronic pain has remained far from

Figures 1A and B: Pain signals are transmitted to the brain by two main pathways. The lateral system (A) is made up of long thick fibres that transmit information about the onset of injury and its precise location and intensity. They are designed to carry a rapid flow of pain signals to the thalamus to stimulate an immediate anti-nociceptive response. The medial system (B) is composed of phylogenetically older fibres that carry slower signals and probably transmit information related to the persistence of injury and level of response induced.

Table 1: Commonly Used Drug Dosages for Pain

Anti-depressants
- Tricyclic anti-depressants—amitriptyline 10 to 25 mg bedtime, increase step-wise to 150 mg twice/day
- Duloxetine 30 mg twice/day, increase to 120 mg/day.
- Venlafaxine: 25 mg tid

Anti-convulsants
- Carbamazepine 200 mg tid;
- Clonazepam 0.5 mg tid;
- Gabapentin 100 to 300 mg at bedtime to 3,600 mg/day in 3 divided doses;
- Pregabalin: 75 mg twice daily to 600 mg/day

Opioid agonist

Tramadol 50 mg once or twice to maximum of 400 mg/day

Morphine Analogues:
- Morphine 30 mg every 4 hours or as needed;
- Codeine 200 mg every 3 to 4 hourly.

Nonsteroidal anti-inflammatory drugs:
- Aspirin 650 mg 4 to 8 hourly

Contd...

Contd...

- Indomethacin 50 mg 8 hourly
- Piroxicam 20 mg 24 hourly
- Ketoprofen 50 mg 8 hourly
- Ibuprofen 400 mg 6 hourly
- Diclofenac 50 mg 8 hourly

satisfactory. Researchers are presently investigating role of nerve growth factor monoclonal antibodies, targeting sodium and calcium membrane ion channels and mechanisms based on activated microglia (non-neuronal cells implicated in the pathophysiology of chronic pain) to achieve breakthrough in alleviating chronic pain.

2.2 Headache

K Ravishankar

INTRODUCTION

Headache is one of the most common of human complaints. It could be due to a number of causes ranging from a mild head injury to a serious brain tumour or more often it could be a disorder unto itself such as migraine.

Headaches can be primary or secondary. Primary headaches are benign headaches where clinical examination and investigation including imaging are normal, e.g. migraine, tension-type headache and cluster headache. Secondary headaches have an underlying structural, vascular, metabolic or infective cause, e.g. headaches due to brain tumours, meningitis or subarachnoid haemorrhage. Approximately 90% of headaches seen in practise are primary headaches.

The skull, much of the pia-arachnoid, the dura over the convexity of the brain, and the parenchyma of the brain are insensitive to pain. The pain-sensitive structures in the head are given below:

1. The skin, subcutaneous tissue, muscles, extracranial arteries, and the periosteum of the skull.
2. The intracranial venous sinuses, especially in the pericavernous region.
3. Parts of the dura at the base of the brain and the arteries within the dura and pia-arachnoid.
4. The middle meningeal and superficial temporal arteries.
5. The structures of the eye, the ear, the nasal cavities, and the sinuses.
6. Optic, oculomotor, trigeminal, glossopharyngeal, vagus and the first three cervical nerves.

Sensory stimuli are conveyed to the central nervous system through the trigeminal nerve, particularly the first and to some extent the second division; they carry impulses from the forehead, orbit, anterior and middle cranial fossa. A specific classification system — 'the classification and diagnostic criteria for headache disorders, cranial neuralgias and facial pain' was proposed by the International Headache Society in 1988 and the same was revised in the year 2004. All headache disorders have been organised into 14 major groups and divided into 257 different subtypes. Groups 1 to 4 cover primary headaches and groups 5 to 14 cover secondary headaches.

APPROACH TO THE PATIENT WITH HEADACHE

History

Pattern recognition is most important for headache diagnosis. The same patient can have more than one type of headache. It is better to generate a routine set of questions under pre-set headings. The following aspects of the history are important in arriving at a diagnosis.

Temporal Profile

The mode of onset and progression are critical in deciding whether one is dealing with a benign or a serious headache. A chronic recurrent headache or a chronic non-progressive daily headache represents a primary headache, such as migraine, cluster headache or tension-type headache. Sudden onset of a severe headache suggests possible vascular involvement such as a subarachnoid bleed or an acute infective cause like meningitis. There are some forms of primary headaches which may have a sudden onset such as coital headache or crash migraine and although the suddenness and severity may suggest an organic illness, it may be possible to diagnose them in retrospect only after their recurrent nature manifests. Progressively worsening headache suggests increasing intracranial pressure or uncontrolled systemic disease. Although presence of focal or lateralising features makes the diagnosis easier, it is the subacute headache which is more difficult to interpret. These headaches develop over weeks or months and the aetiology could be benign or serious. Therefore, specific information regarding progressive worsening needs to be sought.

Some headaches like cluster headache may occur at the same time everyday. In some the headaches may increase towards the evening as with tension-type headache, and in some like migraine, the headaches may occur first thing in the morning and awaken the patient from sleep. Rare primary headaches like cluster headaches and their variants are grouped together as trigemino-autonomic cephalgias (TACs). These are short-lasting and occur several times in a day and are diagnosed by their characteristic pattern and associated autonomic features like conjunctival injection, lacrimation or rhinorrhoea.

The age of onset is also important. Migraine begins at a younger age and is more common in females aged 25 to 40 years whereas tension-type headache is common in middle age. Headaches beginning after 50 years of age should be investigated for potential secondary causes. Any change in headache pattern should always raise suspicion of an organic pathology. The longer the history the more the likelihood of a benign underlying cause.

When the head pain is chronic and occurs on a daily or near daily basis for more than 15 days per month, one uses the label of chronic daily headache (CDH). It is essential to establish if we are dealing with primary CDH or secondary CDH. The following entities are included under the heading of long-lasting primary CDH:

1. Chronic migraine
2. Chronic tension-type headache
3. Hemicrania continua
4. New daily persistent headache

All these conditions may present with or without medication overuse. When faced with a patient who has CDH, it is essential

to determine the duration of the headache. With an arbitrary time limit of 4 hours, daily headaches can be grouped as short-lasting (< 4 hours) or long-lasting (> 4 hours). Examples of short-lasting CDH are cluster headache and other TACs. Recurrent attacks of short duration head pain would favour the diagnosis of cluster headache or one of its variants like chronic paroxysmal hemicrania.

Location and Type of Headache

The type of pain, its location and severity are important for diagnosis. Unilateral pulsating or throbbing headaches indicate an underlying vascular involvement as in migraine but migraine headaches are also known to be bilateral. Other vascular headaches can also be throbbing in nature. Cluster headaches are almost always unilateral in the same location during a cluster period, and rarely shifts sides. Tension-type headaches are diffuse, dull and generally bilateral. With secondary headaches, the location of the headache, the nature and severity would vary depending on the anatomical location of the lesion and the mechanism involved in pain production. In addition to getting the patient to describe the site and quality of the pain, rating the severity on a 10-point scale is useful in assessing progress of the headache and in gauging the response to treatment.

The Accompaniments

In all patients with headache, one must establish the presence or absence of nausea, vomiting, hypersensitivity to light and noise and associated neurological involvement. Absence of an established history of recurrent headaches or precipitation by triggers should prompt consideration of an underlying organic cause. Associated features like fever, arthralgias and malaise suggest systemic disease. Associated neurological deficits or auras, such as transient visual symptoms or hemisensory deficits, support a diagnosis of migraine with aura. Other neurologic accompaniments need appropriate investigations to differentiate between complicated migraine and transient ischaemic attacks (TIAs), vascular anomalies or a seizure disorder.

The typical behaviour of a migraine patient who tries to sleep undisturbed in a dark room is in contrast to that of the patient with a cluster headache who cannot stay still and keeps pacing around. A positive family history can provide a clue to the diagnosis of migraine.

Headache that occurs regularly just before or during the menstrual periods is likely to be menstrual migraine. Hypertensive headache is more common in the morning, sinusitis headache is worse on bending, eyestrain headache occurs more towards the evening and the headache of cervical arthritis is more intense after a period of inactivity.

Provoking and Relieving Factors

Primary headaches such as migraine can frequently be provoked by missing meals or going out in the hot sun. Trigger factors in the Indian setting are listed in **Table 1**.

Medical History

Careful questioning for systemic illnesses is essential, e.g. malignancy anywhere in the body should raise the possibility of cerebral metastases. Likewise vascular headaches in a patient with a history of spontaneous abortions or thromboembolic events should raise the possibility of antiphospholipid antibody syndrome. Systemic diseases can be a contraindication to the use of certain drugs, e.g. beta blockers would be contraindicated in a diabetic or an asthmatic.

Table 1: Migraine Triggers

Food items	Cheese, dairy products, paneer (cottage cheese), citrus fruits, chocolates, onions, sea food
Food additives	Monosodium glutamate (MSG), aspartame, nitrates, caffeine
Alcohol	Red wine, beer
Hormonal changes	Menstruation, ovulation
Physical exertion	Excessive exercise, fatigue
Visual stimuli	Bright lights, glare
Auditory stimuli	Loud noise or music
Olfactory stimuli	Perfumes and certain odours
Sleep	Too much or too little
Weather changes	
Head or neck trauma	
Hunger	
Stress and anxiety	

EXAMINATION OF THE PATIENT WITH HEADACHE

Routine examination helps exclude hypertension, meningitis, or systemic febrile illnesses. Additional examination may be necessary in order to increase the yield in headache patients. Palpation over the head and neck is necessary to detect tender trigger-points; auscultation over the skull, the carotid and vertebral vessels can identify bruits; temporomandibular joint and cervical spine palpation for tenderness and movement limitations; look for temporal artery tenderness; check the mental status, the cranial nerves and look for asymmetry in power and look for reflexes.

INVESTIGATION OF THE PATIENT WITH HEADACHE

Certain features in the history or examination (**Table 2**) should raise the suspicion of ominous disease and warrant further work-up. These are termed as danger signals' or 'red flags'.

Table 2: Headache Danger Signals

Sudden onset of a new severe headache
Progressively worsening headache or change in the pattern of the headache
Headache that is unresponsive to treatment
Onset of headache with exertion, such as sexual activity, coughing or sneezing
Onset of headache after 50 years of age
Headache associated with change in neurological status
Headache with abnormal examination findings

Laboratory Testing

The CBC, erythrocyte sedimentation rate (ESR) and relevant blood chemistry should be obtained in all patients. It helps to rule-out unsuspected systemic diseases. In an elderly patient suspected with giant cell arteritis, ESR and C-reactive protein are helpful.

Cerebrospinal Fluid Examination

Cerebrospinal fluid (CSF) examination must be considered in patients when there is fever or associated cranial nerve deficit. Opening and closing pressures must be documented, particularly in cases of pseudotumour cerebri or idiopathic intracranial hypertension which can sometimes present with

intractable migraine-like headache and may not always be associated with papilloedema.

Neuroimaging

Imaging must be done whenever there are danger signals. Avoid imaging scans if there is a history of similar headaches in the past or if examination is normal, or if the headache improves with treatment.

Magnetic resonance imaging (MRI) is now rapidly becoming the standard diagnostic test for head and face pain, particularly with the advantage of non-invasive evaluation of the vasculature by MR angiography and MR venography. An MRI has many advantages over a CT in a headache patient. In the appropriate setting one must investigate further with digital subtraction angiography (DSA).

PRINICIPAL HEADACHE VARIETIES

Primary Headaches

Migraine

Migraine manifests with recurrent headaches associated with nausea, vomiting, photophobia or phonophobia with or without an aura. It is more common in women (2 to 3:1) and a family history is often present (60% of cases). Attacks begin in late childhood, adolescence and early twenties. Majority of the patients with migraine, 80% have migraine without aura.

Clinical features

Migraine should always be thought of as a complex neurological disorder with headache being one of the common presenting features. There may be other accompanying neurological, gastrointestinal or autonomic features as shown in **Table 3**.

Table 3: Accompaniments of Migraine

Gastrointestinal: Anorexia, nausea, vomiting, diarrhoea
Visual disturbances: Blurring, photophobia
Motor abnormalities
Brainstem features: Vertigo, ataxia, diplopia, dysarthria
Autonomic disturbances: Hypertension, hypotension, tachycardia, bradycardia, nasal congestion, and peripheral vasoconstriction
Fluid retention
Psychological upsets, confusional states

The typical attack of migraine consists of a sequence of events divided into four different phases, that blend imperceptibly with each another: the prodrome, the aura, the headache and the postdrome.

Pathophysiology

The possibility that a migraine attack may be initiated by cortical spreading depression is the most favoured hypothesis. This condition is a transient disruption of neuronal activity in the brain accompanied by a flux of sodium, calcium ions into the cells. This results in a brief burst of electrical activity followed by electrical silence, which progresses as an expanding concentric wave through the brain at the same rate as a developing migraine aura.

Migraine variants

Depending on the accompanying neurologic deficit, there are different variants of migraine, such as hemiplegic migraine and basilar migraine. Status migrainosus is the term applied to severe unrelenting migraine attacks that last more than 72 hours.

Management

Once trigger factors are identified, preferably with the help of a 'headache diary or headache calendar', drug treatment needs to be selected depending on the severity and the level of disability. Ideal management of migraine should concentrate on three major areas:

1. Control of trigger factors
2. Treatment of the acute attack
3. Long-term prophylactic medication

Pharmacotherapy

For mild-to-moderate attacks, simple analgesics like aspirin or acetaminophen suffice. Combining with an anti-emetic like metoclopramide or domperidone, which increases gastric motility and enhances the absorption of other drugs, is more beneficial. Nonsteroidal anti-inflammatory drugs (NSAIDs) are also effective in mild to moderate cases.

For moderate-to-severe attacks, triptans and ergotamine are useful as abortive drugs. When the patient is vomiting, injectable diclofenac or ketorolac is recommended. Narcotic injections should not be used in migraine. Sumatriptan is a 5-HT_{1D} agonist that blocks neurogenic inflammation in the trigemino-vascular system. It is available as 25 mg, 50 mg, and 100 mg tablets and as a nasal spray. Unlike ergotamine, it is effective when given at any time during the attack and has a better safety profile; it works rapidly and also relieves nausea, vomiting, photophobia and phonophobia. Recurrence of headache because of the short half-life is a major disadvantage with sumatriptan, but is less with the newer second generation triptans, like rizatriptan, eletriptan, zolmitriptan and naratriptan. Chest symptoms including tightness and pressure in the throat, neck and chest are more common with sumatriptan than with other triptans. Contraindications to triptans include ischaemic heart disease, uncontrolled hypertension or concomitant use of ergotamine derivatives or other 5-HT_1 agonists. Rizatriptan is available as 5 mg and 10 mg tablets. Steroids may occasionally be used as alternatives when all other drugs fail.

Recurrent episodes of migraine need simultaneous prophylactic treatment. Beta-blockers, calcium-channel blockers, methysergide, cyproheptadine, tricyclic antidepressants and anticonvulsants like divalproex and topiramate are used prophylactically. In most instances, prophylaxis need not be continuous, but is used for specific trial periods with drug-free intervals until the frequency is controlled.

Tension-Type Headache

Tension-type headache occurs more commonly in patients subjected to stress, anxiety and depression. It begins as episodes and progresses to a chronic form where headaches occur almost daily and do not appear to be associated with any overt psychological factors.

Clinical features

The headache is usually generalised and of long duration. The patient experiences a constant pain and obtain temporary relief with analgesics and sleep. There are no associated symptoms,

like vomiting, photophobia or phonophobia. The diagnosis can be established by a good history.

Treatment

The physician should attempt to identify the stress or emotional problem underlying the headache. Anxiety may be controlled by use of a mild antidepressant. Depressed patients may benefit from a tricyclic antidepressant such as imipramine or amitriptyline. When sleep is disturbed, it is important to establish a normal sleep pattern using short-acting hypnotic agents. When tension-type headache is associated with an emotional problem, the patient should be referred for psychiatric evaluation and treatment.

Cluster Headache

Cluster headache is a devastating painful headache, mostly affecting men. The term 'cluster headache' reflects the clustering of headache attacks in time. It is considerably less common than migraine and begins in the second or third decade of life. There is a periodicity to the attacks with seasonal clustering. Typically pain peaks lasts from 30 to 180 minutes and may occur 1 to 3 times per day. The pain is usually spontaneous, but can be provoked by alcohol. Patients describe the pain as excruciating or penetrating and on the same side during each cluster. The pain is accompanied by lacrimation, rhinorrhoea or ptosis. Differential diagnoses include diseases of the orbit, tumours of the brainstem or occipitocervical junction, infiltration/infection of the brainstem and cavernous sinus disorders. MRI should be done in all patients with cluster headache.

Treatment

Symptomatic treatment includes oxygen inhalation at about 7 litres per minute, parenteral dihydroergotamine (DHE), or parenteral sumatriptan 6 mg. Zolmitriptan nasal spray has been found to be useful for the acute treatment of cluster headache. Drugs for the prophylactic therapy of cluster headache include:

1. *Verapamil* given in doses as required, starting with 120 to 240 mg daily.
2. *Lithium carbonate* in a dose of 150 mg twice daily with periodic check-up of drug levels and watch for side-effects.
3. *Steroids* are very effective in preventing attacks, but are not indicated for long-term use.
4. *Methysergide* is an effective medication in treating chronic cluster headaches; 2 mg is the starting dose and the dosage is gradually increased, but retroperitoneal fibrosis is a side-effect.
5. *Divalproex and other anticonvulsants* like topiramate have also been found to be useful in prevention of cluster attacks.

Other Trigemino-Autonomic Cephalgias (TACs) and Short-Lasting Headaches

There are some head pains which are considered variants of cluster headache, but they differ in being very responsive to indomethacin and in their short duration and high frequency of attacks. The best example of this is chronic paroxysmal hemicrania which is characterised by frequent daily attacks of severe, short-lasting, unilateral, orbital, or temporal pain of 20 to 45 minutes duration with associated autonomic features. It is seen mostly in females and is usually responsive to indomethacin.

Secondary Headaches

Raised intracranial pressure

Any lesion that increases intracranial pressure is likely to cause a progressively increasing headache. Headache as a presenting feature will depend on the nature and location of the mass. Posterior fossa lesions raise intracranial pressure rapidly. The headache is usually generalised, may not fit into any particular pattern, slowly increases in intensity and leads to drowsiness and confusion following which focal neurological signs develop. Neuroimaging helps in the early detection of some of these lesions.

Intracranial haemorrhage

Head trauma can lead to epidural or subdural haematomas. Intracerebral haemorrhage is usually sudden in onset and can produce incapacitating headache with focal neurological symptoms and depressed consciousness. A subarachnoid haemorrhage due to rupture of an aneurysm or arteriovenous malformation produces an explosive incapacitating headache with vomiting, decreased level of consciousness and signs of meningeal irritation. This possibility should be kept in mind in every patient who presents with sudden onset headache and the diagnosis must be confirmed by doing a CT or lumbar puncture.

Meningitis

The headache is usually accompanied by fever, stiff neck, vomiting, and the diagnosis is confirmed by CSF examination.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension or pseudotumour cerebri presents with headache and visual obscurations along with other signs of increased intracranial pressure. It usually occurs in young, obese women; CT/MRI reveals small ventricles and on examination the patient may have decreased vision and usually but not necessarily there is papilloedema. Lumbar puncture shows evidence of increased opening pressure. MR Venography is a must in these patients.

Medication overuse headache

Medication overuse headache has been variously referred to as analgesic/ergotamine/drug-rebound headache. The headache sufferer who consumes medications for acute attacks on a regular, repeated and predictable basis is at risk of developing chronic daily headaches that are caused by overuse of medication. The most significant feature is that the headache typically persists throughout the whole day, is present on waking and is described as a dull, diffuse headache. Complete withdrawal of the analgesic is the only effective treatment. Withdrawal headaches can be treated with NSAIDs and, if detoxification fails, in-patient treatment with chlorpromazine or intravenous dihydroergotamine or subcutaneous sumatriptan can be tried.

2.3 Chest Pain

Sanjay Tyagi, Amit Mittal

INTRODUCTION

Chest pain is a very common complaint most often caused by benign conditions, but occasionally it may be due to life-threatening medical emergencies. Chest pain may be caused by almost any condition affecting the thorax, abdomen or internal organs. The approach to chest pain, therefore, is to exclude benign conditions and to rapidly identify and treat potentially fatal and serious conditions. So, it is critically important to distinguish the two major presentations of chest pain: emergent and nonemergent. Many patients are aware that it is a warning of potentially life-threatening disorders and seek evaluation for minimal symptoms. Other patients, including many with serious disease, minimise or ignore its warnings. Pain perception (both character and severity) varies greatly between individuals as well as between men and women. So chest pain as a symptom should never be dismissed without an explanation for its cause.

CAUSES

Chest pain may originate from the cardiovascular, pulmonary, gastrointestinal, neurologic, or musculoskeletal systems (**Table 1**).

Table 1: Common Causes of Chest Pain

Cardiovascular	**Pulmonary**
Acute coronary syndrome	Pulmonary embolism
Aortic dissection	Pneumothorax
Pericarditis and cardiac tamponade	Pneumonia
Stable angina pectoris	Pleurisy
Chest wall	**Gastrointestinal**
Costochondritis or Tietze's syndrome	Oesophageal reflux disease
Fibromyalgia	Hiatus hernia
Radiculopathy	Cholecystitis
Herpes zoster	Gastritis
Psychological	Pancreatitis
Somatisation disorder	**Others**
Anxiety and panic disorders	Da Costa's syndrome
Hypochondriasis	Bornholm disease

Overall, the most common causes are:

- Chest wall disorders (i.e. those involving muscle, rib, or cartilage)
- Pleural disorders
- GI disorders (e.g. oesophageal reflux or spasm, ulcer disease, cholelithiasis)
- Idiopathic
- Acute coronary syndromes

PATHOPHYSIOLOGY

The thoracic viscera provide afferent visceral input through the same thoracic autonomic ganglia as the chest wall. A painful stimulus in these organs is typically perceived as originating in the chest but because afferent nerve fibers overlap in the dorsal ganglia, thoracic pain may be felt (as referred pain) anywhere between the umbilicus and the ear, including the upper extremities. When the sensation is visceral in origin, many patients deny having pain and insist that it is merely 'discomfort'.

APPROACH TO THE PATIENT

While the priority in any patient who presents with chest pain is to exclude catastrophic or life-threatening (cardiac) causes, non-life-threatening aetiologies, which may be functionally disabling, are much more common. The diagnosis of chest pain is difficult but the history often gives an indication of the underlying cause. If there is any suspicion of an acute coronary syndrome (ACS) or other serious cause or any concern regarding the patient's general well being, then urgent hospital admission should be arranged.

The history and physical examination, complemented by selected tests such as an electrocardiogram or chest radiograph help to reach an accurate diagnosis for most causes of chest pain, especially CAD, and to judge which patients are likely to have a benign aetiology (**Tables 2 and 3**).

DESCRIPTION OF THE CHEST PAIN

A thorough description of the pain is an essential first step in the diagnosis of chest pain.

Quality of the Pain

The patient with myocardial ischaemia often vigorously denies feeling chest 'pain'. More typical descriptions include squeezing, tightness, pressure, constriction, strangling, burning, heartburn, fullness in the chest, a band-like sensation, knot in the centre of the chest, lump in the throat, ache, a heavy weight on the chest and toothache (when there is radiation to the lower jaw). In some cases, the patient cannot qualify the nature of the discomfort, but places his or her fist on the centre of the chest (the Levine sign).

A 'sharp' or 'stabbing' pain with a pleuritic or positional component that is fully reproducible by palpation, in patients who have no history of angina or myocardial infarction, probably indicates a low-risk for the episode being ischaemic.

Region or Location of the Pain

Ischaemic pain is a diffuse discomfort that may be difficult to localise. Pain that localises to a small area on the chest is more likely of chest wall or pleural origin rather than visceral. Referred pain is an exception.

Table 2: Causes of Chest Pain

Cause	Suggestive findings	Diagnostic approach
Cardiovascular		
Myocardial ischaemia (acute MI/unstable angina/angina)	Acute, crushing pain radiating to the jaw or arm Exertional pain relieved by rest (angina pectoris) S_4 gallop Sometimes a systolic murmur	Serial ECGs and cardiac markers Stress imaging test considered in patients with negative ECG findings and no elevation of cardiac marker
Thoracic aortic dissection	Sudden, tearing pain radiating to the back Some patients have syncope, stroke, or leg ischaemia Pulse or BP may be unequal in the extremities	Chest X-ray, transthoracic or transoesophageal echocardiography CT scan of aorta for confirmation
Pericarditis	Constant or intermittent sharp pain often aggravated by breathing, swallowing food, or supine position and relieved by sitting leaning forward Pericardial friction rub	ECG and echocardiography usually diagnostic
Myocarditis	Fever, dyspnoea, fatigue, chest pain, recent viral or other infection Sometimes findings of heart failure, pericarditis, or both	ECG, serum cardiac markers ESR, C-reactive protein Usually echocardiography
Gastrointestinal		
Oesophageal reflux (GERD)	Recurrent burning pain radiating from epigastrium to throat that is exacerbated by bending down or lying down and relieved by antacids	Clinical evaluation, endoscopy Sometimes motility studies
Peptic ulcer	Recurrent, vague epigastric or right upper quadrant discomfort in a patient who smokes or uses alcohol excessively that relieved by food, antacids, or both	Clinical evaluation, endoscopy Sometimes testing for *H. pylori*
Pancreatitis	Pain in the epigastrium or lower chest that is often worse when lying flat and is relieved by leaning forward Vomiting, upper abdominal tenderness Often history of alcohol abuse or biliary tract disease	Serum amylase and lipase Sometimes abdominal CT
Pulmonary		
Pulmonary embolism	Often pleuritic pain, dyspnoea, tachycardia Sometimes, mild fever, haemoptysis, shock	D-dimer, echocardiography, CT scan of chest, chest X-ray, lower limb Doppler study
Pneumonia	Fever, chills, cough, and purulent sputum Often dyspnoea, tachycardia, signs of consolidation on examination	Chest X-ray
Pneumothorax	Sometimes, unilateral diminished breath sounds, subcutaneous air	Chest X-ray
Pleuritis	May have preceding pneumonia, pulmonary embolism, or viral respiratory infection Pain with breathing, cough, pleural rub	Usually clinical evaluation
Other		
Musculoskeletal chest wall pain (including trauma, overuse, costochondritis)	Often suggested by history Pain typically persistent (typically days or longer), worsened with passive and active movement Diffuse or focal tenderness	Clinical evaluation
Herpes zoster infection	Sharp, band-like pain mid-thorax unilaterally Classic linear, vesicular rash Pain may precede rash by several days	Clinical evaluation

Table 3: Clinical Features Associated with Specific Diagnostic Categories of Chest Pain

Clinical Features	Cardiac	Diagnostic Category Gastrointestinal	Musculoskeletal
Predisposing factors	Male sex Smoking Hypertension Hyperlipidaemia Family history	Smoking Alcohol use	Physically active New activity Overuse Repeated activity
Onset	At consistent level of exertion	After meals or on an empty stomach	With or after activity
Duration	Minutes	Minutes to hours	Hours to days
Character	Pressure or tightness	Pressure or gnawing pain	Sharp, localised and movement related
Relieved by	Rest, sublingual nitrate	Food, antacids	Rest, analgesics, NSAID

The pain of myocardial ischaemia may radiate to the neck, throat, lower jaw, teeth, upper extremity, or shoulder. A wide extension of chest pain radiation increases the probability that it is due to myocardial infarction. Radiation to both arms is an even stronger predictor of acute myocardial infarction. Acute cholecystitis can present with right shoulder pain, although concomitant right upper quadrant or epigastric pain is more typical than chest discomfort. Chest pain that radiates between the scapulae may be due to aortic dissection.

Temporal Elements

The time course of the onset of chest pain may be a very useful distinguishing feature:

- The pain associated with a pneumothorax or a vascular event such as aortic dissection or acute pulmonary embolism typically has an abrupt onset with the greatest intensity of pain at the beginning.
- The onset of ischaemic pain is most often gradual with an increasing intensity over time. A crescendo pattern of pain can also be caused by oesophageal disease.
- 'Functional' or nontraumatic musculoskeletal chest pain might have a much more vague onset.
- The duration of pain is also helpful. Chest discomfort that lasts only for seconds or pain that is constant over weeks is not due to ischaemia. A span of years without progression makes it more likely that the origin of pain is functional.
- The pain from myocardial ischaemia generally lasts for a few minutes; it may be more prolonged in the setting of a myocardial infarction.
- Myocardial ischaemia may demonstrate a circadian pattern. It is more likely to occur in the morning than in the afternoon, correlating with an increase in sympathetic tone.

Provoking Factors

The patient should be asked about factors that provoke or make the pain worse:

- Discomfort that reliably occurs with eating is suggestive of upper gastrointestinal disease.
- Post-prandial chest pain may be due to gastrointestinal or cardiac disease; in the latter case it can be a marker of severe myocardial ischaemia (e.g. left main or three-vessel CAD).
- Chest discomfort provoked by exertion is a classic symptom of angina, although oesophageal pain can present similarly.
- Other factors that may provoke ischaemic pain include cold, emotional stress, meals, or sexual intercourse.
- Truly pleuritic chest pain is worsened by inspiration and may be exacerbated when lying down.
- Causes of pleuritic chest pain include pulmonary embolism, pneumothorax, viral or idiopathic pleurisy, pneumonia, and a pleuropericarditis.

Relieving Factors

Factors that make the pain better should be established:

- Pain that is reliably and repeatedly palliated by antacids or food is likely to be of gastro-oesophageal origin.
- Pain that responds to sublingual nitroglycerin may be of either oesophageal or cardiac aetiology.
- Relief of pain following the administration of a 'GI cocktail' (e.g. viscous lidocaine and antacid) does not reliably distinguish gastrointestinal from ischaemic chest pain. On the other hand, pain that abates with cessation of activity strongly suggests an ischaemic origin.
- The pain of pericarditis typically improves with sitting up and leaning forward.

Severity

The severity of pain is not a useful predictor of CAD. As many as one-third of myocardial infarctions may go unnoticed by the patient.

ASSOCIATED SYMPTOMS

Associated symptoms may not reliably distinguish between a cardiac and gastrointestinal origin of chest pain.

- Belching, a bad taste in the mouth, and difficult or painful swallowing are suggestive of oesophageal disease, although belching and indigestion also may be seen with myocardial ischaemia.
- Vomiting may occur in the setting of myocardial ischaemia (particularly transmural myocardial infarction), in addition to gastrointestinal problems such as peptic ulcer disease, cholecystitis, and pancreatitis.
- Diabetic ketoacidosis, which can be precipitated by acute myocardial infarction, is another cause of vomiting.
- Diaphoresis is more frequently associated with myocardial infarction than with oesophageal disease.
- *Dyspnoea:* Exertional dyspnoea is common when chest pain is due to myocardial ischaemia and may precede the sensation of angina. Dyspnoea that occurs concurrently with chest pain may be due to myocardial ischaemia or a number of pulmonary disorders including diseases of the airways, lung parenchyma, or pulmonary vasculature.
- *Cough:* The differential diagnosis of chest pain and cough includes infection, as well as congestive heart failure, pulmonary embolus, and neoplasm. Cough, hoarseness, or wheezing may also be the result of gastro-oesophageal reflux disease.
- *Syncope:* The patient with myocardial ischaemia may present with presyncope. However, syncope associated with chest pain should raise a concern for aortic dissection, a haemodynamically significant pulmonary embolus, a ruptured abdominal aortic aneurysm, or critical aortic stenosis (particularly if the patient has a history of exertional dyspnoea).
- *Palpitations:* Patients with ischaemia can feel palpitations resulting from ventricular ectopy, or may have an abnormal awareness of their sinus rhythm. While atrial fibrillation is associated with chronic CAD, new onset, isolated atrial fibrillation is uncommon in patients with acute myocardial infarction.
- *Psychiatric symptoms:* Symptoms of panic disorder, generalised anxiety, depression, or somatisation may occur in patients with chest pain. Panic disorder is present in 30% or more of patients with chest pain who have no or minimal CAD; it may also coexist with CAD.

RISK FACTORS

The clinical impression raised by the patient's description of pain must be interpreted together with other aspects of the history, including risk factors for various aetiologies of chest pain.

Knowledge about such risk factors provides important information regarding disease likelihood, which may ultimately guide the type and extent of evaluation performed. The presence of hyperlipidemia, smoking, cocaine use, or a family history of premature CAD increases the risk for myocardial ischaemia. Hypertension is a risk factor for both CAD and aortic dissection. Cigarette smoking is a nonspecific risk factor for serious diseases; it is associated with CAD, thromboembolism, aortic dissection, pneumothorax, and pneumonia. A recent infection, especially viral or tuberculosis may precede an episode of pericarditis. Other risk factors for pericarditis include a history of chest trauma, autoimmune disease, recent myocardial infarction or cardiac surgery, and the use of certain drugs such as procainamide, hydralazine, or isoniazid. Age is an important risk factor for CAD; among patients older than 40 years, chest pain resulting from stable CAD or an acute coronary syndrome (unstable angina or myocardial infarction) becomes increasingly common. Men older than 60 years are most likely to suffer aortic dissection, while young men are at the highest risk for primary spontaneous pneumothorax.

PAST HISTORY

A past history of CAD, symptomatic gastro-oesophageal reflux, peptic ulcer disease, gallstones, panic disorder, bronchospasm, or cancer is very helpful in making a diagnosis. It is important to establish if the present symptoms are similar to those which occurred when the diagnosis was previously established. A history of diabetes mellitus should heighten the concern for a nonclassic presentation of CAD. It is important to exclude recent blunt trauma to the chest that can result in pneumothorax, disruption of the aorta, tracheobronchial tree, and oesophagus, myocardial or pulmonary contusion, or chest wall injury with associated musculoskeletal discomfort.

PHYSICAL EXAMINATION

The focused physical examination is used to support or disprove hypotheses generated by the history. Thus, the extent of the examination is primarily determined by the diagnoses that are being considered.

General Physical Examination

- The general appearance of the patient suggests the severity and possibly the seriousness of the symptoms (e.g. pallor, diaphoresis, cyanosis, anxiety).
- A full set of vital signs can provide valuable clues to the clinical significance of the pain, and may in some cases aid in establishing its origin.
- A marked difference in blood pressure between the two arms suggests the presence of aortic dissection. So pulses are palpated in both arms and both legs, BP is measured in both arms. Carotid artery is auscultated for a bruit.
- The neck is inspected for venous distension and venous wave forms are noted.

Chest Wall Examination

Palpation of the chest wall may evoke pain; if so the patient should be asked if this sensation is identical to the chief complaint. Chest wall tenderness may be present concomitantly with myocardial ischaemia. Hyperesthesia, particularly when associated with a rash, is often due to herpes zoster.

CVS Examination

A complete cardiac examination including auscultation and palpation should be performed in a sitting and supine position to establish the presence of a pericardial rub or signs of acute aortic insufficiency or aortic stenosis. Ischaemia may result in a mitral insufficiency murmur or an S4 or S3 gallop.

Respiratory System Examination

Determine if the breath sounds are symmetric and if wheezes, crackles or evidence of consolidation is present.

Abdominal Examination

A careful examination of the abdomen is important, with attention to the right upper quadrant, epigastrium and the abdominal aorta.

Findings which Raise Suspicion of a Serious Aetiology of Chest Pain

- Abnormal vital signs (tachycardia, bradycardia, tachypnoea, hypotension) and pulsus paradoxus > 10 mmHg
- Signs of hypoperfusion (confusion, ashen colour, diaphoresis).
- Shortness of breath.
- Asymmetric breath sounds and pulses.
- New heart murmur.

DIAGNOSTIC TESTING

ECG is important in critical evaluation of chest pain particularly when a cardiac aetiology is a possibility. Presence of ECG changes of ischaemia or infarction warrants admission to a CCU. Chest radiography (when cardiac or pulmonary disease is a consideration) may support the initial diagnosis and help avoid missing serious aetiologies of chest pain such as aortic dissection, pneumonia, pulmonary embolism or pneumothorax. Serial measurement of cardiac biomarkers, i.e. creatine kinase (CK), CK-MB and cardiac troponins (I and T) are useful in the emergency department for evaluation of acute chest pain. However, markers may take several hours after the onset of infarction to rise, hence treatment should not be delayed awaiting the results of enzyme levels.

Other Useful Investigations

Other useful investigations are:

- Complete blood counts (to exclude anaemia)
- Renal function tests blood sugar
- Liver function test (Cholecystitis) and amylase (pancreatitis)
- Exercise electrocardiography and stress echocardiography for evaluation of coronary artery disease in non-acute chest discomfort
- Endoscopy for gastrointestinal causes of chest pain.

KEY POINTS/CONCLUSION

- With careful history taking and physical examination, supplemented by targeted diagnostic tests, chest pain caused by serious conditions can often be quickly identified for early and immediate treatment.
- Immediate life threats must be ruled out first. Quick review of ECG is useful.
- Some serious disorders, particularly coronary artery disease and pulmonary embolism, may not have a classical presentation.

2.4 Acute Abdomen—Non-Surgical Causes

Sumeet Singla, AK Agarwal

Acute abdomen is defined as a recent or sudden onset abdominal pain (usually within 24 to 72 hours) with frequently associated gastrointestinal symptoms and signs. Acute abdomen is taught classically as a 'surgical' topic. A significant number of patients presenting with acute abdominal pain suffer from non-surgical conditions. Hence, an effective approach to the patient with acute abdomen must take into account the realisation that 3 out of every 4 such patients will be suffering from disorders requiring non-surgical intervention. This chapter is focussed on the approach to non-surgical causes of acute abdominal pain.

APPROACH TO DIAGNOSIS

The most important attribute of the physician evaluating a patient with acute abdominal pain is the ability to think 'out of the (abdomen) box'. One must be familiar with the various causes of this presentation and then proceed to refute or confirm the individual entities. A structured approach (**Figures 1A to C**) is easy to remember, fast, useful in resource-poor settings and minimises errors. Once a surgical cause has been excluded (no signs of peritonitis, perforation or obstruction), one can search for medical causes (**Table 1**). A non-rigid abdomen suggests a medical cause. However, certain surgical processes, initially confined to the visceral peritoneum, manifest as a non-rigid abdomen and only later progress to frank peritonitis when the parietal peritoneum is involved. Such a progression invariably portends the need for surgery.

CLINICAL CLUES TO MEDICAL AETIOLOGIES

History

- ***Age >65 years*** consider coronary artery disease, abdominal atheroemboli causing mesenteric ischaemia/infarction.
- ***Sex*** in females specific causes like ectopic pregnancy, threatened abortion, endometriosis, ovarian cyst and pelvic inflammatory disease (PID) must be looked for; in males epididymo-orchitis, prostatitis, and varicocoele are common causes of lower abdominal pain.
- ***Nature of the abdominal pain***
  - Insidious onset, diffuse or midline pain—visceral pain
  - Colicky pain—acute enteritis
  - Dysaesthetic type of pain—radiculopathy, neuropathy
- ***Radiation of the pain***
  - To the back—pancreatitis, pericarditis
  - To the right shoulder—Budd-Chiari syndrome, congestive hepatomegaly
  - To the left shoulder—splenic infarct, massive splenomegaly
  - Testicular/penile radiation—epididymo-orchitis
  - Lateralised and radiating from back to front of abdomen—spinal pain associated with radiculopathy
- ***Aggravating factors***
  - Increased on deep inspiration/coughing—pleurisy, pleural effusion, pneumonia, spinal pain
  - Increased during menstruation—endometriosis
  - Increased in supine position—pancreatitis
- ***Associated features***
  - Vomiting—if vomiting precedes pain, a medical cause is more likely
  - Appetite—retention of appetite is more likely in a medical cause
  - Diarrhoea, dysentery—indicates infection or inflammation of the bowel
  - Rectal bleeding—seen in bowel ischaemia/infarction, inflammatory bowel disease

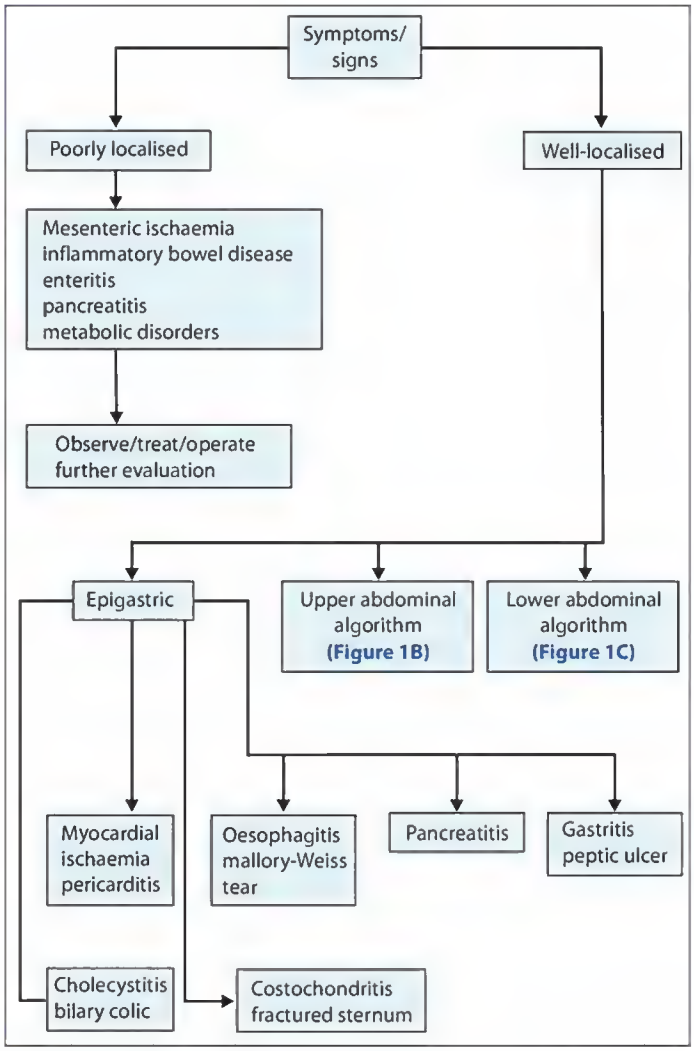

Figure 1A: Approach to the diagnosis of a non-rigid acute abdomen.

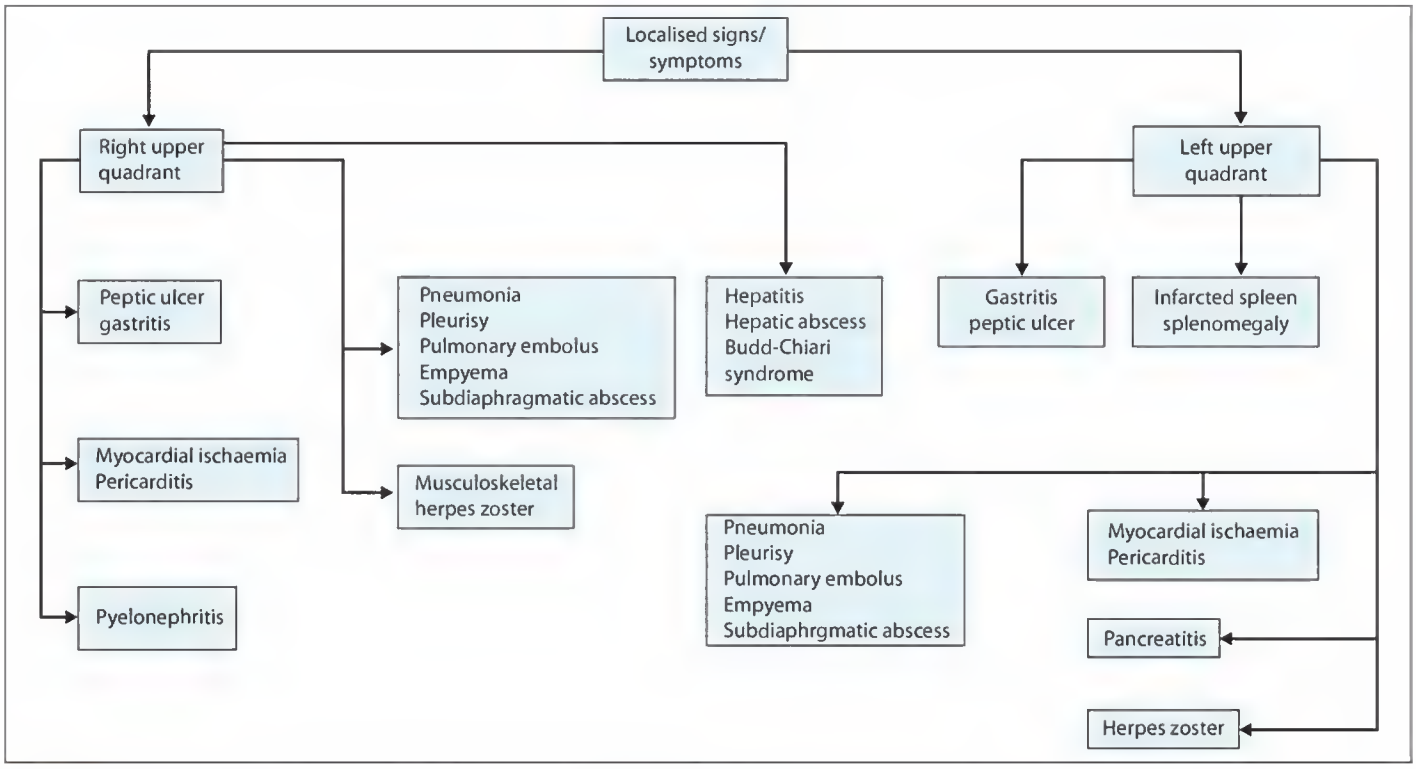

Figure 1B: Algorithm for diagnosing medical causes of upper abdominal pain.

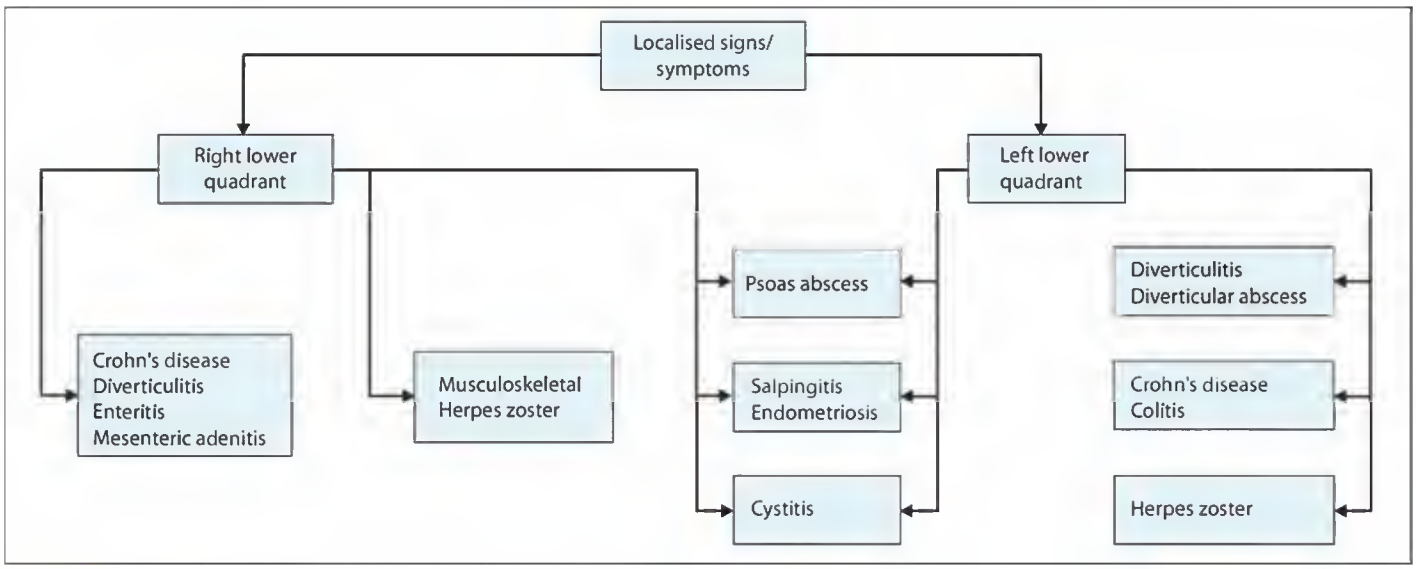

Figure 1C: Algorithm for diagnosing medical causes of lower abdominal pain.

(Figure 1A, 1B, 1C based on Martin RF, Rossi RL. The acute abdomen. An overview and algorithm. Surg Clin North Am 1997; 77: 1227-43).

  - High grade fever with/without chills—suggests pyelonephritis, enteritis, pneumonia
- Urethral/vaginal discharge—suggestive of pelvic inflammatory disease, STD.
- Frequency and urgency of urine associated with dysuria/haematuria/graveluria/lithuria—urinary tract infection.
- Bloody/unusually dark urine—haematuria, haemoglobinuria due to intravascular haemolysis, acute intermittent porphyria.
- Drug history—nonsteroidal anti-inflammatory drugs (NSAIDs) (acute erosive gastritis), vincristine (recent chemotherapy), anti-coagulants (intra-abdominal or abdominal wall haematoma), neuroleptics (neuroleptic malignant syndrome), drugs which can precipitate acute intermittent porphyria (barbiturates, phenytoin, rifampicin, oral contraceptives, etc).
- Drug withdrawal—steroids (withdrawal may precipitate acute Addisonian crisis), narcotics, alcohol, and nicotine.
- Occupational exposure to heavy metals like lead (battery makers, brass makers, cable makers, foundry workers, paint factory workers and painters), mercury (tube light, CFL and mercury vapour lamp industry), arsenic (production of glass or wood preservation), copper (mining, electrical wires, electroplating industry), asbestos (miners, stone crushers,

insulations, asbestos sheet industry); risk of scorpion (black widow spider) or snake bites (common krait or Bungarus caeruleus)—farmers, rural areas, sleeping on the floor, living in mud huts.

- Recent travel to areas endemic for malaria, typhoid, enteric infections.
- Menstrual history—relation of pain with menses; amenorrhoea.
- Psycho-social history—unemployed, living alone, divorced, diminutive personality, treated for anxio-depressive disorders, underlying psychoses. In these groups, a higher possibility of psychosomatic causes exists.

Physical Examination

The overall appearance of the patient can be very helpful. Patients whose pain is relieved by leaning forward may have pancreatitis. Most patients would be having tachycardia; unusual bradycardia should suggest typhoid, inferior wall myocardial infarction, drugs/toxins, and hyperkalaemia. Marked hypertension could signify porphyria, connective tissue disorders, uraemia, and hyperthyroidism. A patient may be dyspnoeic because of underlying pneumonia, pulmonary embolism, massive pleural or pericardial effusion, myocarditis, myocardial infarction, or metabolic acidosis (Kussmaul breathing). Tachycardia, mildly raised blood pressure and

Table 1: Differential Diagnosis of Medical Causes of Abdominal Pain

Metabolic/Haematologic

A. *Familial metabolic*
- Acute intermittent porphyria
- Haemochromatosis
- Hereditary angioneurotic oedema

B. *Endocrine*
- Diabetic ketoacidosis
- Addisonian crisis
- Hyperthyroidism/hypothyroidism
- Hypercalcaemia (hyperparathyroidism)

C. *Haematologic*
- Sickle cell crisis
- Acute haemolytic states
- Leukaemia
- Coagulopathies

Inflammatory Conditions

A. *Infections*
- Enteric infections
  - *Salmonella*, typhoid fever
  - *Shigella*
  - Staphylococcal
  - *Yersinia*
  - *Campylobacter*

tachypnoea may be seen in an apprehensive patient. The elderly, diabetic, uraemic, and immunosuppressed may be normothermic despite being seriously ill. Next, the head and neck should be examined for intraoral lesions, icterus, cyanosis, lymphadenopathy, jugular venous pressure, smell of ketones in the breath, carotid bruits, and lead line on gums. Fundus should be examined for emboli and lipaemia retinalis. Nailbeds should be inspected for infarcts or splinter haemorrhages. Pallor may signify external or internal blood loss, plumbism, addisonian crisis, and haematologic causes such as sickle cell disease, leukaemia or acute haemolysis; patients suffering form chronic diseases such as cirrhosis, uraemia, AIDS and connective tissue disorders, who have become acutely ill, may also be anaemic. Pedal oedema signifies congestive cardiac failure or chronic liver disease. A general visual survey may help characterise the nature of rashes; photosensitive rash of acute intermittent porphyria; purpuric rash of Henöch-Schoenlein purpura or leukaemia; vasculitic rash of systemic lupus erythematosus, polyarterits nodosa or scleroderma; nodular painful rash of fat necrosis in acute pancreatitis; ulcers in sickle cell disease; vesicular rash of herpes zoster and eruptive xanthomas in hyperlipidemia. Examination of joints for active arthritis and of the spine for local tenderness, deformity and paraspinal muscle spasm (suggestive of spinal disease) is not to be missed.

The examination of the cardiovascular and respiratory systems may provide very important information *viz.* rubs, rhonchi, crackles, and murmurs. Examination of the abdomen starts with a careful visual inspection of the skin looking for rashes, discolouration (Grey-Turner's sign, Cullen's sign), distension (ascites). Palpate the abdomen for assessing the site of maximal tenderness, presence or absence of rigidity, any intramural swelling/tenderness (haematoma of the rectus sheath), hepatosplenomegaly (leukaemia, malaria, or tuberculosis), shifting dullness (ascites), and costovertebral angle tenderness (pyelonephritis, pyonephrosis, or perinephric abscess). While a diffusely rigid abdomen strongly points to an underlying surgical cause, a soft, non-rigid abdomen increases the likelihood of a medical cause. As a corollary, when abdominal signs are minimal, but the patient's distress is severe, the physician should consider a medical condition as the cause of pain. Abdominal bruits signify that vascular occlusion may be the cause of pain, as do splenic rubs. A digital rectal examination is not to be omitted. It provides an opportunity to look for perianal skin tags, fistulae and sinuses (Crohn's disease), to detect blood in the anal canal [inflammatory bowel disease (IBD), colonic infarction], to examine the male external genitalia (epididymo-orchitis, varicocoele) and is especially useful in patients with lower abdominal pain (pelvic abscess, mass, prostatitis) and when a rigid abdomen prevents adequate examination. Likewise, *per vaginum* examination by a gynaecologist may provide valuable information. It is a good practice to involve a gynaecologist in the evaluation and management of young female patients with acute lower abdominal pain due to the far higher frequency of gynaecological (and hence, surgical) causes in this group. Finally, a neurological examination should be done in patients with gross neurological deficits (weakness of limbs or cranial muscles, sensory deficits, paraesthesiae, seizures and altered sensorium). Lack of objective clinical findings is most often due to observer error; but, if repeated examinations (and laboratory investigations) do not yield anything, a non-organic cause must be considered.

Table 2: Imaging Studies in Acute Abdominal Pain

Retroperitoneal disease—CT scan
Right upper quadrant and epigastric symptoms—Ultrasound
Left upper quadrant symptoms—CT scan with IV contrast
Left lower quadrant symptoms—CT scan with IV and oral contrast
Right lower quadrant symptoms—Ultrasound

Table 3: Clues to the Diagnosis of Medical Causes of Abdominal Pain

Abdominal pain associated with:
Neurological symptoms and signs—porphyria, snake (krait bite), plumbism, barium carbonate poisoning, collagen vascular disorders, illicit drug use
Dark/cola coloured urine—porphyria, acute haemolysis, renal infarction
Jaundice—cirrhosis with spontaneous bacterial peritonitis, congestive hepatomegaly, acute Budd-Chiari syndrome, acute hepatitis
High fever with/without chills—acute pyelonephritis, atypical pneumonia, basal pneumonia, bacterial enterocolitis, malaria, typhoid fever
Multisystem involvement—SLE, PAN
Anaemia—sickle cell disease, leukaemia, haemolysis, plumbism, coeliac disease, inflammatory bowel disease
Alcoholism—hepatitis, pancreatitis, abdominal tuberculosis, spontaneous bacterial peritonitis
Dyspnoea—metabolic acidosis (DKA, sepsis, mesenteric ischaemia, poisonings), pneumonia, myocardial infarction
Rectal bleeding—inflammatory bowel disease, enterocolitis, bowel infarction
Diabetes—diabetic ketoacidosis, thoracic truncal radiculopathy, acute pancreatitis, acute inferior wall myocardial infarction, mesenteric ischaemia
Arthritis—Henöch-Schoenlein purpura, connective tissue disorders, inflammatory bowel disease, reactive arthritis associated with enteric infections
Pleural effusion—acute pancreatitis, congestive cardiac failure, disseminated tuberculosis, pulmonary embolism, pneumonia, empyema, SLE
Ascites—acute pancreatitis, congestive cardiac failure, spontaneous bacterial peritonitis
Skin rash—herpes zoster, Henöch-Schoenlein purpura, vasculitides
Azotaemia or uraemia—prerenal causes (diarrhoea, dehydration, acute blood loss), acute glomerulonephritis, collagen vascular disorders
Weight loss—tuberculosis, diabetes mellitus, AIDS, chronic liver disease, inflammatory bowel disease
Recurrent episodes of acute abdominal pain—acute pancreatitis, porphyria, vaso-occlusive crisis of sickle cell disease, chronic lead poisoning, peptic ulcer, inflammatory bowel disease, mesenteric ischaemia

DIAGNOSIS

Laboratory/radiologic investigations must be viewed as confirmatory rather than screening tools. Other than a haemogram and a routine urine examination, all other investigations need to be justified keeping in mind the diagnoses being sought. A low haemoglobin suggests blood

loss or haemolysis. Leucocytosis is rather non-specific; however, a neutrophilic leucocytosis suggests an infectious pathology. A lymphocytic or monocytic leucocytosis would be more in line with a viral aetiology, such as infectious mononucleosis. Leucopenia portends a grave prognosis and may be due to severe sepsis, leukaemia, SLE or typhoid. Surgical illness is rare when both TLC and DLC are normal. A routine urine examination is useful in diagnosing urinary tract infections, urolithiasis, glomerulonephritis and diabetic ketoacidosis. An electrocardiogram should be obtained when evaluating a patient with risk factors/past history of atherosclerotic disease and may reveal inferior wall myocardial infarction, myocarditis or pericarditis. A radiograph of the chest is required if physical findings are suggestive of pneumonia, effusion, embolism or congestive cardiac failure. Serum amylase and lipase are required when acute pancreatitis is a strong possibility; beware of false positives due to non-pancreatic hyperamylasemia. Imaging helps to differentiate the two. In a patient with right hypochondrial pain with/without jaundice and hepatomegaly, it is prudent to order serum bilirubin, AST, ALT, and ALP levels. Serum sodium and potassium estimation may help in diagnosing certain conditions. Hyponatremia may be seen in porphyria, acute Addisonian crisis, and diabetic ketoacidosis. Only 45% of patients in Addisonian crisis will have hyponatremia and potassium levels will be typically normal (as opposed to 65% who have hyponatremia and 95% who have hyperkalemia in chronic Addison's insufficiency). Microscopic examination of the stool is useful in patients with fever and diarrhoea/dysentery. Arterial blood gas estimation is useful for patients in cardio-respiratory distress, suspected illicit drug use, poisonings, and unexplained causes (unexplained metabolic acidosis is the hallmark of mesenteric ischaemia). In young female patients with lower abdominal pain with/without amenorrhoea, it is mandatory to obtain a urine β-hCG test to rule-out pregnancy. Free fluid in the peritoneal cavity/pleural cavity should be tapped if the situation demands or if the diagnosis is unclear. In critically ill patients, peritoneal lavage is a good bedside test to detect peritoneal inflammation. A red cell count of ≥100,000/mm^3 and/or a white cell count of ≥500 /mm^3 in the lavage fluid represent a positive finding, as does the return of grossly purulent material, enteric contents, or other fluids that should not be present in the peritoneal cavity. A surgical cause, and the need for surgery, is then much more likely. Imaging of the abdomen should be a planned activity and not ordered blindly. When considering the use of imaging, the presence of localised symptoms can be useful in directing the choice of study as shown in **Table 2**.

A simplified, syndromic approach for the diagnosis of medical causes of acute abdomen is shown in **Table 3**.

2.5 Cough

Suman Kirti

Cough is a sudden, explosive, often-repetitive expiration, which helps to clear the tracheobronchial tree of secretions, irritants, foreign particles and microbes. Often called the watchdog of the respiratory tract, it is the commonest and most important respiratory symptom.

MECHANISM

Cough can be initiated voluntarily or reflexively. The cough reflex has an afferent limb with receptors in the sensory distribution of trigeminal, glossopharyngeal, superior laryngeal, and vagus nerves, that carries impulses to the cough centre located in the tractus solitarius in the medulla of the brainstem, which is connected to the central respiratory generator. The efferent limb consists of the recurrent laryngeal nerve and the spinal nerves. Cough starts with a deep inspiration followed by glottic closure, relaxation of the diaphragm and muscle contraction against a closed glottis causing airway pressure to rise (50 to 300 mmHg). This causes marked rise in positive intrathoracic pressure that results in tracheal narrowing. As the glottis opens the large pressure differential between airways and the atmosphere coupled with tracheal narrowing produces rapid flow rates (600 to 800 km/hr) through the trachea. These shearing forces aid in the elimination of mucus and foreign materials.

AETIOLOGY

Exogenous irritants like smoke, fumes, dust, foreign bodies or endogenous irritants like upper airway secretions or gastric contents may trigger cough, by stimulating the receptors in the upper airway (pharynx or larynx) or inhalation or aspiration in the lower airways (tracheobronchial tree). Endogenous irritants from postnasal drip or gastric contents may go unrecognised and cough may continue. Prolonged exposure to irritants initiates airway inflammation, which sensitises the airway to other irritants, and both cause persistent cough. Gastro-oesophageal reflux disease (GERD) causes cough by aspiration of gastric contents into the upper airways as well as vagal reflex secondary to acid in the distal oesophagus.

Cough occurs whenever there is inflammation, constriction, infiltration or compression of the airways. Inflammation occurs due to infections like viral or bacterial bronchitis or bronchiectasis. Viral bronchitis is usually acute, but persistent inflammation can cause a prolonged cough. Pertussis can also cause prolonged cough in adults. Constriction and inflammation occur in asthma and the diagnosis is made clinically. Rarely, there is a cough-variant asthma where there is cough without wheezing or dyspnoea. Tropical pulmonary eosinophilia (TPE) also causes cough. Infiltration of airways with granulomas as in tuberculosis (TB), which is common in India or endobronchial sarcoidosis, or by neoplasms like bronchogenic carcinoma and carcinoid, also triggers cough. Extrinsic compression of airways from lymph node masses, mediastinal tumours or rarely aortic aneurysm also causes cough.

Parenchymal lung diseases causing cough are pneumonia, interstitial lung disease and lung abscess. Congestive heart failure (CHF) can cause cough by interstitial as well as peribronchial oedema.

A dry cough may occur with angiotensin-converting enzyme (ACE) inhibitors in 5% to 20% of users usually within a week or up to 6 months of starting the drug, possibly due to accumulation of bradykinin or substance P which are degraded by ACE. The angiotensin II receptor antagonists do not increase bradykinin levels and do not cause cough.

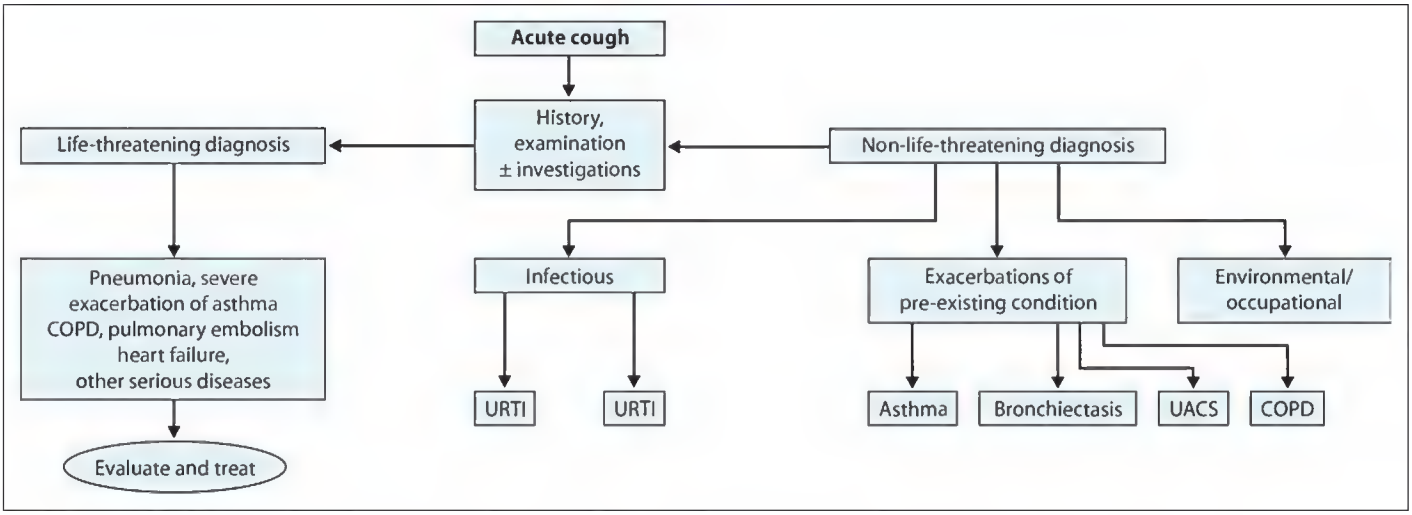

Figure 1: Acute cough algorithm for the management of patients ≥15 years of age with cough lasting <3 weeks.
Based on: Irwin RS et al. Chest 2006; 129: 1S-23S. (With permission).

Beta-blockers can cause increased airway resistance due to unopposed para-sympathetic activity especially in patients who already have obstructive airway disease.

CLASSIFICATION

Cough can be classified by its onset and duration, character, quality, and timing. The onset may be acute (<3 weeks) which is most often due to upper respiratory infections like common cold, bacterial sinusitis and pertussis; or lower respiratory tract infections like pneumonia, acute exacerbation of chronic obstructive pulmonary disease (COPD); acute episodes of asthma. CHF and pulmonary embolism can also present with acute cough. Inhalation of a foreign body is another cause. An algorithm for evaluating acute cough is shown in **Figure 1**.

Sub-acute cough (3 to 8 weeks) is commonly post-infectious due to persistent airway inflammation and/or postnasal drip following viral infection, pertussis or *Mycoplasma* or *Chlamydia* infection. In India, TB and TPE are important causes. An algorithm for the approach to a case of sub-acute cough is shown in **Figure 2**.

Causes of chronic cough (> 8 weeks) include TB, TPE, sarcoidosis, cystic fibrosis, COPD and bronchogenic carcinoma. In non-smokers with a normal chest radiograph, the common causes are postnasal drip [PNDs now called upper airway cough syndrome (UACS)], asthma, GERD, non-asthmatic eosinophilic bronchitis (NAEB) and ACE inhibitors. Left ventricular failure can cause sub-acute or chronic cough. Evaluation of chronic cough can be done using the algorithm shown in **Figure 3**. The differential diagnosis of sub-acute and chronic cough is shown in **Table 1**.

Cough can be dry or productive of sputum, the product of mucus glands and goblet cells of the bronchial walls. In a normal individual, 100 mL of secretions are produced daily. In respiratory disease, secretions may be mucoid, mucopurulent or purulent. Mucoid sputum is white or colourless, and gelatinous [as in chronic bronchitis (CB)]. Purulent sputum is yellow or green due to pus from infection. Large number of eosinophils can give a yellow colour. Foul smelling sputum can occur in bronchiectasis and lung abscess.

Cough may occur more at night (asthma, left heart failure, pulmonary eosinophilia) or early morning (CB). It may be seasonal as in asthma.

Cough may be aggravated by or related to occupational irritant exposure (e.g. byssinosis). It may increase after eating as in GERD or in tracheo-oesophageal fistulas and swallowing disorders. Sometimes GERD may complicate asthma or COPD.

Cough may be postural as in patients with bronchiectasis, lung abscess or bronchopleural fistula. These patients have large amounts of sputum. Sputum increases on waking in the morning in CB. Worsening of cough in CB may herald a bronchial carcinoma.

The character of cough may be like barking in children with croup. Staccato cough is seen in *Chlamydia pneumoniae*. Patients with chronic postnasal drip try to clear the throat and cough. Patients with bronchial and lung parenchymal diseases have a deep, 'loose' cough; those with tracheal compression have a brassy cough and those with laryngeal paralysis have a 'bovine' sounding cough.

DIAGNOSTIC APPROACH

History

Is it acute, sub-acute or chronic? Are there any symptoms of infection? Is it seasonal? Aggravating factors? Nasal discharge, frequent throat clearing, tickle in the throat (postnasal drip)? Is there heartburn or a sensation of regurgitation (GERD)? Postural? Description of sputum produced. ACE-inhibitor or beta-blocker use? Risk factors like smoking, environmental exposures, HIV risk factors, immunosuppressive agents, chronic renal disease (opportunistic infections).

Examination

General physical

Signs of heart failure, primary non-pulmonary neoplasm, cervical lymph nodes suggestive of tuberculous infection,

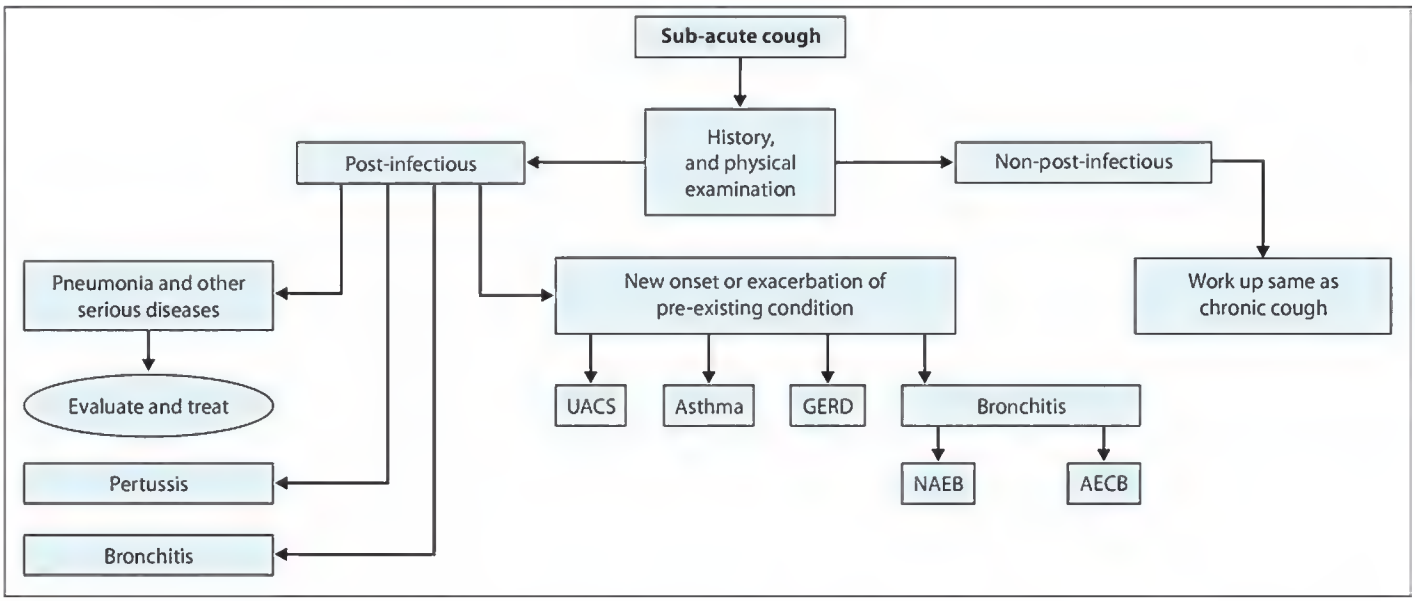

Figure 2: Sub-acute cough algorithm for the management of patients ≥15 years of age with cough lasting 3 to 8 weeks.
Based on: Irwin RS et al. Chest 2006;129: 1S-23S. (With permission).

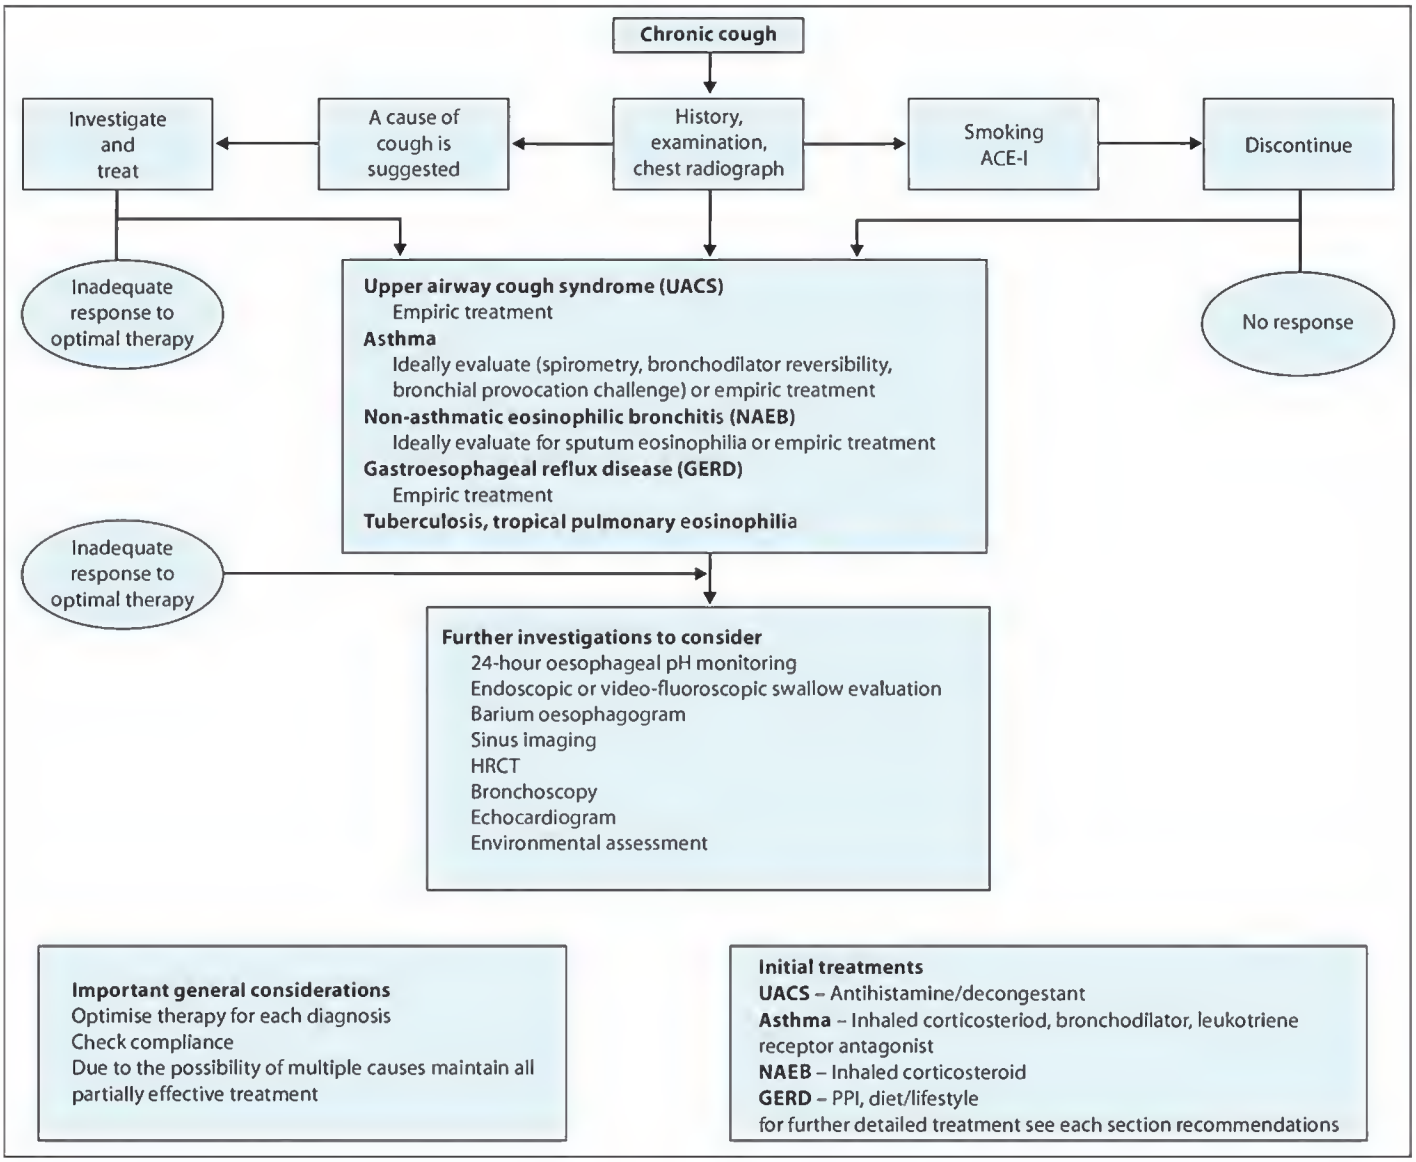

Figure 3: Chronic cough algorithm for the management of patients ≥15 years of age with cough lasting >8 weeks.
Modified from: Irwin RS et al. Chest 2006; 129: 1S-23S. (With permission).

fever, rash, cyanosis, clubbing. Oro-pharynx may show oro-pharyngeal mucus or erythema, 'cobblestone' mucosa (postnasal drip).

Examination of the Chest

Inspiratory stridor in upper airway disease, rhonchi or expiratory wheezing in lower respiratory disease, inspiratory crackles in lung parenchymal disease like pneumonia, interstitial lung disease (ILD) or pulmonary oedema.

Examination of Blood and Stool

Complete blood counts may reveal leucocytosis, high erythrocyte sedimentation rate, and marked eosinophilia in TPE and hemoparasites on peripheral smear. Stool examination may reveal helminths that cause TPE.

Chest Radiography

May reveal fibro-infiltrative or cavitatory lesions suggestive of TB, reticulo-nodular shadows with prominent hila suggestive of TPE, diffuse interstitial or alveolar disease, honey-combing or cysts as in bronchiectasis, or bilateral hilar adenopathy as in sarcoidosis, or a mass lesion.

Sputum Examination

Purulent sputum is seen in CB, bronchiectasis, pneumonia and lung abscess. Haemoptysis occurs in the same conditions as well as in TB and tumours. Sputum eosinophils >3% in patients without asthma suggests NAEB. Gram-stain, acid-fast bacilli stain and sputum culture will identify bacteria, TB and fungal infections. Cytology will help in identifying malignancy.

Pulmonary Function Tests

Assess functional abnormalities of the lung. Reversible airflow obstruction is seen in asthma. If airflow rates are normal but there is strong suspicion of asthma broncho-provocation tests may be done with methacholine or cold-air inhalation or capsaicin to show bronchial hyper-reactivity. Restrictive pattern and abnormality in diffusion studies are seen in diffuse ILD. Oxygen saturation and arterial blood gas analysis are also useful in assessing lung function.

Fibreoptic Bronchoscopy

Helps diagnose endobronchial granulomas (TB, sarcoidosis, fungi), tumours, foreign bodies, and collection of secretions

Table 1: Differential Diagnosis of Sub-acute and Chronic Cough

Common Causes	Clinical Features
Transient airway hyper-responsiveness	Cough persistent for many weeks, resolves (e.g. post-viral upper-respiratory infection)
Rhinosinus infection/inflammation	Cough follows infection or exposure to allergen; post-nasal drip is common
Asthma	Worse at night, on exercise, or following exposure to allergen, cold air or dust
Cough-variant asthma	Absence of wheezing or dyspnoea, dry nocturnal cough, bronchial hyper-responsiveness
Non-asthmatic eosinophilic bronchitis	No variable airflow obstruction; no hyper-responsiveness; sputum eosinophils >3%; Increased CO_2 in exhaled air
Chronic obstructive pulmonary disease	Usually seen in smokers. When smoking, and environmental irritants stop, cough eventually ceases
Gastro-oesophageal reflux	Heartburn, acid reflux, throat clearing, hoarseness or asymptomatic reflux
Pulmonary tuberculosis	Constitutional symptoms (fever, night sweats, weight loss, haemoptysis)
Bronchiectasis	Productive sputum, often purulent; cough (and sputum production) often positional
Tropical pulmonary eosinophilia	Cough, dyspnoea, wheeze, scanty sputum, blood and sputum eosinophilia, helminthic infestation
Bronchial carcinoma	Cough worse than usual in a smoker; sometimes, new persistent cough
Less Common Causes	
Repeated bronchial aspiration	Oesophageal disorders, neurological swallowing disorders
Pulmonary fibrosis	Patient is breathless; cough 'dry'
Aspirated foreign body	May have no history of aspiration
Lung compression (e.g. pleural effusion, mass)	Sometimes positional
Drug-induced cough	ACE-inhibitors: dry cough; beta-blockers: cough and usually wheezing
Pneumocystis jiroveci	Immune deficient patients with persistent cough
Psychogenic	Patient otherwise well; no cough at night or when distracted; no response to cough suppressants

Based on: Symptoms and Signs. Medicine International (Indian Ed) 1995; 9: 222; Philp EB. Chronic cough. Am Fam Physician 1997; 56: 1395-1408.

and endobronchial biopsies and transbronchial lung biopsies helps in further diagnosis.

High Resolution Computed Tomography (HRCT)

Helps in diagnosing ILD and can confirm the presence of bronchiectasis. CT of para-nasal sinuses can help in diagnosing UACS.

COMPLICATIONS

The complications of coughing can be classified as either acute or chronic. Acute complications include cough syncope due to markedly positive intrathoracic and alveolar pressures, decreased venous return, and decreased cardiac output when cough is prolonged and forceful, insomnia, cough-induced vomiting, sweating, rupture of bullae causing pneumothorax, sub-conjunctival haemorrhage, cardiac arrhythmias, seizures, splenic and venous ruptures, disruption of surgical wounds, coughing defaecation, cough syncope and in women with a prolapsed uterus, urinary incontinence. Chronic complications are common and include abdominal or pelvic hernias, fatigue, fractures of lower ribs and costochondritis.

TREATMENT

Specific treatment can be given once the cause is evident such as stopping smoking or an ACE-I, or beta-blocker, treating post-nasal drip or GERD, infections, bronchodilators for airway obstruction, inhaled glucocorticoids for NAEB, treating TB, TPE, sarcoidosis and ILD, tumours, bronchiectasis. In patients with chronic unexplained cough empirical therapy with antihistamines, decongestants, nasal glucocorticoids, nasal ipratropium may help improve UACS. In the absence of an appropriate response, empirical treatment for asthma, NAEB and GERD can be tried. Symptomatic therapy for cough is given when the cause is unidentified or no specific treatment is available or there is sleep disturbance and distressing cough. Dextromethorphan or codeine are cough suppressants and provide relief in dry irritating cough. Productive cough should not be suppressed, as the sputum will be retained in the respiratory tract and result in reduced ventilation. Cough suppressants should be strictly avoided in obstructive airway disease.

2.6 Haemoptysis

Randeep Guleria, Jaya Kumar

INTRODUCTION

Haemoptysis is defined as coughing up of blood from the respiratory tract. It can range from streaks of blood in the expectoration to coughing up of large quantities of blood. Haemoptysis is alarming for the patient and can be caused by a spectrum of disorders ranging from a respiratory tract infection, bronchogenic carcinoma and rarely with systemic diseases which causes alveolar haemorrhage. Sometime, a minimal haemoptysis initially may be followed by a bout of massive haemoptysis which can be life-threatening. Massive haemoptysis is a medical emergency, most often due to asphyxiation which occurs due to flooding of the airways and alveoli with blood and also due to significant haemodynamic compromise. Despite a lot of focus on the management of massive haemoptysis the definition is highly variable. It is most commonly defined as expectoration of 100 to 600 mL of blood in 24 hours. The problem with this definition is that it is very difficult for a patient to quantify haemoptysis. Also the morbidity and mortality depends on the rate of bleeding, the condition of the underlying lungs and the ability of the patient to clear the airways of the blood rather than on the absolute quantity of blood loss. Any amount of haemoptysis which causes haemodynamic instability or respiratory embarrassment should be considered massive. Life-threatening haemoptysis is recommended as a better term which encompasses the quantity of haemoptysis, haemodynamic instability and impairment of gas exchange. The unpredictable course of haemoptysis with a possibility of potentially life-threatening massive haemoptysis and the various serious aetiologies mandates a prompt and focused assessment and management.

AETIOPATHOGENESIS

Vascular Anatomy

It is important to understand the blood supply of the lung to get an idea of the mechanism of significant haemoptysis. The lungs have a dual blood supply from the pulmonary and bronchial circulation. The pulmonary circulation is a low pressure system which is responsible for gas exchange. The pulmonary arteries run along the bronchial tree and carry the entire cardiac output for oxygenation in the pulmonary capillaries, but the only interaction with the airways is at the level of the terminal bronchioles where the pulmonary capillary bed arises around the alveoli for gas exchange. The bronchial tree on the other hand carries a small portion of the cardiac output but has a pressure at par with the systemic pressure. The bronchial arteries arise from the aorta or the intercostals arteries and supplies blood to the airways, hilar lymph nodes visceral pleura and parts of the mediastinum. They branch along the bronchial tree and form an extensive plexiform network in the peri-bronchial space and in the submucosa of the bronchial wall. Bleeding from the pulmonary vasculature is less common and minimal as it is a low pressure system. Also hypoxic pulmonary vasoconstriction diverts blood away from the diseased portion of the lung. Massive haemoptysis originating from the pulmonary circulation is therefore uncommon. The bronchial circulation is a more important cause of significant haemoptysis as it runs along the bronchial tree and supplies blood to the airways. Inflammation in the airways leads to hypertrophy of the bronchial vessels and an increased propensity to bleed. Also being a high pressure system it leads to more profuse bleeding and accounts for most cases of massive haemoptysis.

Causes

Haemoptysis has a varied aetiology with the common causes being tuberculosis (TB), bronchiectasis, bronchitis, bronchogenic carcinoma and pneumonia in different proportions depending on the population studied. The causes can be categorised according to the site of origin within the lung and the underlying disorder (**Table 1**).

The frequency of the different causes of haemoptysis varies in the developed and developing world. Recent literature from the developed world shows TB to be an infrequent cause of haemoptysis. The leading causes of haemoptysis in these countries are bronchitis, pneumonia, bronchiectasis and bronchogenic carcinoma with TB accounting for only 1.4% to 8% in different studies. In our country and most of the developing world TB still remains the most common cause for haemoptysis. In a study from Lucknow, India, the TB accounted for 79.2% cases of haemoptysis followed by bronchogenic carcinoma.

Various mechanisms are responsible for haemoptysis in active TB and post-tubercular sequelae:

A. Active tuberculosis

1. Bronchiolar ulceration and necrosis of adjacent vessels and alveoli.
2. Erosion of a vessel wall of a cavity.
3. Tubercular involvement of the vessel wall causes formation of aneurysms called Rasmussen's aneurysm. Rupture of these aneurysms can cause massive haemoptysis.

B. Sequelae of tuberculosis

1. Bronchiectasis due to destruction of the normal lung architecture by TB.
2. Aspergilloma formation in an old tubercular cavity.
3. Erosion of bronchial arteries due to healed, calcified nodes rupturing through the bronchial tree.
4. Scar carcinoma.

Table 1: Causes of Haemoptysis

- **A. Pulmonary**
  - *1. Airway disease*
    - Bronchiectasis
    - Bronchitis (acute and chronic)
    - Neoplasms
      - Bronchogenic carcinoma
      - Endobronchial metastatic carcinoma
      - Bronchial carcinoid
      - Kaposi's sarcoma
    - Foreign body
    - Airway trauma
  - *2. Parenchymal disease*
    - Infectious
      - Tuberculosis
      - Pneumonia/lung abscess
      - Aspergilloma
      - Lung parasite (ascariasis, schistosomiasis)
    - Inflammatory or immune disorders
      - Wegener's granulomatosis, SLE
      - Good pasture's syndrome
      - Idiopathic pulmonary haemosiderosis
      - Other pulmonary vasculitis
  - *3. Vascular causes*
    - Pulmonary embolism
    - Pulmonary arteriovenous malformation
- **B. Cardiovascular**
  - Pulmonary hypertension per se, Mitral stenosis
  - Tricuspid endocarditis
  - Aortic aneurysm
- **C. Trauma**
  - Chest injury
  - Iatrogenic
    - Percutaneous lung biopsy
    - Bronchoscopy with bronchial biopsy or transbronchial lung biopsy
    - Swan ganz catheterisation causing pulmonary artery perforation
- **D. Miscellaneous**
  - Drug induced (anti-coagulants, penicillamine, bevacizumab, cocaine)
  - Pulmonary endometriosis
  - Cryptogenic

Table 2: Differences Between Haemoptysis and Haematemesis

Haemoptysis	Haematemesis
Clinical evidence of lung disease	Clinical evidence of gastric or hepatic disease
Bright red or pink blood Liquid clotted appearance	Brown to black, coffee ground appearance
Cough, breathlessness chest pain present	Nausea vomiting, abdominal pain
Malaena rare	Malaena may be present
Examination shows macrophages or neutrophils	Mixed with ingested food particles
Alkaline pH	Acidic pH

DIAGNOSTIC APPROACH

A good history is very essential as it guides towards a likely aetiology. The first step is to distinguish haemoptysis (bleeding from the upper respiratory tract) from haematemesis (bleeding from upper G.I. tract) (**Table 2**). Once haemoptysis is confirmed the history should include assessment of the quantity of haemoptysis as an aggressive approach is required for massive haemoptysis. Also history of associated symptoms, including fever, cough, expectoration, dyspnoea, constitutional symptoms related to the underlying aetiologies helps the physician to narrow the differential diagnosis and develop a focused approach. History related to any suspected, underlying systemic illness, smoking, use of any drug, past illnesses like TB, severe or recurrent pneumonia should also be included. A complete physical examination including the vitals, general physical examination, respiratory and cardiovascular system is essential.

The priority in massive haemoptysis is to protect the airway, maintain ventilation and circulation and avoid the other lung from flooding. An evaluation for cause would follow once the patient is stabilised. Non-massive haemoptysis entails an evaluation for the cause of haemoptysis so as to start treatment for the same. Initial evaluation, depending on the presentation, should include—haemogram with haematocrit , white blood cell count and platelet count, erythrocyte sedimentation rate (ESR), arterial blood gas analysis, sputum for acid fast bacilli (AFB), Gram-stain, culture, and cytology, blood urea and serum creatinine, serum chemistry, HIV serology, autoimmune work-up and urine analysis if systemic vasculitis is suspected; prothrombin time, partial thromboplastin for coagulation disorders; D-dimer for suspected pulmonary embolism.

The evaluation for the aetiology begins with a chest radiograph and has changed drastically with the advent of computed tomography (CT) scans and bronchoscopy. When the chest radiograph is normal with a history suggestive of airway disease and there is no apparent risk factors for carcinoma lung the patient can be observed. No further evaluation is necessary if bleeding does not recur. Further evaluation with a contrast enhanced and high resolution computed tomography (HRCT) is indicated even if the chest radiograph is normal if bleeding recurs or if risk factors for carcinoma lung are present or the history is not compatible with bronchitis. When the chest radiograph shows parenchymal involvement sputum for AFB must be done. If the sputum is negative for AFB, the CT of the chest is required followed by treatment of the underlying disease, if a specific diagnosis is established. Further evaluation with bronchoscopy is advised when the CT chest does not suggest a specific diagnosis. When a chest radiograph reveals a mass, further evaluation with CT chest, bronchoscopy and a biopsy from the mass is indicated.

CT scan of the chest specially contrast enhanced HRCT has changed the diagnostic algorithm for haemoptysis. CT scan can help diagnose several conditions where the chest radiograph is normal or help in further characterising lesions seen on the radiograph. These include bronchiectasis, lung carcinoma, sequelae of TB, aspergilloma, pulmonary aneurysm and lung nodule. In addition it may also help to direct fine needle aspiration cytology (FNAC) and biopsy. Also it may help in deciding the better mode of tissue sampling in a particular case, bronchoscopic biopsy or CT guided per-cutaneous biopsy.

Flexible fiberoptic bronchoscopy (FOB) along with HRCT chest is the mainstay of diagnosis in patients with haemoptysis.

Bronchoscopy helps in the diagnosis when the radiology is normal or non-localising and if done acutely may help identify the source of bleeding. It is specifically useful in diagnosing endobronchial lesions, bronchitis and subtle mucosal abnormalities. A bronchoscopy should always be done in a patient with haemoptysis if there are risk factors for lung carcinoma even if the CT scan is normal.

The rigid bronchoscopy is being more and more infrequently used as the flexible scope gives greater access to the distal airways, but it has the advantage of providing better airway control and suctioning and can be used to remove large clots or foreign bodies. Bronchial and pulmonary angiography is rarely done as a diagnostic test with the advent of CT and bronchoscopy. It is done when bronchial artery embolisation is planned to stop bleeding. Specific tests like CT pulmonary angiography, ventilation perfusion scan and echocardiography may be required depending on the underlying aetiology.

MANAGEMENT

The goal of the management is to stop the bleeding, prevent asphyxiation and to treat the underlying disorder. The most important step is to quantify the haemoptysis and ensure that airway, breathing and circulation are maintained. It is important to remember that a minor bleed may herald a massive, life-threatening haemoptysis.

Management of Non-Massive Haemoptysis

Non-massive haemoptysis can be managed on an out-patients basis. However, the patient should be advised to report immediately to the emergency, if the haemoptysis increases or does not settle. The management is based on preventing further bleed from occurring and to find and treat the underlying cause. Basic investigations including a chest radiograph, haemogram and sputum for AFB must be done. Once the cause of haemoptysis is found appropriate treatment should be initiated. To prevent further bleeding cough suppressants, haemostatic agents and anxiolytic should be used. A broad spectrum antibiotic is given at times to prevent secondary bacterial infection in the lung.

Management of Massive Haemoptysis

It is a medical emergency, as it can cause sudden death by asphyxiation. The first step is to protect ABC—airway, breathing and circulation. Protection of the airway is of utmost importance, as asphyxiation is the most common cause of death in these patients.

The steps in management include:

1. Airway protection and haemodynamic stability: The patient should be admitted in the intensive care unit. If the site of bleeding is known the patient should be placed in a lateral position with the bleeding lung in the dependent position. This helps to protect the non-bleeding lung from spillage. Endotracheal intubation with a wide bore tube is indicated in patients with massive ongoing haemoptysis, haemodynamic instability and inadequate gas exchange. This also helps in better airway protection, suction and resuscitation in case of cardio-respiratory arrest.
2. Localisation of the bleed and protection of the non-bleeding lung: Bronchoscopy is the procedure of choice to identify the side and specific site of bleeding. If the side is identified but the specific site cannot be seen selective single intubation of the lung can be done to prevent flooding of the other lung. Double lumen endotracheal tube can be used in experienced centres when the side cannot be localised and bleeding persists. Rigid bronchoscopy may be required when there is massive bleeding because it is difficult to visualise the airway with an FOB in such a situation.
3. Bronchoscopic measures to stop bleeding: Once the specific site of bleeding is located, specific measures can be used to control the bleeding.
   - Bronchial lavage with iced saline has been successfully used in several studies.
   - Vasoconstrictive agents like epinephrine can be used to control bleeding.
   - Bronchoscopic balloon tamponade: A 4 French, 100 cm fogarty catheter is inflated in the segmental/sub segmental bronchus leading to the bleeding site for 24 to 48 hours. It is deflated for several hours after 1 to 2 days and removed if bleeding does not recur.
   - Laser photocoagulation and electrocautery have been tried in endobronchial tumours to control bleeding.
4. Angiography and embolisation: Patients who continue to bleed despite above measures can be taken up for angiography to localise the bleed and the bleeder can then be embolised. This procedure is used as a bridge to surgery or in patients who are not candidates for surgery. It is considered to be semi-definitive as rebleeding can occur in 10% to 20% patients in the next one year. Currently bronchial artery embolisation is a commonly used method to stop massive haemoptysis in most centres. It is also used in patients who have recurrent moderate to massive haemoptysis and are not candidates for definitive surgery.
5. Surgery: It is the only definitive option in massive haemoptysis not responding to above mentioned measures. Unfortunately most patients are not fit for surgery which is contraindicated in patients with diffuse/bilateral disease, active TB and in patients with poor respiratory reserve. Also the mortality and morbidity is much higher in emergent surgery in comparison to elective surgery in the non-bleeding patient.

PROGNOSIS

The outcome of haemoptysis varies in various series depending on the underlying aetiology, the number of patients with massive haemoptysis and the expertise of the treating centre. The mortality is 8% to 10% in various studies. The prognosis is improving with the newer modalities of treatment. All patients with haemoptysis, minimal or massive should be aggressively managed at well equipped centres to further improve the outcome.

2.7 Jaundice

Aparna Agrawal

Jaundice is a common presentation of liver and biliary tract disease, characterised by yellowish discoloration of skin, sclerae and mucous membranes. It is clinically detectable when serum bilirubin is >3.0 mg/dL. It manifests more in tissues with – high elastic content (skin, sclera, blood vessels), high blood flow, low interstitial fluid and in fluids with high protein content (urine, sweat, semen, milk, exudates, etc.).

It manifests less in paralysed parts and oedematous areas.

Yellowing of the skin can also occur in carotenoderma (spares the sclera), with use of quinacrine and with excessive exposure to phenols.

CLINICAL EVALUATION

- Inspection should be done in bright day light to detect jaundice.
- Inspect the sclera, tongue, hard palate, skin and fingers.
- Ask the patient to look down and inspect the unexposed portion of the sclera because bulbar conjunctiva can be discoloured due to dust.
- Note whether the hue is lemon yellow (unconjugated hyperbilirubinaemia stains the tissues lightly because of its water insolubility); orange yellow (in patients with hepatocellular and cholestatic jaundice there is increase in conjugated bilirubin which penetrates body fluids more because of its water solubility), or greenish yellow (in prolonged cholestasis because of formation of biliverdin).
- Staining of clothes by secretions is a good clue (specially urine, sweat, milk and semen).
- Look for high coloured urine and pale coloured stools (avoid early morning specimen).

AETIOPATHOGENESIS

Jaundice results from a disorder of bilirubin metabolism in the form of increased formation or a decrease in hepatic clearance of bilirubin. Unconjugated bilirubin is lipid soluble and it is converted to water soluble bilirubin mono-and-diglucuronide by conjugation, which allows its excretion into the bile.

Some Practice Points

- In late stages of cholestatic or hepatocellular jaundice, despite high serum bilirubin levels, none can be detected in the urine. This is due to a third type of bilirubin—a bilirubin mono conjugate (not mono-and-diglucuronide), covalently bound to albumin, which is not filtered by the glomerulus, hence absent in the urine.
- The high elastic content of tissues is responsible for the disparity between the depth of jaundice in the skin and sclera and serum bilirubin levels during recovery from hepatitis or cholestasis.
- In unconjugated hyperbilirubinaemia due to haemolysis, usually serum bilirubin is < 5 mg/dL. If it is more than this, check for combination of haemolytic anaemia with an inherited disorder of bilirubin metabolism—Gilbert's syndrome or Crigler Najjar syndrome, coexistent renal and hepatocellular dysfunction or acute haemolytic crisis.

CLASSIFICATION AND CAUSES OF JAUNDICE

These are given in **Table 1.**

APPROACH TO JAUNDICE

A careful history, physical examination and standard laboratory tests help us in arriving at an accurate diagnosis in >80% of patients. In adult patients with a new-onset jaundice, the following disorders account for >95% of the diagnosis:

- Viral hepatitis.
- Alcohol-induced liver disease.
- Drug induced liver disease.
- Infections involving the liver including liver abscess and sepsis.
- Chronic hepatitis (all causes).
- Gall stones and their complications.
- Pancreatitis.
- Carcinoma of the pancreas.
- Haemolytic anaemia.

I. History

The onset, evolution and duration of jaundice should be noted. The associated features should also be enquired into.

History suggestive of acute viral hepatitis

- Low grade fever for 1 to 2 days, usually associated with headache, myalgias, anorexia, nausea and vomiting followed by jaundice.
- Change in taste and smell of food.
- Contact with individuals with jaundice.
- Needle stick exposure or any injection, body piercing, tattoos, shared razors or tooth brushes.
- Blood or blood product transfusions.
- Intravenous drug abuse.
- Health care professionals.
- Sex with commercial sex workers, multiple partners or with individuals with hepatitis B or C.
- History of sexually transmitted disease.
- Travel to endemic areas or eating raw shell fish (especially for hepatitis A).
- Occasionally, pain with or without swelling of joints and transient skin rash may indicate hepatitis B or C.

Table 1: Classification and Causes of Jaundice

Type	Cause	Basic Laboratory Abnormalities
Pre-hepatic	**↑ Bilirubin production** Haemolysis (a) Intravascular haemolysis – G6PD deficiency, PNH, malaria – Blood transfusion – Ineffective erythropoiesis	Unconjugated ↑ SBR Normal STA + ALP
	(b) Extravascular haemolysis – Pneumonia, PTE, resorption of haematomas, haemoglobinopathies	
Hepatic	(a) **↓ Hepatocellular uptake** – Drugs (Rifampicin, probenecid, ribavirin) – Gilbert's syndrome	
	(b) **↓ Conjugation** – Gilbert's syndrome, Crigler-Najjar Syndrome I and II – Physiologic jaundice of newborn – Drugs (e.g. Indinavir)	
	(c) **↓ Transport** i. Congenital hyperbilirubinaemia – Dubin-Johnson syndrome – Rotor's syndrome	Conjugated ↑ SBR Normal STA+ALP
	ii. Acute/ subacute hepatocellular disease – Viral hepatitis A-E, EBV, CMV, HSV – Hepatotoxins (ethanol, Amanita Phalloides) – Drugs – Dose dependent (Acetaminophen) Idiosyncratic (INH, phenytoin, etc.) – Ischaemia (hypotension, Budd-Chiari syndrome, hepatic veno-occlusive disease) – Metabolic disorders (Wilson's disease, Reye's syndrome) – Pregnancy related (AFLP, pre-eclampsia)	Mixed ↑ SBR (↑ SBR + ↑ STA ± ↑ ALP)
	iii. Chronic hepatocellular disease – Viral hepatitis (B, C, D) – Alcohol – Hepatotoxins (Vinyl chloride, Vit. A. hypervitaminosis) – Autoimmune hepatitis – Metabolic (haemochromatosis, Wilson's disease, NASH, α_1-antitrypsin deficiency) – Coeliac sprue	
Cholestatic	(a) Hepatic disorders with prominent cholestasis i. Diffuse infiltrative disease of liver – Granulomatous disease (Mycobacterial infection, Brucella, fungal disease, sarcoidosis, lymphoma, drugs, Wegener's granulomatosis) – Amyloidosis – Malignancy	↑ SBR + ↑ STA + ↑ ALP
	ii. Inflammation of intrahepatic bile ductules and/or portal tracts – Primary biliary cirrhosis – Drugs (erythromycin, trimethoprim-sulphamethoxazole) – Graft versus host disease	
	iii. Miscellaneous – Benign recurrent intrahepatic cholestasis – Intrahepatic cholestasis of pregnancy – Drugs (estrogen, anabolic steroids) – Total parenteral nutrition – Infections – Post-operative cholestasis – Vanishing bile duct syndrome	
	(b) Obstruction of bile ducts i. Choledocholithiasis – Cholesterol gall stones – Pigment gall stones	
	ii. Diseases of the bile ducts – Cholangiocarcinoma – Inflammation/Infection – Primary sclerosing cholangitis – AIDS cholangiopathy – Post surgical strictures	Conjugated ↑ SBR + Normal STA + ↑↑ ALP
	iii. Extrinsic compression of the biliary tree – Neoplasms (pancreatic carcinoma, hepatocellular carcinoma, nodes at porta hepatis) – Pancreatitis – Vascular enlargement (e.g., aneurysm, cavernous transformation of portal vein)	

SBR = Serum bilirubin, STA = Serum transaminases, ALP = Alkaline phosphatase, AFLP = Acute fatty liver of pregnancy.

History suggestive of chronic hepatitis/cirrhosis with portal hypertension

- Recurrent jaundice.
- Swelling of feet.
- Distension of abdomen.
- Massive haematemesis or melena may indicate portal hypertension and variceal bleed.
- Amenorrhoea.

History suggestive of alcohol-induced liver disease

- Details of quantity and type of alcohol being consumed now or in the past should be obtained from the patient, friends and family members. (The threshold for alcohol-induced hepatic injury appears to be 30 gms/day for women and 60 gms/day for men if ingested over 5 to 10 years. Less, if additional factors for liver disease are present).
- History of binge drinking and day time drinking should be noted.
- History of withdrawal symptoms or seizures should be taken. CAGE criteria (cut down, annoyed, guilty, eye opener) should be looked for as indicators of excessive alcohol usage.
- History suggestive of other alcohol related illness, e.g. pancreatitis, gastritis, peripheral neuropathy should be taken.

History suggestive of drug induced liver disease

- Review all prescription medications.
- Enquire specifically about alternative forms of medicine being taken.
- History of pruritic rash, joint pain or swelling related to some drug intake.

History suggestive of infections/liver abscess

- Fever moderate to high grade with chills/rigors, with dull aching pain right upper abdomen especially when associated with dysfunction of other organs.
- Rule-out leptospirosis in patients with combined renal and hepatic dysfunction.

History suggestive of cholestatic jaundice

- High coloured urine with pale coloured stools.
- Pruritus.
- Colicky pain right upper abdomen associated with fever, rigors/chills (suggestive of choledocholithiaisis with ascending cholangitis).

History suggestive of pancreatitis

- Recurrent upper abdominal pain with radiation to the back.
- History suggestive of steatorrhoea.
- Fever with severe pain and distension of the abdomen may be suggestive of acute pancreatitis.

History suggestive of haemolytic anaemia

- History of pale coloured urine with mild yellow discolouration of eyes.
- History of anaemia not responding to haematinics and requiring regular blood transfusions.
- History of recurrent jaundice or non-healing ulcer.
- Family history of anaemia.
- Known haemoglobinopathy or having artificial heart valves.

Miscellaneous

- Age and sex: Type A hepatitis decreases as age advances but no age is exempt from hepatitis B and C.
  - A multiparous, middle-aged, obese female with dyspepsia may have gall stones.
  - Chances of malignancy increase with increasing age.
- Occupation should be noted (particularly involving alcohol, other hepato-toxic industrial chemicals or contact with rats for Weil's disease).
- Painless jaundice—check for malignancy.
- Significant weight loss—check for malignancy.
- History of joint pain or swelling (check for hepatitis B or C, autoimmune hepatitis, drug induced hepatitis, inflammatory bowel disease with primary sclerosing cholangitis or granulomatous disorders such as sarcoidosis).
- Diabetes, arthritis and pigmentation—check for haemochromatosis.
- Chronic obstructive pulmonary disease with jaundice—suspect α_1 antitrypsin deficiency.
- Chronic diarrhoea with blood and mucous—rule-out primary sclerosing cholangitis.
- Family history of liver disease (check for Wilson's disease, haemochromatosis, α_1 antitrypsin deficiency).
- Family history of biliary disease.

Jaundice after biliary tract surgery

Check for:

- Residual calculus
- Traumatic stricture of bile duct
- Sepsis
- Drug induced hepatitis
- Hepatic metastasis in case of malignancy

Jaundice in a liver transplant recipient

Causes:

- Hepatocellular injury resulting from impaired organ preservation
- Vascular occlusion in immediate postoperative period
- Graft rejection
- Obstruction of the bile ducts
- Acute viral hepatitis especially cytomegalovirus infection
- Immunosuppressive drug toxicity
- Recurrent disease (e.g. Hepatitis B or C, primary sclerosing cholangitis)

Jaundice in pregnancy

The following causes are specific to pregnancy:

- Hyperemesis gravidarum (first trimester; self limiting)
- Intrahepatic cholestasis of pregnancy (third trimester; pruritus; resolves within 2 weeks of delivery; tends to recur with subsequent pregnancies)

- Acute fatty liver of pregnancy (third trimester; may be fatal unless delivery is performed promptly)
- Pre-eclampsia (third trimester; associated with hypertension and proteinuria)
- HELLP syndrome (severe form of pre-eclampsia; urgent delivery is indicated)
- Hepatitis E induced fulminant hepatic failure is more common in pregnancy.

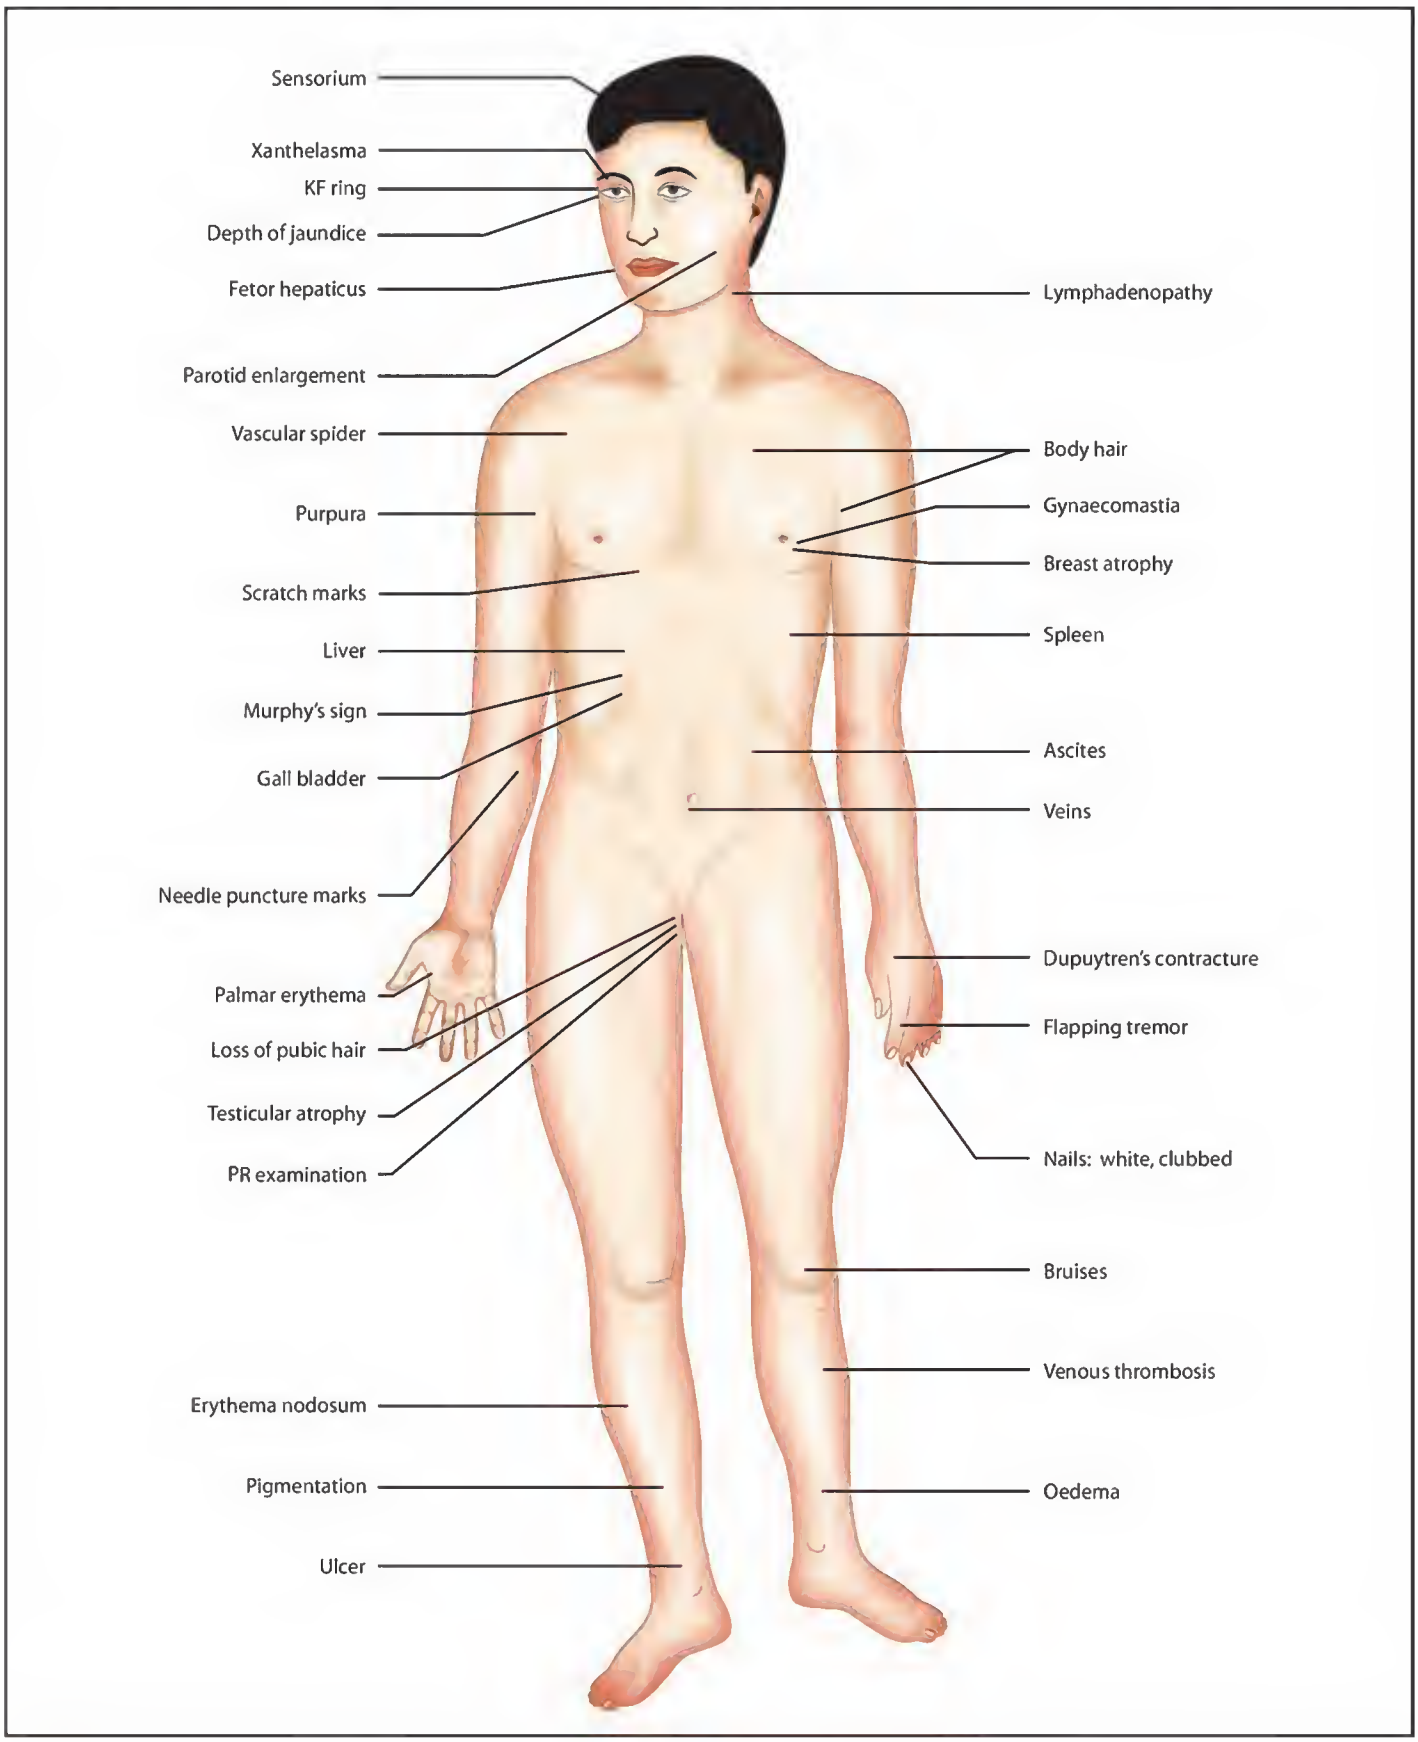

Figure 1: Clinical signs in jaundice.

II. Examination

There are many signs that we need to check in a patient present with jaundice (**Figure 1**).

General examination

- Anaemia may indicate haemolysis, chronic liver disease or malignancy.
- Pedal oedema may indicate chronic liver disease, inferior vena cava obstruction due to malignancy or procoagulant state; severe anaemia with volume overload or hypoproteinaemia due to nutritional deficiency or malabsorption.
- Lymphadenopathy may indicate an infectious aetiology, lymphoma, tuberculosis or sarcoidosis. An enlarged left-supraclavicular node (Virchow's node) or periumbilical nodule (Sister Mary Joseph's nodule) suggests an abdominal malignancy.
- Altered mental state may indicate hepatic encephalopathy, sepsis or brain metastasis in patients with late stages of malignancy.
- Kayser-Fleischer (KF) ring is usually seen in Wilson's disease.
- Xanthomas in primary biliary cirrhosis.
- Pigmentation of the shins and non-healing ulcer may indicate haemoglobinopathy. Hyperpigmentation may also be present in haemochromatosis or in primary biliary cirrhosis.
- Erythema nodosum may be seen in tuberculosis, sarcoidosis or syphilis.
- Migratory thrombophlebitis is suggestive of carcinoma of the body of pancreas.

Abdominal examination

- Dilated abdominal veins can be seen in:
  - Portal hypertension
  - Inferior *vena cava* obstruction (functional or organic—dilated and tortuous veins indicate organic obstruction).

  The direction of flow in the infraumbilical veins helps in distinguishing between portal hypertension (from above-below) and IVC obstruction (from below-up).
- Severe right upper quadrant tenderness with respiratory catch on inspiration (Murphy's sign) suggests cholecystitis or occasionally, ascending cholangitis.
- Ascites may be due to:
  - Cirrhosis
  - Malignancy
  - Infections, e.g. tuberculosis, spontaneous bacterial peritonitis
  - Acute pancreatitis (Grey Turner's sign, i.e. discolouration of the abdomen is highly suggestive).
- Liver: In liver examination the following should be noted:
  (i) The size and consistency of the liver
    - hard liver indicates malignancy.
    - Shrunken liver indicates:
      (a) Cirrhosis
      (b) Fulminant hepatic failure

      [Localised dilatation of the transverse colon (toxic megacolon), fulminant colitis and ileus associated with peritonitis or a perforated viscus may decrease the liver dullness without a decrease in liver size].

  (ii) Massive hepatomegaly (>10 cm below the costal margin) may indicate:
    (a) Malignancy (primary/secondary)
    (b) Congestive liver (chronic congestive cardiac failure (CCF)/Budd-Chiari syndrome)
    (c) Alcoholic liver disease
    (d) Primary biliary cirrhosis
    (e) Prolonged extrahepatic cholestasis
    (f) Infiltrative disease of the liver
      - Myelofibrosis
      - Amyloidosis (especially when associated with macroglossia, peripheral neuropathy, malabsorption, CCF or proteinuria)

    (g) Chronic myeloid leukaemia
- Whether it is tender (infections, congestion, bile stasis) or not.
- Whether the surface is nodular (malignancy, cirrhosis) or smooth.
- Whether the edge is rounded or sharp.
- Whether the left lobe is palpable. A palpable left lobe suggests:
  - Chronic liver disease
  - Malignancy
  - Abscess/cyst
  - Obstruction of left hepatic vein
- Bruit over the liver indicates increased vascularity:
  - Acute alcoholic hepatitis
  - Hepatocellular cancer
  - Hepatic artery aneurysm
  - Hepatic arterio-venous fistula
- Friction rub over the liver suggests
  - Liver metastasis
  - Primary hepatocellular carcinoma
  - Infarction of the liver (as in sickle cell anaemia and polyarteritis nodosa)
  - Liver abscess
  - Haematoma around the puncture site.
- Check for pulsatile liver (indicative of significant tricuspid regurgitation)

Peripheral stigmata of chronic liver disease

- Parotid enlargement
- Gynaecomastia
- Spider angioma (usually found in the distribution of superior *vena cava*; >12 in number indicate portal hypertension)
- Paucity of axillary and pubic hair
- Testicular atrophy
- Palmar erythema
- Dupuytren's contracture

Signs suggestive of decompensated liver disease

Jaundice

Ascites

Hepatic encephalopathy
Oliguria, hepatic failure
Altered behaviour
Fetor hepaticus
Asterixis

- Check for any masses in the abdomen.
- Genitalia must be examined and per rectal examination is a must for piles, growth or nodules in the pouch of Douglas.
- Jaundice with extrapyramidal neurological features suggests Wilson's disease especially in patients born of consanguinous marriage and having KF ring.

III. Laboratory Diagnosis

Integration of the patient's history, clinical examination findings and laboratory results is essential for accurate interpretation because non-specific aberrations in these tests may occur. We can divide all jaundiced patients into three broad categories of patients (**Table 1**).

A. Isolated elevation of serum bilirubin (SBR) with normal serum transaminases (STA) and alkaline phosphatase (ALP)

Hepatocellular disease or biliary obstruction is unlikely in these patients. If SBR is predominantly unconjugated (>80%) we need to check for haemolysis (Hb, peripheral smear, reticulocyte count, Coomb's test, plasma and urine haemoglobin and other special tests for diagnosing the type of haemolytic anaemia). A detailed description is beyond the purview of this chapter.

If there is no evidence of haemolysis on the peripheral smear, the diagnosis is congenital hyperbilirubinaemia in the absence of history of drug intake. These can be definitely diagnosed with the help of special enzyme assays, genetic studies and liver biopsy (black pigmentation on liver biopsy in Dubin-Johnson Syndrome).

B. Increased serum bilirubin with increased serum transaminases and normal to mildly increased alkaline phosphatase

The most likely cause is hepatocellular jaundice (**Table 1**). The patient needs to be evaluated for acute versus chronic liver disease and for aetiology.

Two biochemical tests that suggest chronic liver disease are a low serum albumin (<2.8 gm/dL) and a prolonged prothrombin time (>16 sec. prolonged). A bedside diagnosis of cirrhosis can be made when it is associated with two physical findings of ascites and asterixis. Serum globulin levels are elevated in cirrhosis, resulting in reversal of A:G ratio. Electrophoretic analysis shows increased γ-globulin fraction in hepatocellular jaundice (versus raised α_2- and β-globulins in cholestatic jaundice). The other tests that need to be done in suspected hepatocellular jaundice are:

- Viral markers (serological tests for hepatitis A-E viruses, viral load for hepatitis B and C especially, serological tests for cytomegalovirus and Epstein-Barr virus infection) should be done for suspected acute or chronic viral hepatitis.
- If serum AST:ALT is > 2 : 1, suspect alcoholic hepatitis in the setting of alcoholism.
- Anti-mitochondrial antibody positivity indicates primary biliary cirrhosis.
- ANA, anti-SMA (smooth muscle antibodies) and anti-LKM Ab positivity suggests autoimmune hepatitis.
- Serum Fe, transferrin and ferritin are elevated in haemochromatosis.
- Serum ceruloplasmin is reduced in Wilson's disease.
- Serum ALP: SBR of <2 or AST: ALT of >4, in a young patient with Coomb's –ve haemolytic anaemia and KF ring on slit lamp examination is suggestive of Wilson's disease.
- α_1-antitrypsin phenotype for α_1-antitrypsin deficiency.
- Transglutaminase Abs for coeliac sprue.
- Serum α-fetoproteins for hepatocellular carcinoma.
- UGI endoscopy for any malignancy, evidence of portal hypertension (esophageal or gastric varices and portal gastropathy features).
- Doppler ultrasonogram to detect patency of hepatic veins, portal vein and inferior *vena cava*.
- Liver biopsy is especially indicated in patients with undiagnosed persistent jaundice. It permits diagnosis of viral hepatitis, alcoholic and non-alcoholic steatohepatitis, haemochromatosis, Wilson's disease, α_1-antitrypsin deficiency, fatty liver of pregnancy, primary biliary cirrhosis, granulomatous hepatitis and neoplasms with the use of special stains. Though liver histology may be entirely normal in acute biliary obstruction, it may occasionally provide a clue to unsuspected biliary tract obstruction. Iron and copper content of the liver can also be measured. In patients with prolonged prothrombin time (PT)—a transjugular biopsy is advisable.

C. Increased serum bilirubin with markedly elevated alkaline phosphatase with normal to mildly elevated serum transaminases

It is suggestive of cholestatic jaundice. Prolonged prothrombin time which normalises on Vitamin K administration is suggestive of extra-hepatic biliary obstruction.

Imaging studies are very important in this group of patients with ultrasonogram (USG) of the abdomen being the basic investigation. Dilated ducts on imaging confirm the diagnosis of biliary obstruction (i.e. distinguishes between intra-hepatic and extrahepatic biliary obstruction) and further imaging tests can be planned based on the availability of the procedure, presence or absence of dilated bile ducts on initial imaging, technical expertise, cost of the procedure and risk versus benefit of the procedure.

The various imaging techniques available are:

- Contrast enhanced computed tomography (CECT)
- Magnetic resonance cholangiopancreatography (MRCP)
- Endoscopic retrograde cholangiopancreatography (ERCP)
- Percutaneous transhepatic cholangiography (PTC)
- Endoscopic ultrasound (EUS)
- Nuclear imaging studies

Both ERCP and PTC permit direct visualisation of the biliary tree as well as the pancreatic ducts. Biopsy can be done from any suspicious lesion and therapeutic intervention can be done in the same sitting. ERCP is used for lesions distal to the bifurcation of the right and left hepatic bile ducts whereas PTC is preferable when the level of biliary obstruction is proximal to the common hepatic duct or altered anatomy precludes ERCP. The sensitivity and specificity of MRCP, ERCP and PTC are comparable.

Table 2: Differences between the Three Basic Types of Jaundice

Features	Haemolytic Jaundice	Hepatocellular Jaundice	Extrahepatic Cholestatic Jaundice
Colour of urine	Pale	High coloured	High coloured
Colour of stools	Normal	Normal to dark	Pale coloured
Pruritus	–	–/+	++
Jaundice	Lemon yellow	Deep yellow	Orange yellow/greenish yellow
Antecedent history	H/o anaemia requiring blood transfusions (BT)	Injection/BT/tattoos contact with a jaundiced patient	Biliary surgery or gall stones
Family history	Anaemia	Jaundice	Gall stones
Urine urobilinogen	++	+	–
Haemogram	Evidence of haemolysis	Normal	Normal
Serum bilirubin	↑ <5 mg/dL (usually) (unconjugated)	↑ – ↑↑↑ (mixed)	↑ – ↑↑↑ (predominantly conjugated)
Serum transaminases	Normal	↑ – ↑↑↑	Normal/↑
Alkaline phosphatase	Normal	Normal/↑	↑↑
Ultrasonogram/CT	Hepatosplenomegaly liver ↑/normal spleen ↑ – ↑↑↑	Liver ↑/N spleen N/↑	Liver ↑↑ with dilated ducts

These tests help in delineating the exact site of obstruction, the cause of obstruction (by direct visualisation and biopsy) and the back pressure changes.

Intrahepatic biliary duct may not be dilated in some conditions with extrahepatic biliary obstruction—early or partial biliary obstruction,

- Primary sclerosing cholangitis
- Co-existent cirrhosis (fibrosis prevents dilatation of biliary ducts)

- In patients with suspected cholelithiasis, USG is the primary diagnostic imaging procedure but in patients with suspected choledocholithiasis, ERCP is the preferred diagnostic procedure. Papillotomy may be indicated.
- In patients with obstructive jaundice due to suspected pancreatic carcinoma, EUS is superior to CT scanning with regard of detecting a pancreatic mass but comparable with regard to tumour staging and predicting resectability or nonresectability.
- In patients with unexplained hepatomegaly, either USG or CT scanning are appropriate initial imaging procedures.
- Liver imaging procedures are usually not necessary in patients with a diagnosis of acute viral hepatitis or non-alcoholic steatohepatitis (NASH).
- Increased serum amylase is suggestive of acute pancreatitis.

IV. Therapeutic Options

- Haemolytic anaemia has to be treated with repeated blood transfusions as and when required to maintain adequate haemoglobin level and some patients may require iron chelation if blood transfusion requirement is high. Bone marrow transplantation is an option for thalassaemia , being done in a few centres.
- Hepatocellular jaundice has to be treated as per the cause. Drug induced hepatitis has to be recognised and the offending drug needs to be stopped. Cessation of alcohol, administration of antiviral agents, phlebotomy for haemochromatosis, copper chelation for Wilson's disease and steroids for autoimmune hepatitis are a few of them.
- Supplementation of fat soluble vitamins may be required in some patients with cholestatic liver disease.
- In patients with obstruction of the bile ducts, the obstruction has to be relieved by interventional endoscopic or radiologic approach (sphincterotomy, balloon dilatation and placement of drains or stents) or surgery depending on the location and the likely aetiology of the obstructing lesion.
- The various drugs that can be used for treatment of pruritus are cholestyramine, rifampin, ursodeoxycholic acid and naltrexone.

With the approach outlined above we are able to arrive at an accurate diagnosis in most patients with jaundice. The differences between the three types of jaundice are summarised in **Table 2**.

RECOMMENDED READINGS

2.8 Upper Gastrointestinal Bleeding

JC Vij

Gastrointestinal bleeding is a challenging emergency which is associated with a high mortality. The clinical presentation of GI bleeding depends on the location, rate of bleeding and aetiology of the disease. Haematemesis defined as vomiting of blood indicates upper gastrointestinal (UGI) bleeding and the site of bleeding is above the ligament of Treitz. The blood may be fresh and red coloured or may be old having the appearance of coffee grounds. Malaena is defined as passage of black tarry stools which are often foul smelling. This results from degradation of blood to haematin and other haemochromes. Melena is usually the result of UGI bleeding, but slow bleeding from distal small bowel, caecum and ascending colon can also lead to melena; about 50 to 100 ml of bleeding in the GI tract is required to cause melena. Haematochezia refers to the passage of fresh red blood from the rectum, which suggests a lower GI source of bleeding but can also occur with massive bleeding from the UGI tract (usually more than 1000 mL). About 30% of patients with UGI bleeding present with haemetemesis, 30% with melena and 50% with both.

AETIOLOGY

The common causes of UGI bleeding include peptic ulcer disease, oesophageal/gastric varices, Mallory-Weiss tear, erosive gastritis/duodenitis, malignancy, angiodysplasia and Dieulafoy's lesions. Peptic ulcer disease is the most common cause, accounting for 50%. Bleeding from varices—oesophageal or gastric—accounts for 10% to 30%. Studies from central and north India have described variceal haemorrhage to be more common (45% to 50%). About 10% of patients with portal hypertension may have a non variceal source of bleeding such as peptic ulcer or Mallory-Weiss tear. Mallory-Weiss tear usually occurs in the gastric mucosa at the gastro-oesophageal junction and is considered to be caused by forceful retching. Dieulafoy's lesion denotes erosion of mucosa by an underlying large sized arteriole. Though Dieulafoy's lesions can be located anywhere in the GI tract, they are typically found in the upper part of the stomach.

MECHANISM

Bleeding from an ulcer occurs when it erodes into the wall of a blood vessel. Though the exact cause of haemorrhage from a pre existing ulcer is not clear, a number of factors can predispose an ulcer to bleed. Use of aspirin and other non-steroidal anti inflammatory drugs (NSAIDs) are perhaps the most important factors. The mechanism of action is complex and involves reduced production of prostaglandins, (a cytoprotective agent) and platelet dysfunction. Though controversial, ethanol, *H.pylori* infection and glucocorticoids may potentiate the deleterious effect of NSAIDs and increase the risk of bleeding. Cyclo oxygenase-2 (Cox-2) inhibitors also increase the risk of ulcer bleeding, though the risk is less than with NSAID use. Antiplatelet agents such as clopidogrel, though less injurious to gastric mucosa, increase the risk of bleeding from ulcers as do anticoagulants. The role of intragastric acid in causing peptic ulcer is well established, but its role in causing haemorrhage is not well understood. Several studies have shown the beneficial effects of acid-reducing agents like proton pump inhibitors in controlling bleeding from ulcers, emphasising the important role of acid. Portal hypertension, a serious complication of cirrhosis, is associated with bleeding. The most common cause of portal hypertension is cirrhosis followed by portal vein thrombosis, splenic vein thrombosis, non-cirrhotic portal fibrosis (NCPF), schistosomiasis. Bleeding may occur from various lesions associated with portal hypertension including oesophageal varices, gastric varices, portal hypertensive gastropathy and rarely ectopic varices. In patients with cirrhosis, bleeding from varices carries a high mortality and also a high morbidity. Varices form at the rate of 5% to 15% per year and only 1/3rd of them bleed. The risk of haemorrhage from varices is related to their size and location. Endoscopic appearance, portal pressure and the severity of the underlying liver disease. Large sized varices and those having red wheal sign (a manifestation of thinning of overlying mucosa) carry a high-risk of haemorrhage. Bleeding usually occurs from varices present near the gastro-oesophageal junction. Haemorrhage from varices stops spontaneously in about 50% of cases and the risk of rebleeding is high within six months. Interestingly 50% of re-bleeding episodes occur within 3 to 4 days of the first bleed. Bleeding from gastric varices is usually associated with a very high mortality rate.

DIAGNOSIS

Endoscopy is the best method of diagnosing the cause of UGI bleeding. Barium radiography although can diagnose some of the lesions in the oesophagus, stomach and duodenum, it has no value in patients who are bleeding actively. Besides, endoscopy has tremendous therapeutic value.

MANAGEMENT

Basic management of all patients with GI bleeding whether variceal or non-variceal remains almost the same and includes: monitoring of vital signs particularly hypotension, tachycardia and anoxia and clearing of the airways. Two large bore peripheral intravenous catheters should be placed for aggressive volume replacement in a haemodynamically unstable patient and such patients should be managed in a medical ICU. It is preferable to replace blood loss by packed red cells which may take some time to arrange. In the meantime crystalloids and saline infusion should be started. The hematocrit should be maintained around 30% and haemoglobin level kept approximately at 9 to 10 g/dL. Over infusion of blood or fluids should be avoided in patients with variceal bleed to avoid increase in portal pressure which may precipitate early rebleeding. Coagulopathy and

thrombocytopaenia should be adequately corrected. Patients with aggressive bleeding and/or altered mental status should be intubated. Other supportive measures include administration of prophylactic antibiotics, preferably third generation cephalosporines in patient with cirrhosis and maintenance of urine output above 50 mL/hour. Acid base and electrolyte disturbances should be monitored and treated. The blood glucose level should also be maintained.

Placement of a nasogastric tube, though controversial, is helpful in clearing the gastric contents. Gastric lavage along with intravenous administration of metoclopramide or erythromycin (not available in India) is helpful in improving the examination of the gastric mucosa on endoscopy and decreases the need for repeat endoscopy. Besides, it provides information about the type of blood present in the stomach, which may be helpful in planning the time of endoscopy. Fresh red blood indicates active bleeding and the patient will need early endoscopic evaluation. However, an aspirate negative for blood does not rule-out upper GI bleeding. Use of nasogastric aspiration as a primary tool for assessing GI bleed should not be relied upon. Assessment of vital signs is the most effective means of determining bleeding activity. The use of a nasogastric tube has not been shown to influence the outcome in patients with GI bleeding.

MANAGEMENT OF PEPTIC ULCER BLEEDING

Peptic ulcers are the most common and important cause of upper GI bleeding. Management aims to: (a) stop active bleeding, (b) prevent rebleeding, and (c) treat the peptic ulcer. Endoscopic examination is useful in identifying lesions which have a high-risk of re-bleeding. Ulcers with a clean base, flat pigmented spot are at a low risk of re-bleeding (5%), while those with active bleeding or with non-bleeding visible vessel and adherent blood clot (Forrest classification) are at a high-risk of rebleeding (40% to 55%). The presence of co-morbidities, old age (>60 years), clinical evidence of severe bleeding and ulcers greater than 2 cm in size are associated with a poor outcome. Bleeding stops spontaneously in 70% to 80% of patients with peptic ulcers. In the remaining patients endoscopic therapy controls bleeding in 80% to 90%. Surgery is needed in about 5% to 10% of patients.

Endoscopic therapy is the most effective method of controlling bleeding and to some extent preventing re-bleeding thereby reducing mortality. Endoscopic methods of controlling ulcer bleeding fall into three broad categories: (a) injection therapy, (b) thermal methods, and (c) mechanical devices.

Injection Therapy

Submucosal injection of diluted epinephrine (1:10,000) is a simple, effective and widely practiced method of controlling bleeding. Local injection acts by a tamponade effect on nearby vessels thus causing haemostasis. Besides it causes vasoconstriction and platelet aggregation. It is recommended that a large volume (30 to 45 mL) of epinephrine solution be injected in the four quadrants near an actively bleeding or visible vessel.

Endoscopic Thermal Therapy

This can be divided into two categories: (i) contact thermal; and (ii) noncontact thermal modalities.

Contact thermal modalities include heater probe coagulation and bipolar/multipolar electrocoagulation. Noncontact thermal modalities consist of organ plasma coagulation (OPC) and laser therapy. Contact thermal methods are preferred as besides causing coagulation of tissue due to thermal heat, they also cause tamponade of vessels by direct probe pressure. Noncontact thermal methods are cumbersome and expensive and are not shown to be more efficacious.

Mechanical Devices

These include metal haemoclips, rubber band ligation, endoloops and sewing devices. Haemoclips have been widely used to treat active bleeding ulcers or visible vessels. They act by direct compression of opposing tissues or vessels causing thrombosis and haemostasis.

Several studies have shown that a combination of endoscopic therapy such as injection plus thermal therapy or injection plus haemoclips application are superior to monotherapy alone.

Pharmacological Therapy

Proton pump inhibitors (PPI) due to their inhibitory action on hydrogen potassium adenosine triphophatase raise intragastric pH. They have been found effective when given in high doses intravenously for 72 hours after successful endoscopic treatment of an ulcer with high-risk bleeding signs. They reduce the recurrence of bleeding and need for blood transfusion but not the mortality rate. The recommended dose is 80 mg omeprazole given as an intravenous bolus followed by 8 mg per hour intravenous infusion. In patients with low-risk ulcer bleeding oral proton pump inhibitors in high doses are recommended. In one study it was shown that PPI if administered for 24 to 48 hours before endoscopy significantly lowered the prevalence of high-risk stigmata and decreased the need for endoscopic therapy but did not decrease the incidence of recurrent bleeding, surgery or mortality.

HEALING OF PEPTIC ULCER

Proton pump inhibitor therapy has similar healing rates for bleeding and non-bleeding ulcers. The long-term treatment of ulcers depends on their aetiology. Patients with bleeding ulcers who have been taking NSAIDs should discontinue them. Patients with *H. pylori* infection should receive therapy for *H. pylori* eradication.

MANAGEMENT OF BLEEDING VARICES

Oesophageal variceal bleeding should be controlled swiftly and promptly as continued bleeding is associated with high mortality. The first episode of variceal bleeding is associated with about 30% mortality. Haemostasis can be achieved by pharmacological treatment and endoscopic therapy.

Pharmacological Treatment

In the past, vasopressin, a powerful vasoconstrictor, was widely used to control bleeding from varices. The drug causes splanchnic arteriolar vasoconstriction leading to decrease in portal inflow and thus portal pressure. However, this drug is associated with myocardial ischaemia, mesenteric ischaemia and cerebrovascular accidents. Some of adverse effects of vasopressin can be reduced by concomitant use of nitrates, used as intravenous infusions, sublingual or transdermal route. It is rarely used now because of its adverse effect profile. This led to the development of a safer synthetic analogue—terlipressin

which has a longer biological half life and is administered in a dose of 1 to 2 mg every four hours. Terlipressin is as effective as other vasoactive drugs as well as endoscopic treatment. This drug has been found to be associated with improved survival in several randomised trials.

Somatostatin and its analogues

Somatastatin is a naturally occurring peptide. Its exact mechanism of action is not clear. It causes an increase in splanchnic vascular resistance by causing vasoconstriction and decrease in portal blood flow. Somatostatin is given as an intravenous bolus of 250 ug followed by continuous infusion of 250 ug per hour and therapy is continued for two to five days. Boluses of 500 ug can be administered intermittently if fresh episodes of bleeding occur during the course of treatment. Octreotide, a synthetic analogue of somatostatin, has a longer duration of action, and has been found to be effective in controlling variceal haemorrhage. Octreotide is given in the doses of 25 to 50 ug/hour by a continuous intravenous infusion. Somatostain and octreotide should be started immediately while waiting for more definitive endoscopic therapies to be employed or when endoscopy is not possible due to non-availability of trained personnel or contraindicated because of haemodynamic instability. They can also be used as an adjunct to endoscopic therapies. Both somatostatin and octreotide have an excellent safety profile, with low complication rates. Their use may cause hyperglycaemia and abdominal cramping.

Endoscopic Therapy

Endoscopic therapy is the cornerstone of controlling haemorrhage from varices. These are two principal forms of endoscopic treatment:

(a) Endoscopic sclerotherapy (EST)

(b) Endoscopic variceal band ligation (EVL)

Endoscopic sclerotherapy (EST)

It involves injection of sclerosing agents into the veins causing thrombosis and scarring. Various sclerosing agents used are ethanolamine oleate, aethoxyskerol, sodium tetradecyl sulphate, sodium morrhuate and absolute alcohol. Tissue adhesive such as N-butyl-cyanoacrylate have been used for sclerosing of gastric varices. Variceal injections are started at gastro-oesophageal junction and are restricted to distal 5 cm of oesophagus. Usually 1 to 2 ml of sclerosing agent is injected into each varix and a total of 10 to 15 mL is effective in controlling bleeding. Sclerotherapy is repeated usually at intervals of 2 to 3 weeks. Endoscopic sclerotherapy is associated with some local and systemic complications, which include retrosternal pain, transient dysphagia, fever and mild pleural effusions. Oesophageal stricture leading to dysphagia is seen in approximately 15% of patients. Bleeding from post-EST ulcers and oesophageal perforation are potentially life-threatening complications of endoscopic sclerotherapy.

Endoscopic variceal band ligation (EVL)

It involves applying rubber bands around varices which lead to occluding the veins mechanically. The elastic rubber band strangulates the varix producing thrombosis, inflammation, necrosis and finally sloughing of mucosa that heals by scar formation. EVL is performed by using multiband ligating system. The banding device consists of a cylinder preloaded with 6 to 8 elastic bands. The cylinder is attached to the tip of the endoscope and bands are released by pulling a trigger wire of a device placed over the biopsy channel after the varix is sucked into the cylinder. EVL is associated with fewer complications than EST. The procedure is effective in controlling bleeding in 75% to 85% of patients.

With the available pharmacological and endoscopic treatments, the rate of failure to control acute bleeding is approximately 10% to 20%. Balloon tamponade using Sangstaken-Blakemore balloon, though associated with complications, can accomplish haemostasis in a difficult situation, such as massive variceal bleeding. Transjugular intrahepatic shunt (TIPS) represents an artificial communication by placing a metallic stent between the hepatic and the portal vein. It is an effective method of controlling active bleeding from oesophageal and gastric varices. It also prevents recurrent variceal bleeding. Although the TIPS procedure needs expertise (not available at many centres in India), when placed successfully it can achieve haemostasis in 90% to 100% cases. TIPS is associated with long-term complications of thrombosis and occlusion of stent and hepatic encephalopathy. It is contraindicated in patient with poor cardiac function, pulmonary hypertension and polycystic liver disease.

Prevention of Variceal Bleeding

Non-selective beta-blockers such as propranolol and nadolol in doses that decrease the heart rate by 25% have been shown to be effective in preventing primary and secondary variceal haemorrhage.

The majority of episodes of upper GI bleeding can be controlled with endoscopic and pharmacological therapy. Angiographic therapy or surgery may be needed in those patients where bleeding cannot be controlled or localised or in those with recurrent bleeding.

Upper GI bleeding is a serious emergency which carries a high mortality. Overall survival is improving due to the availability of new therapeutic methods and improved medical care.

2.9 Fever of Unknown Origin

Priscilla Rupali

Pyrexia or fever of unknown origin (FUO) remains an intellectual and diagnostic challenge. A developing country like India, with its burden of endemic diseases like tuberculosis, fungal infections and limited access to diagnostic facilities, requires a radically different approach from that of the developed countries for arriving at a diagnosis in a patient of FUO.

DEFINITION

In 1961, FUO was defined by Petersdorf and Beeson as fever greater than 38.3°C (101°F) documented on several occasions, for more than 3 weeks with no diagnosis despite 1 week of inpatient investigation. With the advent of acquired immunodeficiency syndrome (AIDS), complex surgical and ICU protocols and increased diagnostic investigations, Durack and Street proposed classifying FUO into four different categories: (1) classic FUO, (2) nosocomial FUO, (3) neutropaenic FUO and (4) human immunodeficiency virus (HIV) associated FUO.

TYPES OF FUO

Classic FUO: The newer definition is similar to the one proposed in 1961. Keeping in mind increasing diagnostic capabilities, this has been modified to fever greater than 38.3°C (101°F) for more than 3 weeks with no diagnosis after 3 outpatient visits or 3 days as inpatient in the hospital or 1 week of 'intelligent and invasive' ambulatory investigations.

Nosocomial FUO: Fever greater than 38.3°C (101°F) on several occasions in a hospitalised patient receiving acute care, not manifesting or incubating an infection on admission with no diagnosis after 3 days of investigations, including 2 days' incubation of cultures.

Neutropaenic FUO: Fever greater than 38.3°C (101°F) on several occasions in a neutropenic (absolute neutrophil count <500 cells/mm^3 or expected to fall to this level in 1 to 2 days) patient with no diagnosis after 3 days of investigations, including 2 days' incubation of cultures.

HIV-associated FUO: Fever greater than 38.3°C (101°F) on several occasions in a HIV-infected patient, with no diagnosis after investigations for more than 4 weeks as an outpatient, or 3 days as an inpatient.

AETIOLOGY

Classic FUO

The major causes of a classic FUO have remained the same over the last 10 decades. The three major categories include infections, neoplasms and non-infectious inflammatory diseases (collagen vascular diseases and sarcoidosis). Other minor categories include drug fever, factitious fever and habitual hyperthermia. In a large series of classic FUO from Eastern India, infections were the most dominant cause seen in 53% (half of these were tuberculosis), neoplasms in 17% and collagen vascular diseases in 11%. Among the infections tuberculosis, abscesses and bacterial endocarditis predominated; neoplasms were mostly non-Hodgkins' lymphoma, Hodgkins' lymphoma and leukaemia and collagen vascular diseases causing fever were systemic lupus erythematosus (SLE), Takayasu's arteritis and mixed connective tissue disease (MCTD). About 14% remained undiagnosed in this series. This is in contrast to that seen in the Western world where infections contribute to less than a third of cases and about 30% to 50% remain undiagnosed.

Nosocomial FUO

There is no systematic series of nosocomial FUO in literature. However, when evaluating a hospitalised patient with fever, the underlying susceptibility of the patient, surgical or investigative procedures done, invasive devices *in situ*, and the patient's own flora need to be taken into consideration. About 50% of nosocomial fever is due to infections. Non-infectious causes include drug fever, deep venous thrombosis, acalculous cholecystitis, pancreatitis and pulmonary embolism. Repeated physical examinations with multiple blood and fluid cultures often yield a clue towards diagnosis. For critically ill patients, intravenous (IV) lines/invasive catheters must be changed swiftly. Empirical therapy with antibiotics after taking at least three blood cultures must be started only if there is evidence of hypotension, acute respiratory distress syndrome (ARDS) or multiple organ damage.

Neutropaenic FUO

Data from Western literature documents that at least 50% of neutropaenic patients who become febrile have an established or occult infection and 20% of febrile patients with absolute neutrophil count (ANC) less than 100 cells/mm^3 are bacteraemic. True neutropaenic FUO with no diagnosis at 96 hours varies in each series from 25% to 40%. Most often these are fungal (*Candida, Aspergillus*) and viral infections [cytomegalovirus (CMV) and herpes simplex virus (HSV)]. A detailed physical examination including the fundus, skin, peri-rectal area and paranasal sinuses is mandatory to localise a possible source of infection. Risk factors for occult infection include the degree of neutropenia, disruption of skin and mucosal barriers, a rapid decline in ANC, prolonged duration of neutropaenia, cancer not in remission, co-morbid illnesses, venous catheters and use of monoclonal antibodies against cellular receptors. Empiric antibiotic regimens recommended for use in India, after at least 3 blood cultures, based on the studies available should include coverage against extended spectrum β lactamase (ESBL) producing Gram-negative organisms like *E.coli, K.pneumoniae,* and *P.aeruginosa* and Gram-positive organisms like *S.aureus*, coagulase negative *Staphylococcus spp.*

HIV-Associated FUO

Prolonged fever in HIV-infected persons is due to an infection in 90% of cases. Risk of an opportunistic infection (OI) depends on the degree of immunosuppression and the burden of

endemic pathogens in the environment. In India, tuberculosis accounts for about 70% of cases of prolonged fever, followed by disseminated cryptococcosis (10%), *Pneumocystis jiroveci* pneumonia (7%), community acquired pneumonia (2%) and liver abscess (2%). A CD4 count, if available, can help and predict which disease could be contributing to the cause of prolonged fever. The spectrum of HIV associated FUO in India is slightly different from that reported in Western literature. *Mycobacterium avium intracellulare* complex (MAIC) is not a common cause of FUO in India. One theory proposed to explain this is that we have so much endemic burden with *Mycobacterium tuberculosis* that it confers some sort of immunity against atypical mycobacteria. With the advent of highly active antiretroviral therapy (HAART) it also becomes imperative for us to consider possible causes for fever after start of HAART. In the initial 6 months after the start of HAART, immune reconstitution inflammatory syndrome (IRIS), drug fever, and antiretroviral therapy associated OIs (when the baseline CD4 counts are really low and the person is still susceptible to OIs) are common whereas after 6 months, causes of prolonged fever include various forms of tuberculosis, neoplasms and non-infectious inflammatory diseases similar to a classic FUO. The common causes in each of these categories are shown in **Table 1**.

- Bites (arthropod or others)
- Pre-existing cardiac abnormalities
- Prostheses *in situ*
- Exposure to other ill people
- High risk behaviour and exposure to sexually transmitted infections
- Co-morbid conditions like alcoholism, IV drug use, HIV and malignancies
- Previous visit to hospital for trauma, burns or laceration
- Foreign bodies like tampons, nasal packs and barrier contraceptives
- Involvement or exposure to any domestic or international bioterrorist activity

On examination, if a person appears ill, investigations should be expedited. A detailed skin and soft tissue examination to look for rashes, eschar, petechiae, dusky skin and discoid lesions should be performed inclusive of the hidden areas like axillae, groin, inframammary folds and behind the ear. Palpation of muscles or spine often reveals myositis and inter/intramuscular abscesses or spinal tenderness. The importance of looking for nuchal rigidity, per-rectal exam to look for prostatic abscess and inspection of the genitalia and oral cavity cannot be over emphasised.

Table 1: Causes of FUO

Classic FUO	Nosocomial FUO	Neutropaenic FUO	HIV-associated FUO
Tuberculosis	Post-operative	Bacterial infections – *E. coli*	Tuberculosis
Abscesses	– abscesses – haematomas	– *Klebsiella spp.* – *Pseudomonas spp.*	Cryptococcosis
Bacterial endocarditis	– foreign bodies Infected prostheses	– *S. aureus* – Coag neg staph	*Pneumocystis jiroveci* pneumonia
Visceral leishmaniasis	Infected catheters	Central venous catheter (CVC) infections	Bacterial pneumonia
Non-Hodgkins lymphoma	*Clostridium difficile* colitis	Invasive fungal infections:	Amoebic liver abscess
Hodgkins lymphoma	Acalculous cholecystitis	Pneumonia and sinusitis	Disseminated histoplasmosis
Acute leukaemia	Deep venous thrombosis	Dental abscesses	Non-Hodgkins lymphoma
Systemic lupus erythematosus	Pulmonary embolism	Perianal infections, cytomegalovirus,	Immune reconstitution
Takayasu's arteritis	Drug fever	Herpes simplex virus infections	inflammatory syndrome

DIAGNOSTIC APPROACH

It is often said that a good clinician is the one who makes least mistakes in diagnosis of common conditions, not the one who makes occasional brilliant guesses. A detailed history and physical examination often reveals potential diagnostic 'clues' which could be critical towards making a diagnosis. The first step would be a consistent documentation of fever (38.3°C or 101°F) on several occasions by a health care professional. Significant weight loss, night sweats and anaemia usually also confirm an organic pathology. A detailed history should include the following:

- Immune status-immunocompromised state (HIV infection, immunosuppressive drugs, neutropenia, lymphopenia, malignancies like lymphomas and congenital immune deficiencies)
- Occupation
- Medications
- Travel
- Immunisations
- Exposure to pets

An initial laboratory evaluation inclusive of a total and differential count, three blood smears for malarial parasites, urine microscopy, chest radiograph, typhidot and blood cultures could rule out a possible cause of an acute undifferentiated febrile illness. If the patient is not in multi-organ system failure, previous antibiotics/drugs should be stopped, the patient observed for at least 72 hours, at which point multiple blood (and fluid, if indicated) cultures should be taken. Increased number of blood cultures and a large volume in each culture bottle increases the yield significantly. A second tier of investigations, depending on the constellation of symptoms and signs, could include liver function test (LFT), cerebrospinal fluid (CSF) analysis, an ultrasound of the abdomen and bone marrow aspiration with a biopsy and routine, mycobacterial and fungal cultures. Rarely, an inappropriately treated enteric fever may be picked-up on a bone marrow culture even when the blood cultures are negative, however, it is extremely rare for typhoid fever to present after 3 weeks as it is most often an acute febrile illness and should not usually present as a FUO. Endemic diseases peculiar to specific geographic locations in

India also need to be kept in mind while evaluating FUO (**Figure 1**). The diagnostic algorithms to evaluate prolonged fever in India also depend on cost-effectiveness and not just diagnostic yield and hence invasive tests like bone marrow aspiration and biopsy with suitable cultures or even liver biopsy may often be done before expensive tests like computerised tomography (CT) scan of the abdomen and thorax or positron emission tomography (PET) scans. It would be difficult to encompass all the FUO causing conditions into one single algorithm, especially as most patients would have clues on history and physical examination. However, there could be certain pointers in a person with prolonged fever and weight loss towards a diagnosis and these are as follows:

- Resident of North-East India with oral ulcers, skin lesions and adrenal enlargement on imaging suggests disseminated histoplasmosis.
- Diabetic or immunosuppressed individual with non-resolving pneumonia with cutaneous, visceral or pleural abscesses suggests melioidosis.
- Resident of Bihar or Jharkhand with pancytopaenia and large spleen suggests visceral leishmaniasis.
- Resident of Karnataka, North India or Kashmir with history of some exposure to animals, either by occupation or consumption of unpasteurised dairy products with skeletal or joint involvement and hepatosplenomegaly suggests brucellosis.
- Resident of Nagaland or Manipur, possibly HIV-infected with anaemia and umbilicated skin papules with evidence of systemic involvement suggests 'disseminated penicilliosis'.
- Oral ulcers, arthralgia and discoid lesions with frothy urine in a young person suggests SLE.
- Young individual with arthragia, maculopapular rash, leucocytosis, lymphadenopathy and hepato or splenomegaly suggests adult onset still's disease.

Despite the fact that there are numerous algorithms available in different textbooks, it would be important to follow 'Sutton's law' or 'look where the money is'. Do not carry out a battery of 'routine' tests in a conventional sequence. Suggested algorithms, with the disclaimer that not all diseases would fit into these, are shown in **Figures 2 to 4**.

ADDITIONAL LABORATORY TESTS USEFUL IN THE DIAGNOSIS OF FUO

Additional tests that may provide clues include thick and thin blood smears to rule out malaria, babesia and trypanosomes if relevant travel history is present. Febrile serology for rickettsial

infections, salmonella and dengue may not be useful if history of fever is around 3 weeks as most of these diseases would have run through their natural course by this time. However, febrile serology may be useful for brucellosis, visceral leishmaniasis and prolonged mononucleosis syndromes. If bacteremia or endocarditis is suspected, it may be prudent to maintain blood cultures for 2 weeks to rule out HACEK organisms or use alternative blood culture techniques like 'lysis centrifugation' if bacterial load is suspected to be low. Autoimmune work-up should be considered early along with a check-list of signs and symptoms of an autoimmune disorder to allow early categorisation to a specific collagen vascular disease. In an elderly individual with symptoms of anorexia and anaemia, examination for occult blood in stools should be considered with early gastroscopy or colonoscopy as indicated. Diagnostic clues like pancytopaenia may prompt an early bone marrow evaluation. Similarly, an elevated alkaline phosphatase (ALP) concurrent with an elevated gamma glutamyl transferase (GGT) indicative of an infiltrative liver disease or elevated enzymes indicative of a granulomatous hepatitis may prompt a blind or ultrasound guided liver biopsy for histopathology and relevant cultures. Exploratory laparotomy would be advocated only if there is moderate splenomegaly with all other investigations being non-contributory and a high chance of a malignancy localised to the spleen, e.g. splenic lymphoma or T-cell lymphoma.

Non-invasive whole body radionuclide scans like ^{111}Indium-labelled leucocytes, ^{67}Ga-citrate scan and Technetium Tc 99m delineate and localise inflammatory foci. Recently, 2-[^{18}F] fluoro-2-deoxy-D-glucose (FDG)-positron emission tomography (PET) has replaced other radionuclide techniques as it accumulates in pyogenic infectious foci, malignancies, granulomatous and non-infectious inflammatory diseases. FDG-PET, as a second line or third line procedure in FUO, has a sensitivity of 81% and specificity of 86% in detecting the cause of fever. In most diagnostic protocols of FUO in Western literature, FDG-PET is a second line procedure. This is unrealistic in India due to the enormous cost-constraints and hence we would need to develop our own protocols which would be cost-effective and generalisable in a resource-limited setting.

TREATMENT

In a classic FUO, the emphasis should be on obtaining a diagnosis and empirical antibiotics, anti-tuberculous therapy (ATT), nonsteroidal anti-inflammatory drugs (NSAIDs) or steroids may mask fever while permitting the spread of infection. Hence, these are to be avoided while attempting to make a diagnosis. However, if the patient has deranged vital signs, is asplenic or neutropenic, after taking suitable cultures cautious use of antibiotics appropriate to the local flora or clinical picture may be advised. 'Shotgun therapy' with antibiotics, ATT, NSAIDs and steroids is to be assiduously avoided as it minimises the chance of a future diagnosis. Repeated physical examinations often reveal localising clues as the disease evolves. In the case of non-

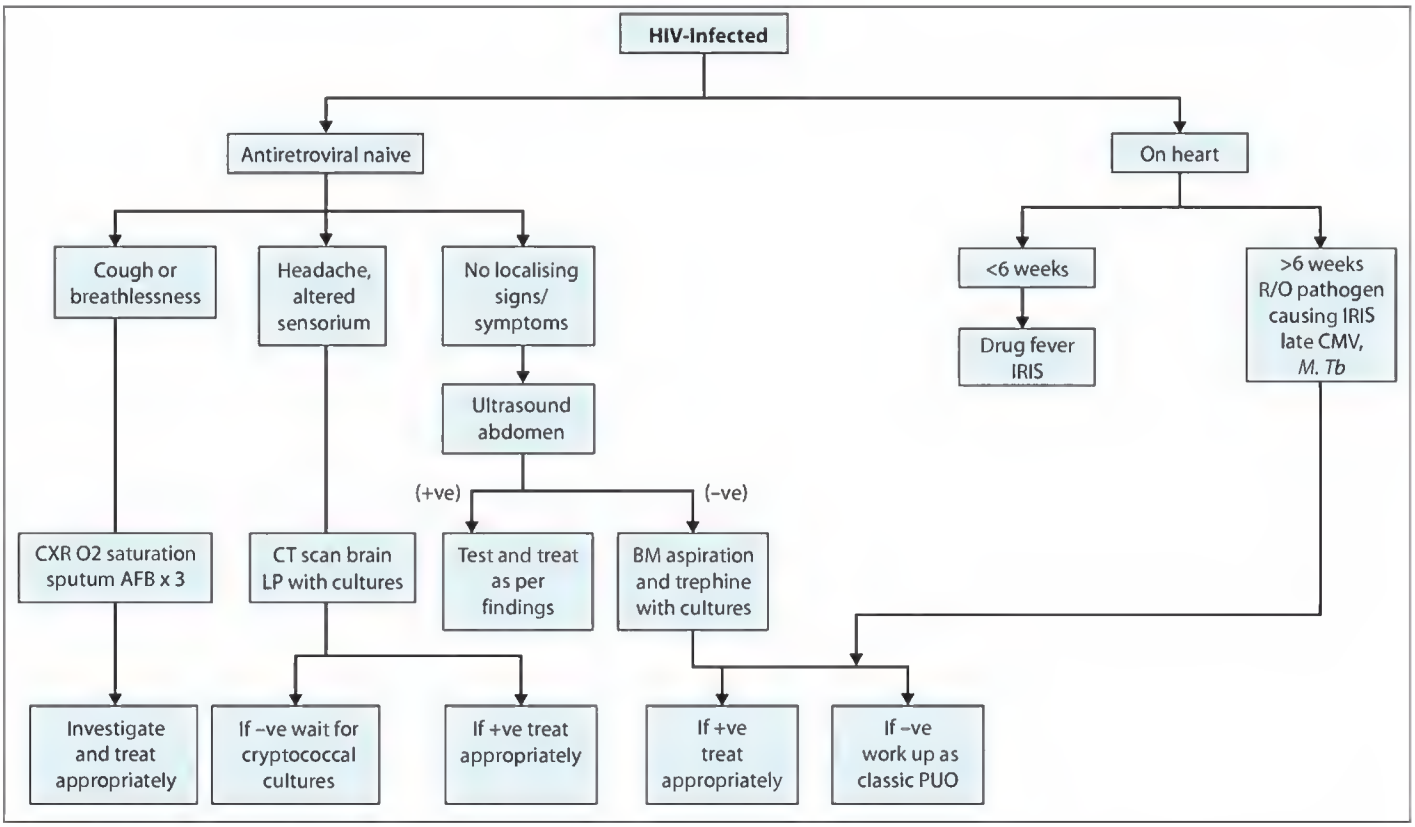

Figure 4: Evaluation of fever in PLWHA (people living with HIV/AIDS).

IRIS = Immune reconstitution inflammatory syndrome; CXR = Chest X-ray; CT scan = Computerised tomography scan; AFB = Acid fast bacilli; M. Tb = Mycobacterium tuberculosis; CMV = Cytomegalovirus; LP = Lumbar puncture; HAART = Highly active antiretroviral therapy; BM = bone marrow.

infectious inflammatory diseases, a repeated evaluation after a follow-up of 2 to 3 months often helps characterisation into a particular autoimmune or granulomatous disease. Over the years, in the many series of classic FUO, the number of patients with no diagnosis ranges from 30% to 50%. However, even if no diagnosis is obtained, the prognosis has usually been good in these patients.

CONCLUSION

- The four types of FUO include classic, nosocomial, neutropenic and HIV related.
- The important causes of classic FUO include the big three, i.e. Infections, neoplasms and connective tissue diseases.
- Nosocomial FUO is most often due to an infection, however non-infectious causes need to be kept in mind.
- Neutropaenic FUO most commonly is due to fungal infections like candidiasis and aspergillosis and viral infections like CMV and HSV.
- Tuberculosis contributes to 70% of the cases of HIV-associated FUO.
- Emphasis in any FUO should be on obtaining a diagnosis. Steroids, antibiotics or empirical ATT often mask the diagnosis and should be avoided unless there is evidence of serious organ dysfunction.

2.10 Generalised Lymphadenopathy

SK Verma

DEFINITION

Lymphadenopathy is an increase in the size of lymph nodes. Enlargement of lymph nodes in three or more non-contiguous areas is considered as generalised lymphadenopathy.

BACKGROUND

Generalised lymphadenopathy (GL) is a common clinical problem faced by primary care physicians. The majority of cases have infective and non-specific aetiology or a reactive lymphadenopathy whereas less than 1% have malignancy as the aetiology. GL usually occurs in response to systemic causes such as infections, autoimmune diseases, drug reaction but less commonly due to malignant disorders, histiocytoses and storage disorders. As age advances, the incidence of serious illnesses causing GL increases. Hence, it is important to have a systematic approach to GL so as to avoid unnecessary investigations while at the same time not missing a serious disorder.

PATHOPHYSIOLOGY

Lymphadenopathy may be caused by the following:

1. Multiplication of cells within the node, e.g. lymphocytes, monocytes, plasma cells, or histiocytes.
2. Infiltration by cells from outside, such as malignant cells or neutrophils.
3. Lymph nodes draining a source of infection.
4. Depositions or storage disorders.
5. Benign hyperplasia.

CAUSES

Causes of GL include infections, autoimmune diseases, malignancies, histiocytoses, storage diseases, benign hyperplasia, and drug reactions.

Infections

1. *Viral infections:* Human immunodeficiency virus (HIV), infectious mononucleosis, cytomegalovirus, varicella, and adenovirus.
2. *Bacterial infections:* Tuberculosis, brucellosis, plague, *Streptococci, Staphylococci,* cat-scratch disease, chancroid, melioidosis, atypical mycobacterial infection, primary and secondary syphilis, leprosy.
3. *Fungal infections:* Histoplasmosis, coccidioidomycosis, paracoccidioidomycosis.
4. *Chlamydial infections:* Lymphogranuloma venereum.
5. *Parasitic infections:* Toxoplasmosis, filariasis, leishmaniasis, trypanosomiasis.
6. *Rickettsial infections:* Scrub typhus, Q fever, rickettsial pox.

Malignancy: Acute leukaemias, lymphomas, chronic lymphocytic leukaemia.

Autoimmune disorders: Juvenile rheumatoid arthritis, serum sickness, rheumatoid arthritis, systemic lupus erythymatosis (SLE), mixed connective tissue disorder, sarcoidosis and graft versus host disease.

Metabolic and storage disease: Gaucher disease, Niemenn-Pick disease, cystinosis.

Drug hypersensitivity: Phenytoin, mephenytoin, carba-mezapine, pyrimethamine, phenylbutazone, allopurinol, and isoniazid.

Other non-neoplasic aetiologies: Langerhans cell histiocytosis, Epstein-Barr virus (EBV)-associated lympho-proliferative disease, Castleman disease and Kawasaki disease.

APPROACH

Approach to a case of GL requires detailed history, physical examination and appropriate lab testing to find out a possible aetiology before attempting advanced testing and biopsy.

History

Age and duration

Most cases of GL in younger patients are due to infectious or benign aetiology whereas in older adults autoimmune or malignant causes are more commonly seen. GL in younger patients usually resolves within 2 to 3 weeks. Non-resolving GL and progressive increase in size should raise a suspicion and requires further work-up. In adults and in the elderly, GL should be taken seriously at the onset without any delay in work-up.

Exposures

A history of chronic use of drugs, such as anti-epileptic drugs, exposure to pets, animals and insect bites is important and a history of travel to endemic areas must be noted. Occupational and environmental exposures such as smoke, fumes, pesticides, tobacco and radiations must be evaluated.

Personal and family history

Sexual history is important and HIV positivity is associated with increased chances of rare and opportunistic infections and malignancies as a cause of GL. Family history of certain cancers raises suspicion of cancer as a cause of GL.

Specific symptoms

GL associated with fever, upper respiratory symptoms, irritability and anorexia points towards infective aetiology whereas weight loss and cachexia suggest malignancy. The presence of joint pain, mild fever, morning stiffness, skin and constitutional symptoms suggests autoimmune disorder as the cause of GL. Although fever is a very important feature of infection, it may be absent in patients who are diabetic, immunocompromised or those on steroids or immunosuppressive drugs.

Physical Examination

Physical examination includes examination of lymph nodes and their characteristics, presence of splenomegaly, bone tenderness, purpura, skin and complete systemic examination for clues to the underlying cause for GL.

Lymph node examination

Size: Lymph nodes measuring (<1 cm) are often palpable in normal adults and inguinal nodes up to 2 cm in size may be considered normal. Lymph nodes measuring <1.0 cm^2 in area (1.0 cm × 1.0 cm or less) are usually benign or reactive where as lymph node size of 2.25 cm^2 (1.5 cm × 1.5 cm) should be investigated further for the underlying cause. Lymph nodes measuring 1 cm to 2.25 cm^2 in size may be kept under close observation or investigated depending upon other features. However, the presence of even shotty (< 0.5 cm) supraclavicular, scalene, iliac, popliteal or epitrochlear nodes is considered significant. Persistence and increasing size of a lymph node are definite indications for further evaluation.

Texture: A lymph node may be soft, rubbery, firm or hard in consistency, discrete or matted, movable or fixed and may be tender or non-tender with or without features of inflammation. Small, soft, discrete, non-tender nodes are seen mostly with benign conditions. Pain and tenderness is mostly a feature of inflammatory aetiology and rarely due to rapid enlargement of nodes due to acute leukaemia. Large, symmetrical, discrete, rubbery to firm, mobile and non-tender nodes are seen in lymphoma. Hard, non-tender and fixed nodes are highly suggestive of malignant deposits. Matted, firm and non-tender nodes are mostly due to tuberculous lymphadenitis or a malignancy. Development of draining sinuses is characteristic of tuberculous lymphadenitis.

Location: Certain locations may provide a clue to the possible aetiology of GL. Supraclavicular, scalene, iliac, popliteal and epitrochlear nodes are to be investigated to rule out malignancy. Presence of mediastinal nodes with GL points towards lymphoblastic leukaemia, lymphoma, sarcoidosis, tuberculosis, histoplasmosis and coccidioidomycosis. Presence of supra-clavicular nodes suggests lymphoma, tuberculosis, toxoplasmosis, histoplasmosis, and coccidioidomycosis. Abdominal and mesenteric nodes with GL may suggest lymphoma, tuberculosis, ulcerative colitis, brucellosis and salmonellosis.

Systemic Examination

GL is commonly caused by systemic disorders and systemic infections, so detailed systemic examination may provide a clue to its aetiology. Autoimmune disorders and HIV infection may have numerous clues in the history and physical examination. Splenomegaly with GL is seen in lymphoproliferative disorders like lymphoma, acute and chronic lymphatic leukaemia or systemic illnesses like infectious mononucleosis, tuberculosis, brucellosis, salmonellosis, toxoplasmosis, leishmaniasis, filariasis, cat-scratch disease, SLE, rheumatoid arthritis and sarcoidosis. Hepatomegaly and splenomegaly with GL is a common presentation of rare infiltrative, metabolic and storage disorders.

INVESTIGATIONS

Since most patients with GL have benign or reactive lymph-adenopathy, extensive work-up is to be done only in cases suspected to have significant lymphadenopathy on physical examination. Supraclavicular, scalene, iliac, popliteal and epitrochlear nodes should be investigated to rule-out a malignancy. Complete blood counts with blood picture may rule-out leukaemias and immune cytopaenias. Viral serological testing including HIV and immunological markers like anti-nuclear antibody (ANA) should be done when suspected on history and physical examination. Chest radiographs and abdominal ultrasonography may show nodes and provide clues to the aetiology. A computed tomography or magnetic resonance imaging may be used to visualise deep seated nodes like mediastinal and retroperitoneal nodes, when appropriate. Biochemical testing adds little to aetiological diagnosis although lactate dehydrogenase (LDH) is frequently raised in cases of lymphoma.

LYMPH NODE BIOPSY

The decision to obtain a biopsy should be based on lymph node characteristics, systemic examination and laboratory testing. Excision biopsy should be taken from the most representative node. Inguinal nodes are best avoided. Fine needle aspiration cytology is not a good method for initial diagnostic work-up. Indications for biopsy include lymph node area of >2.25 cm^2 (1.5 cm × 1.5 cm), hard, fixed, supra-clavicular, scalene, iliac, popliteal and epitrochlear nodes of any size or increasing size of nodes.

2.11 Dizziness and Vertigo

M Maiya

'Dizziness' is a common symptom. It refers to various types of abnormal sensations relating to perception of the body's relationship to space. These sensations may be a feeling of rotation or spinning—known as vertigo; or others like non-rotatory swaying, light-headedness, faintness and unsteadiness. This 'Dizziness syndrome' is mostly benign but it may be a manifestation of serious underlying cardiac or neurological disease. Hence, it is essential to analyse the complaint of 'Dizziness'.

The first step in the analysis of dizziness is to differentiate vertigo from other abnormal sensations of imbalance. If the patient complains of a sensation of spinning or motion sickness, one should suspect vertigo. It indicates a vestibular system disorder involving the inner ear or its connection to the brain; whereas the other sensations of imbalance suggest a non-vestibular disorder. The clinical approach to a patient with dizziness is shown in **Figure 1**.

NON-VESTIBULAR DISORDERS

1. *Syncope or pre-syncope:* Pre-syncope is a feeling of light headedness and a sensation of an impending faint (syncope). It is episodic, lasting for a few seconds to minutes. Pathophysiologically, it is due to decrease in cerebral blood flow, due to an underlying cardiovascular disorder.
2. *Disequilibrium:* It refers to a sense of imbalance involving the legs and the trunk, without a sensation in the head. It is seen in cerebellar ataxia and multiple sensory deficit syndromes. The cerebellar diseases are cerebellar degeneration or a tumour in or near the cerebellum. The multiple sensory deficit syndromes involve abnormalities in various proprioceptive systems like visual, auditory disorders and peripheral neuropathy. The patient may complain of dizziness at night.
3. There may be a group of patients who complain of ill-defined light-headedness which the patient finds difficult to define. Such patients usually suffer from anxiety or depression.

VESTIBULAR DISORDER: VERTIGO

Vertigo is a cardinal symptom of vestibular disease. Hence, it is essential to understand the neuro-anatomy and physiology of the vestibular system before analysing the symptoms of vertigo.

Anatomy and Physiology of the Vestibular System

The end organ of the vestibular system consists of 3 semi-circular canals and otolith apparatus (utricle and saccule) on either side, situated in the bony labyrinth of the inner ear. It is concerned with the detection of head position, head movement and control of the vestibulo-ocular reflex (VOR). This reflex automatically compensates for any movement of the head with an equal and opposite movement of the eyes.

The paired vestibular nuclei, situated in the medulla and lower pons receive neural input from three sensory systems—vestibular, visual (retina to occipital cortex) and the somato-sensory system (information from the skin, joints, and muscle receptors). The vestibular nuclei transmit the information to the

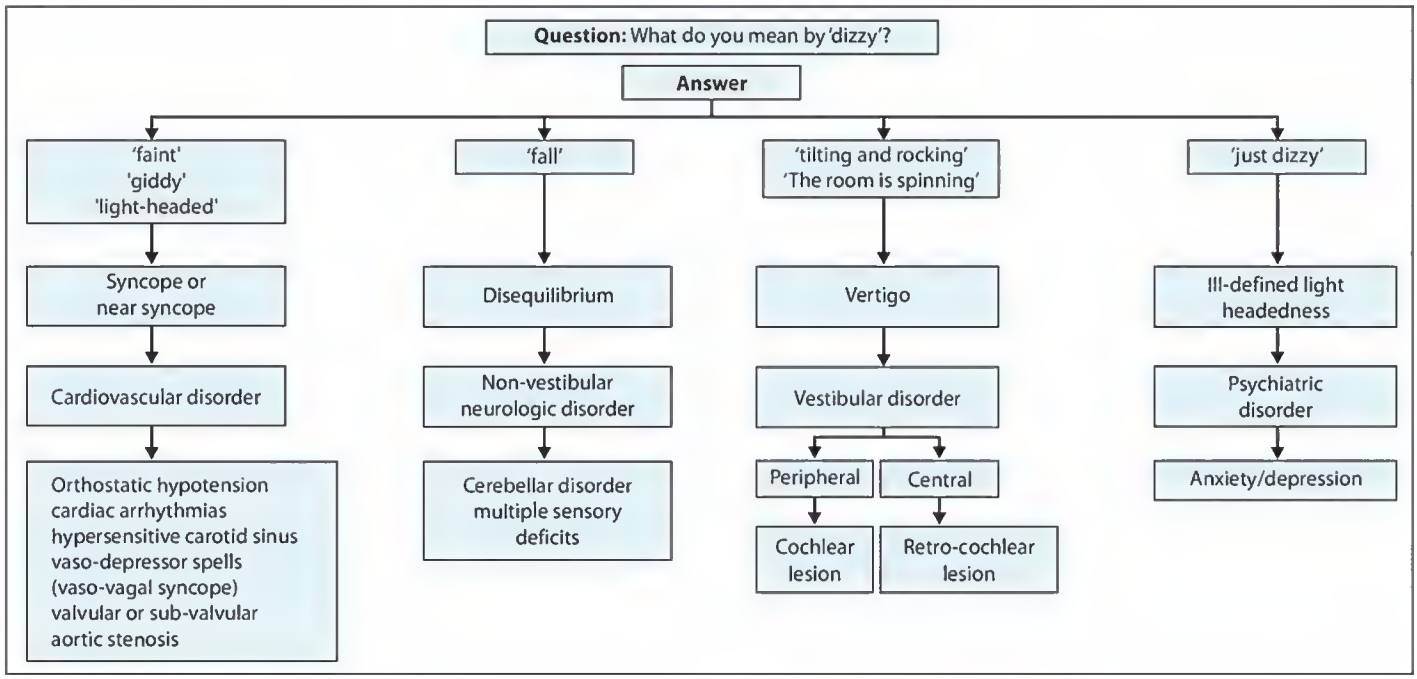

Figure 1: Approach to patient with 'dizziness'.

upper brainstem (nuclei of III, IV and VI cranial nerves), cerebellum, cerebral cortex and spinal cord through neural projections (**Figure 2**).

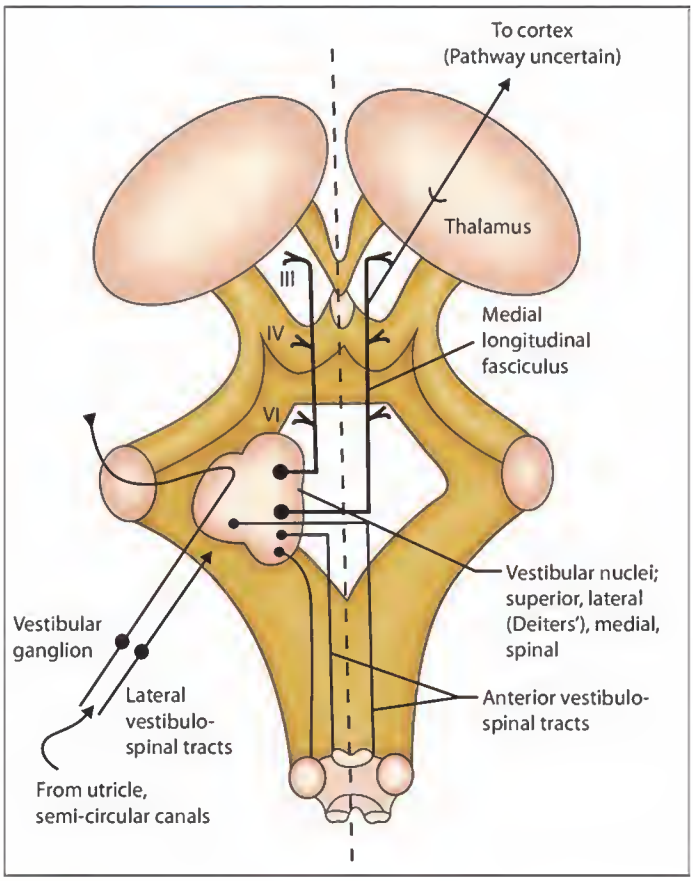

Figure 2: Connections of the vestibular system.

The projection of the vestibular nuclei to the nuclei of the III, IV and VI cranial nerves is essential for VOR. This reflex maintains visual stability during head movement. Lesions of these pathways result in nystagmus. The vestibulo-cerebellar connection helps in modulation of VOR. The abnormal activation and dysfunction of vestibulo-spinal pathway results in postural imbalance and vestibular ataxia. Vertigo itself is due to disturbance of cortical projections. The associated nausea and vomiting are due to activation of the reticular formation and the vomiting centre in the medulla.

Vertigo may be due to physiological or pathological causes. Physiological vertigo is seen in normal individuals with unfamiliar head movements, unusual head and neck position or following spinning.

Pathological vertigo results from lesions of the visual, somatosensory or vestibular system. Visual vertigo is caused by incorrect eye-glasses, and extra-ocular muscle paresis. Somatosensory vertigo is due to myelopathy or peripheral neuropathy and is rarely seen in isolation.

The most common cause of pathological vertigo is vestibular dysfunction. If may involve the end organ (labyrinth), the nerve or central connections. Vertigo is associated with jerk nystagmus frequently accompanied by nausea, postural unsteadiness and gait ataxia.

Clinical Manifestations

Depending on the frequency and duration of attacks, vertigo can be classified into 3 clinical types: prolonged spontaneous attacks, recurrent spontaneous attacks and recurrent positional vertigo. The lesion may be central or peripheral and can be differentiated as shown in **Table 1**.

Prolonged Spontaneous Attacks of Vertigo

This occurs when due to unilateral loss of vestibular function. The vertigo is acute in onset, may last for days and is aggravated by head movement. The patient prefers to sit upright with the head still or to lie with the intact side down. On movement the patient may fall towards the affected side. The vertigo is associated with nausea, vomiting and malaise. This type of vertigo may be peripheral or central. Common causes of this type of vertigo include acute labyrinthine/vestibular dysfunction due to infection, trauma or ischaemia, brainstem or cerebellar infarction/haemorrhage, multiple sclerosis and brainstem tumours/vascular malformations.

Table 1: Features of Peripheral vs Central Vertigo

Sign/Symptoms	Peripheral	Central
Direction of associated nystagmus	Unidirectional; fast phase opposite lesion	Bidirectional or unidirectional
Purely horizontal nystagmus without torsional component	Uncommon	Common
Vertical or purely torsional nystagmus	Never present	May be present
Visual fixation	Inhibits nystagmus and vertigo	No inhibition
Severity of vertigo	Marked	Often mild
Direction of spin	Towards fast phase (away from lesion)	Variable
Direction of fall	Towards slow phase	Variable
Duration of symptoms	Finite (minutes, days, weeks) but recurrent	May be chronic
Tinnitus and/or deafness	Often present	Usually absent
Associated CNS abnormalities	None	Extremely common (e.g., diplopia, dysarthria, hiccups, cranial neuropathies, ataxia, hemi-sensory loss or even paralysis)
Common causes	None, BPPV, infection (labyrinthitis), Meniere's disease, neuronitis, ischaemia, trauma, toxins	Vascular, demyelinating disease, neoplasm

CNS = Central nervous system, BPPV: Benign paroxysmal positional vertigo.

The vestibulopathy can be identified by the head thrust test. Head thrust test is a bed-side test of horizontal VOR. With the patient's head held by the examiner's hand he/she is asked to focus on the examiner's nose. The head is then quickly moved about 10° to one-side. In patients with normal vestibular function the VOR results in the movement of the eye in the direction opposite the head movement, so that the patient's eye remain fixed on the examiner's nose after the sudden movement. The test is repeated in the opposite direction. Loss of VOR will prevent eye movement opposite to the direction of head movements on the affected side.

Recurrent Spontaneous Attacks of Vertigo

The vertigo is sudden, temporary and reversible due to impairment of labyrinthine function. The vertigo of vascular origin like transient ischaemic attacks (TIA) lasts for minutes, whereas, that due to disease of the inner ear may last for hours. The common causes of recurrent spontaneous vertigo include Meniere's disease, autoimmune inner ear disease, syphilitic labyrinthitis, migraine equivalent and vertebro-basilar TIA.

Meniere's Syndrome

This disease is due to recurrent unilateral labyrinthine dysfunction associated with signs and symptoms of cochlear disease. It is characterised by severe vertigo, vomiting, tinnitus, fluctuating and progressive hearing loss with spontaneous recovery over hours to days. The age of onset is 40 to 60 years and the underlying pathology is endolymphatic hydrops due to inflammatory, autoimmune, traumatic or idiopathic aetiology.

Positional Vertigo

Positional vertigo is precipitated by the movement of the head either to the right or to the left from the recumbent position, triggering the vestibular pathway. The peripheral type of positional vertigo is more common than that of central origin and the differentiating features are shown in **Table 2**.

Table 2: Peripheral vs Central Positional Vertigo

	Peripheral	Central
Latency[a]	3-40 seconds	Immediate vertigo and nystagmus
Duration	< 1 min	May persist longer
Fatiguability[b]	Yes	No
Habituation[c]	Yes	No
Intensity	Severe vertigo, marked nystagmus	Mild vertigo, less intense nystagmus
Reproducibility[d]	Variable	Good
Mechanism	Debris moving in semi-circular canal	Damage to central VOP

a = Time between attaining head position and onset of symptoms
b = Disappearance of symptoms with maintenance of offending position
c = Lessening of symptoms with repeated trials
d = Livelihood of symptom production during any examination session

Benign Paroxysmal Positional Vertigo (BPPV)

BPPV is characterised by sudden onset of a peripheral vestibular syndrome with no auditory component. The vertigo occurs when the patient rolls to the side on lying down, or while gazing upwards, or bending forwards. The episode lasts for 10 to 20 seconds. BPPV occurs in bouts lasting for a few days or weeks and may recur after several weeks or months.

BPPV can be caused by head injury, stapes surgery, otitis media, labyrinthine ischaemia and viral infection of the ear. Occasionally, the cause is not obvious. The diagnosis is confirmed by standard positional testing test (Dix-Hallpike test).

Dix-Hallpike Test

With the patient seated, the examiner turns the head of the patient 45° to one-side. Next, the examiner moves the patient to the supine position with tilted head and open eyes. He slightly extends the neck so that the chin moves upwards. The latency, duration and direction of nystagmus is noted along with that of vertigo.

Central Positional Vertigo

Rarely, positional vertigo may be due to lesions near the fourth ventricle affecting the vestibular nuclei or the cerebellar vermis. The common causative lesions are multiple sclerosis, cerebellar tumours and atrophy.

Psychogenic Vertigo

The vertigo develops gradually, increasing with associated anxiety and terminates abruptly. Organic vertigo occurs abruptly and disappears gradually. Psychogenic vertigo is sometimes called phobic postural vertigo, associated with panic attacks or agoraphobia (fear of large open spaces or crowds). The vertigo is not associated with nystagmus or vomiting. Most patients adapt to being 'house-bound', whereas in organic vertigo patients attempt to function in spite of the incapacity.

APPROACH TO THE PATIENT

The first step in the diagnosis of dizziness and vertigo is to take a detailed history focussing on the meaning of 'dizziness'. Does it suggest 'faintness', sense of imbalance, light headedness or a sensation of spinning? This is followed by general medical examination, which should focus on the presence of orthostatic hypotension, cardiac arrhythmias, visual acuity and examination of the musculo-skeletal system for evidence of arthritis and impairment of gait. The neurological examination is done with particular reference to the VIII nerve (vestibular and cochlear component).

Provocative tests to induce cerebral ischaemia or vestibular dysfunction may be necessary where the patient is vague in the description of 'dizziness'. These tests include the Valsalva manoeuvre inducing orthostatic hypotension, and forced hyperventilation which decreases cerebral blood flow.

Vestibular dysfunction is demonstrated by a simple 'head shaking nystagmus test'. The patient is asked to close his eyes and bend his head down 30°. The head is oscillated horizontally 20 times. Elicitation of nystagmus after the manoeuvre suggests vestibular imbalance. Further evaluation of vestibular dysfunction is essential to determine the side of the lesion, the type of lesion and to distinguish central from peripheral lesions. The standard tests include head thrust test, Dix-Hallpike test and electro-nystamography. If a central aetiology is suspected, MRT is mandatory.

MANAGEMENT OF VERTIGO

Treatment of acute vertigo consists of bed rest for 1 to 2 days and use of anti-vertiginous drugs. These drugs give

symptomatic relief in acute vestibulopathy (Meniere's syndrome, vestibular neuritis), acute brain-stem lesions near the vestibular nuclei and prevent motion sickness. These are also used in frequent attacks of vertigo, vomiting and severex BPPV. The drugs used with their recommended dosages are mentioned in **Table 3**. Surgical procedures like labyrinthectomy, and section of 8th nerve are used in selected patients.

Table 3: Drugs Used in the Treatment of Vertigo

Drug Category	Drugs and Dosage
Anti-histamine	Dimenhydrinate 25 to 50 mg 1 to 2 times per day Meclizine 25 mg three times per day Cyclizine 50 mg daily
Anti-cholinergics	Scopolamine – patch 0.5 mg per day
Phenothiazine	Promethazine 50 mg per day Prochlorperazine 10 mg IM or 25 mg rectally Cinnarizine 25 mg per day
Benzodiazepines	Diazepam 2.5 to 5 mg oral or IV Clonazepam 0.25 mg 1 to 3 times per day
Histamine analogue	Betahistine 16 mg three time a day

IM = Intramuscular; IV = Intravenous.

In chronic and recurrent vertigo, exercises which provoke vertigo may be tried in order to habituate the patient. Patients who are refractory to conventional therapy may benefit from a formal rehabilitation programme, habituation customised programme and use of instruments, like tilt tables.

2.12 Syncope

Pushpa Yadav, Vivek Arya

Syncope is a clinical syndrome characterised by sudden, transient loss of consciousness and postural tone followed by spontaneous and prompt complete recovery. It is most often due to transient, self-terminating global cerebral hypoperfusion. Syncope accounts for 1% to 3% of emergency department visits and 1% to 6% of all hospital admissions in the USA . The lifetime risk of a syncopal episode is 50%. Advancing age is an independent risk factor for syncope.

PATHOPHYSIOLOGY

Reduction of blood flow to both cerebral hemispheres or to the brainstem reticular activating system leads to loss of consciousness and postural tone. A positional change from supine to erect causes a shift of 300 to 800 mL of blood from the thoracic cavity to the lower extremities. This is well tolerated in normal individuals without any compromise in cerebral blood flow which is maintained within a narrow range due to cerebrovascular autoregulation. Loss of autoregulatory mechanisms or depletion of blood volume will cause a fall in cerebral blood flow. Older patients and patients with hypertension or aortic valve disease tend to have syncope with a relatively small decrease in systemic blood pressure.

DIFFERENTIAL DIAGNOSIS

The first step in the assessment of syncope is to make a correct diagnosis, ruling out other disorders with a similar presentation, especially transient loss of consciousness.

A seizure is a common differential diagnosis. The presence of an aura, cry and tonic-clonic movements are suggestive of a seizure. Unconsciousness lasting more than 5 minutes, disorientation after the event and slowness in returning to consciousness are characteristic of seizures. Clenching of teeth, frothing from the mouth and sphincter incontinence are more commonly seen with seizures. In dizziness, pre-syncope, and vertigo there is no loss of consciousness. Drop attacks present as a sudden fall without loss of consciousness or warning and with immediate recovery. Concussions, metabolic disturbances, intoxications and psychogenic pseudoepilepsy and cataplexy also have to be excluded.

Syncope is often precipitated by exercise, pain, cough, micturition, defaecation or a stressful event. A pre-syncopal prodrome consisting of weakness, light-headedness, sweating and palpitations may precede the loss of consciousness. Episodes rarely occur in the supine position and are often brought on by sitting or standing. Some limb jerking may be seen in 15% of patients during a syncopal event.

CAUSES OF SYNCOPE

Common causes of syncope are listed in **Table 1**. Based on the underlying mechanism, syncope can be divided into different categories. Neurally mediated syncopes are the commonest cause of syncope. This type of syncopal event usually occurs in the standing position and is mediated by reflex mechanisms causing changes in vascular tone, heart rate or both. It is frequently recurrent and commonly precipitated by a hot or crowded environment. Episodes are often preceded by pre-syncopal prodrome lasting seconds to minutes, and rarely occur in the supine position. The two common variants include: vasovagal (e.g. in response to micturition, cough or defaecation) and carotid sinus syncope. Syncope associated with pain, neuralgia, or panic and episodes associated with exercise (without heart disease) are also included in this category. Reflex-mediated syncope does not carry an increased risk of cardiovascular morbidity or mortality.

Table 1: Causes of Syncope

Neurally-Mediated Syncope
Vasovagal (common faint)
Situational: cough, sneeze, laughter, micturition, defaecation, excessive heat, venipuncture (needle or blood phobia), post-parandial
Valsalva induced (weight lifting, brass instrument playing)
Carotid sinus syncope
Glossopharyngeal neuralgia
Post-exercise
Orthostatic Hypotension
Autonomic failure
Primary autonomic failure syndromes (e.g. pure failure, multiple system atrophy, Parkinson's disease with autonomic failure) and Shy-Drager syndrome
Secondary autonomic failure syndromes (e.g. diabetic neuropathy, amyloid neuropathy)
Use of medications (anti-hypertensives, vasodilators, negative chronotropes).
Volume depletion (e.g. haemorrhage, diarrhoea, Addisonism, diuretics)
Alcohol abuse
Postural intolerance syndromes
Neurologic
Migraine
Vascular steal syndromes
Transient ischaemic attacks
Arrhythmias
Sinus node dysfunction (including bradycardia/tachycardia syndrome)
Atrioventricular conduction system disease
Paroxysmal supraventricular and ventricular tachycardias
Inherited syndromes (e.g. long QT syndrome, Brugada syndrome, short QT syndrome, arrhythmogenic right ventricular dysplasia)
Implanted device (pacemakers, defibrillator) malfunction
Structural Cardiac or Cardiopulmonary Disease
Acute myocardial infarction/ischaemia
Obstructive valvular disease
Obstructive cardiomyopathy
Acute aortic dissection
Pericardial disease/tamponade
Pulmonary embolus/pulmonary hypertension
Psychiatric Disorders

Orthostatic hypotension is a drop in systolic blood pressure of 20 mmHg or in diastolic pressure of 10 mmHg within 3 minutes of standing. It is considered clinically important if the reduction in blood pressure is sustained at or beyond 3 minutes and the original symptoms are reproduced during active or passive standing. This occurs when the autonomic nervous system is incapacitated either as a result of age-related physiologic changes, use of certain medications (anti-hypertensives, vasodilators and negative chronotropes), volume depletion, primary autonomic failure or secondary autonomic failure due to diabetes mellitus, amyloidosis or alcohol abuse. Orthostatic hypotension is more common in the elderly because of blunted barorecepter responses resulting in the failure of compensatory cardio-acceleration.

APPROACH TO SYNCOPE

An algorithm for the evaluation of a patient with syncope is shown in **Figure 1.** In the absence of a diagnostic gold standard, history, physical examination and electrocardiography (ECG) are the cornerstones for the assessment of syncope and their combined diagnostic yield is about 80%.

The first step is to differentiate syncope from the other causes of transient loss of consciousness, and the next step is to separate benign causes of syncope from potentially sinister ones. The clinical features suggestive of specific causes of syncope are shown in **Table 2.** Serious causes of syncope, such as critical aortic stenosis, aortic dissection, pulmonary embolism, visceral bleeding, dysrrhythmias, myocardial ischaemia and subarachnoid haemorrhage should first be ruled out. In elderly persons a sudden faint without an obvious cause should arouse the suspicion of a complete heart block or tachyarrhythmia.

Table 2: Clinical Features Suggestive of Specific Causes of Syncope

Type of Syncope	Clinical Features/Precipitants
Neurally mediated syncope	Posture change, coughing, defaecation, micturition, strong emotions, fear, prolonged standing, crowded hot places
Carotid sinus syncope	With head rotation, pressure on carotid sinus (as in shaving, tight collars, tumours)
Syncope caused by orthostatic hypotension	After standing up, autonomic neuropathy
Cardiac syncope	Structural heart disease, during exertion or while in supine position, palpitations, acute or old myocardial infarction, family history of sudden death
Cerebrovasular syncope	
Subclavian steal syndromes	Arm exercise
Aortic dissection	Differences in blood pressure or pulse in both arms
Psychiatric illness	Frequent syncope with somatic symptoms but no heart disease

A complete physical examination should be performed in all patients. Special attention should be paid to the following aspects (**Table 3**):

1. Vital signs: Fever may point to an infection. Blood pressure must be measured in both arms and in supine and standing positions. Tachycardia may be due to pulmonary embolism, hypovolaemia, tachyarrhythmia, or an acute coronary syndrome. Bradycardia may point towards a cardiac conduction defect, an acute coronary syndrome or a vasodepressor cause of syncope.
2. Cardiac rhythm and auscultatory signs of aortic stenosis, pulmonary hypertension, idiopathic hypertrophic subaortic

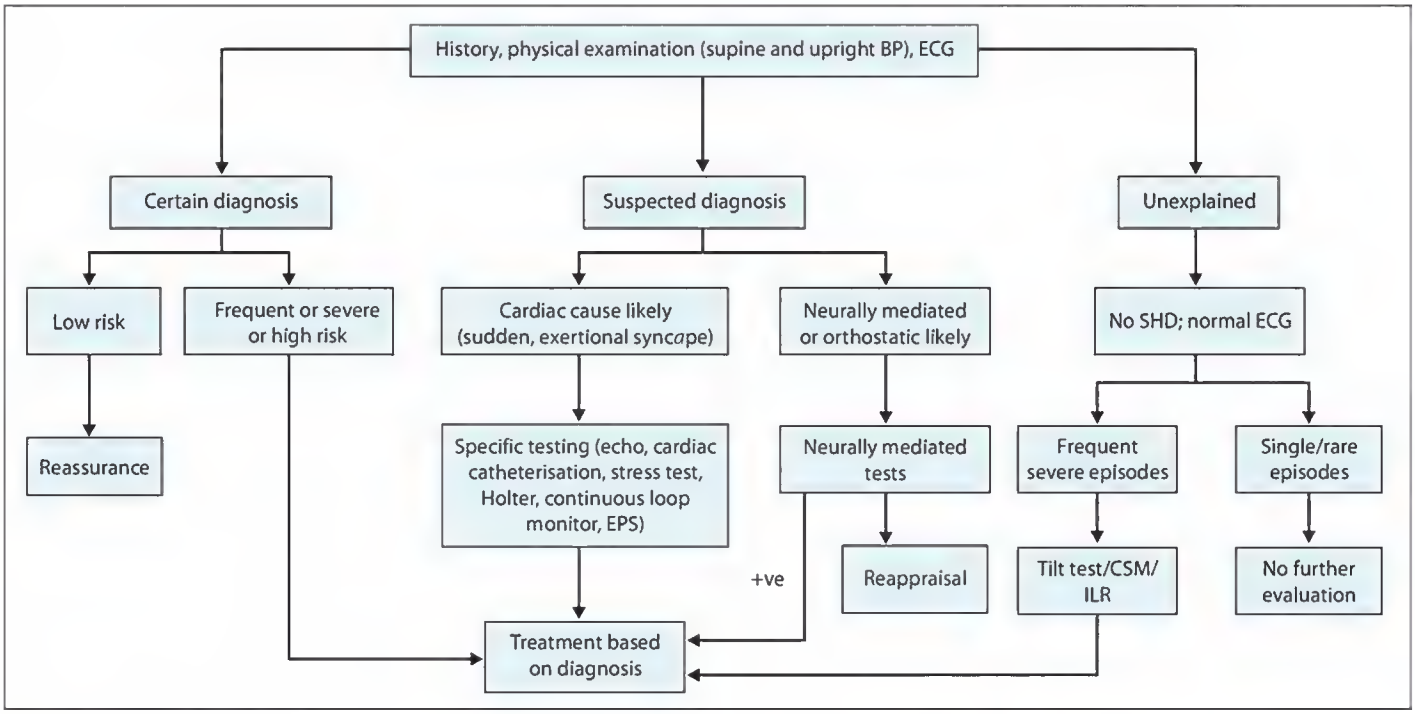

Figure 1: Appraach ta syncape.

BP = Blaad pressure; ECG = Echacardiagraphy; SHD = Structural heart disease; ILR = Insertable loap recarder; EPS = Electraphysialagical studies; CSM = Caratid sinus massage

stenosis, myxomas, congestive heart failure (CHF) or aortic dissection.

3. Carotid bruits, cranial nerve deficits, motor and sensory deficits.
4. Signs of trauma which may be secondary to syncope or may have caused syncope.

Table 3: Clinical Features Suggestive of the Cause of Syncope

Clinical Feature	Likely Cause of Syncope
Orthostatic hypotension	Drugs like beta blockers and clonidine, diabetes mellitus
Murmur changes with position	Atrial myxoma or thrombus
Headache, diplopia, dysarthria, pain in occipital region	Subarachnoid haemorrhage, transient ischaemic attack, subclavian steal, basilar migraine
Tachypnoea, syncope in a bedridden patient or in the post-operative period	Pulmonary embolism
Asymmetric pulses, back pain	Dissecting aneurysm of aorta, subclavian steal
Elevated jugular venous pressure	Right heart failure, myocardial ischaemia, tamponade or pulmonary embolus
Abdominal tenderness or mass in an elderly patient	Visceral bleed (abdominal aortic aneurysm)
Amenorrhoea in young women, uterine spotting, adnexal tenderness	Ruptured ectopic pregnancy

INVESTIGATIONS

Cardiac Evaluation

Electrocardiography

ECG should be performed in all patients. Abnormal ECG findings occur in about 90% of patients with cardiac-induced syncope, but in only 6% of patients with neurally mediated syncope.

Exercise testing

Indicated if clinical evaluation suggests ischaemic heart disease or exercise-induced tachyarrhythmia. In patients with exertional syncope, echocardiography should be done first to exclude hypertrophic cardiomyopathy.

24-hour Holter monitoring

Indicated when symptoms suggest arrhythmic syncope (palpitations with syncope, episodic unconciousness with no prodrome) or in those with an abnormal ECG, heart disease or unexplained syncope.

Continuous-loop event monitoring

Recommended if no arrhythmias are found and no syncope occurs during 24-hour Holter monitoring; in patients with recurrent syncope and a normal heart; syncope of unexplained cause; heart disease and abnormal ECG.

Electrophysiologic studies (EPS)

Patients with underlying organic heart disease and non-diagnostic prolonged ECG monitoring, and those whose hearts are normal, but ECG show conduction disturbances should undergo electrophysiologic studies.

Signal-averaged electrocardiography

The signal-averaged ECG filters multiple QRS complexes to uncover late potentials arising from abnormal myocardium, where re-entry and ventricular tachycardia may arise. It is useful for selecting patients for electrophysiologic studies when ventricular tachycardia is suspected in the presence of ischaemic heart disease.

Head-up tilt table (HUTT) testing

It is recommended in patients with recurrent syncope in whom a cardiac cause of syncope, including arrhythmias has been excluded and in patients with unexplained recurrent syncope. It may also be indicated for differentiation of convulsive syncope from epilepsy and for assessment of recurrent and unexplained falls.

HUTT testing uses changes in position to reproduce the symptoms of the syncopal event by inducing bradycardia or hypotension suggestive of reflex mediated syncope. Pharmacologic augmentation with isoproterenol intravenously or low dose nitroglycerine is required in patients who have a high pre-test probability of neurally mediated syncope but a negative result on a passive tilt table test.

The test should not be performed in pregnant patients. In men older than 45 years of age and women older than 55 years of age should have stress testing before HUTT. A positive HUTT can be used to reassure the patients about the usually benign nature of the diagnosis. It can also be used to minimise, if not eliminate, the unnecessary use of anti-epileptic drugs.

Carotid sinus massage

Carotid sinus massage should be carried out when carotid sinus syncope is suspected (**Table 2**). The contraindications for carotid sinus massage are recent myocardial infarction, transient ischaemic attacks, or stroke, ventricular fibrillation, ventricular tachycardia or a carotid bruit.

Psychiatric Evaluation

Syncope due to psychiatric disorders is usually seen in younger patients with no heart disease and does not cause injury. Such events may be precipitated by anxiety, panic, or major depression as a neurally-mediated response.

Laboratory Studies

The yield of most routine laboratory studies is low. A haemogram, blood glucose levels, serum electrolytes, renal function tests, cardiac enzymes, brain natriuretic peptide (BNP) levels and urinalysis may provide diagnostic clues in selected patients.

Imaging Studies

Computed tomography (CT) and magnetic resonance imaging (MRI) of the head may be useful in the presence of head trauma or neurological deficits.

SYNCOPE IN SPECIFIC SITUATIONS

Exercise-Related Syncope in Young Athletes

Exercise-related syncope, while generally a benign event, can signal sudden death in young adults. It occurs either during or immediately after a period of exercise. Causes of exercise-related syncope include hypertrophic cardiomyopathy , aortic stenosis, critical coronary artery disease, right ventricular dysplasia,

congenital coronary artery anomaly, prolonged QT syndrome, high grade atrioventricular block, idiopathic ventricular tachycardia, hyponatraemia, hypoglycaemia and hyperthermia (heat stroke).

The commonest cause is neuro-cardiogenic syncope. In all cases of unexplained exertional and pre-exertional syncope, an echocardiogram followed by a stress test should be done. In such individuals, temporary restriction from vigorous activity should be considered. Reassuring clinical features are non-recurrent syncope, occurring after exercise, no family history and a normal cardiac examination with ECG, echocardiogram, and stress test being normal. Such athletes may return to vigorous activity with an appropriate follow-up plan.

Syncope in Elderly Patients

Syncope in elderly patients portends a poor prognosis. The high mortality rate is due to co-morbidites. Common risk factors for syncope in the elderly are susceptibility to situational syncope, polypharmacy and adverse drug effects on heart rate, intravascular volume and vascular tone (with use of beta-blockers, calcium-channel blockers anti-arrhythmics, diuretics and anti-depressants) resulting in orthostatic hypotension. Several entities including carotid sinus hypersensitivity, aortic stenosis, myocardial infarction, arrhythmias and transient ischaemic attacks are more common in the elderly.

HOSPITALISATION AND PROGNOSIS

Indications and risk factors for hospital admission in patients with syncope are listed in **Table 4**.

Table 4: Indications for Hospital Admission in Patients with Syncope

Definitely hospitalise patients with 'high risk' who meet any of the following criteria:
History of coronary artery disease, congestive heart failure or ventricular arrhythmia
History of chest pain
Physical signs of congestive heart failure, valvular disease or focal neurological deficit or new stroke, acute pulmonary embolism, aortic dissection
Electrocardiographic findings showing ischaemia, arrhythmia, increased QT interval or bundle-branch block
Cardiac devices (pacemaker or defibrillator) with dysfunction

Strongly consider hospitalising patients with 'intermediate risk' who meet any of the following criteria:
A history of exertional syncope even in the absence of any evidence suggestive of aortic stenosis or left ventricular outflow obstruction
Sudden recurrent loss of consciousness with injury
Age >70 years
Haematocrit <30 mL/dL
Frequent syncope, suspected cardiac disease or arrhythmia (e.g. use of medications associated with torsades de pointes)
Moderate-to-severe orthostatic hypotension
Congenital heart disease
Family history of sudden death

Patients with 'low risk' may be evaluated as outpatients
No structural heart disease and a normal ECG
Suspicion of psychogenic pseudosyncope
Neurally mediated syncope

TREATMENT

The treatment of a patient with syncope depends on the underlying mechanism and identification of precipitants and contributory factors.

1. For neurally mediated syncope, orthostatic hypotension and carotid sinus syncope, patient education is the foundation of treatment. Patients must be reassured about the benign nature of the problem. Measures that help abort an incipient attack include sitting with the knees drawn, squatting, lying with raised legs and performing physical counter-pressure manoeuvres, sustained hand grip and isometric exercises to raise blood pressure. The importance of assuming an upright posture slowly should be emphasised in patients with orthostatic hypotension.

   For long-term prevention of attacks, adequate fluid and salt intake should be advised. In some cases, fludrocortisone for volume expansion and other drugs such as midodrine (an alpha-1 agonist with vasopressor activity) may be needed. Compression stockings may also be beneficial. Medications must be reviewed carefully to eliminate drug associated with hypotension. Beta-blockers are no longer recommended for vasovagal syncope. For situational syncope, it might be possible to ameliorate or avoid triggers. Avoidance of tight collars, neck ties, and abrupt neck movements is prudent advice for carotid sinus syncope, but cardiac pacing may be recommended in some.

2. Syncope related to arrhythmias requires specific therapy. Supraventricular tachycardia may respond to drugs or radiofrequency ablation. Bradyarrhythmias require pacing. Implantable defibrillators are helpful in the treatment of both ventricular tachyarrhythmias and bradyarrhythmias.

2.13 Coma

B Vengamma

INTRODUCTION

The prompt diagnosis and effective management of a patient with altered consciousness, especially coma, is one of the difficult tasks faced by a physician. The physiologic components that govern conscious behaviour include *content* (sum of cognitive and affective mental function) and *arousal* (appearance of wakefulness). The physiology of arousal emerges from the action of the reticular activating system (RAS), a poorly localised network of cells in the rostral brainstem and the diencephalon. The RAS receives stimuli from the environment via the somatosensory pathways, the autonomic pathways and limbic system inputs. In turn, the RAS stimulates the brain, activating the cortex. Because it is a diffuse network of cells, there is no single transmitter system involved with the RAS. Physicians try to induce arousal in comatose patients by stimulating the RAS. Although the term 'coma' is derived from the Greek word *koma*, meaning a deep (presumably unarousable) sleep, a range of anatomical sites, causes, and mechanisms may be involved in producing coma.

While consciousness is the state of awareness of the self and the environment, coma is its exact opposite. Between the extreme states of consciousness and coma stand a variety of altered states of consciousness (**Table 1, Figures 1 and 2**).

DIAGNOSTIC APPROACH

Early, appropriate diagnosis of the cause of unconsciousness is important because, several causes of coma (e.g. subdural, epidural haematomas, hypoglycaemia) can be fatal if not recognised early and treated. The approach to a comatose patient begins with a good, detailed history and clinical examination.

Functional abnormality of the brain causes unconsciousness, either due to bilateral dysfunction of the cerebral hemispheres or damage or depression of the RAS or due to metabolic damage.

The key to making a correct diagnosis in coma consists of accurate interpretation of a limited number of physical signs that reflect the integrity or impairment of various levels of the brain. The abnormal findings of the examination indicate whether the cause of altered consciousness is supratentorial (starts rostrally and evolves caudally), subtentorial (starts focally in the brainstem), metabolic (produces from the onset signs of diffuse or multifocal dysfunction), or psychiatric (lacks signs of physiologic brain dysfunction (**Table 2**).

Table 1: Various States of Consciousness

Alert
A state where the patient is fully responsive and able to interact with the physician

Confusion
A state of disorientation in time, place and person or situation resulting in bewilderment, perplexity and lack of orderly thought

Delirium
An acute confusional state that may sometimes be marked by periods of irritability and hallucinations

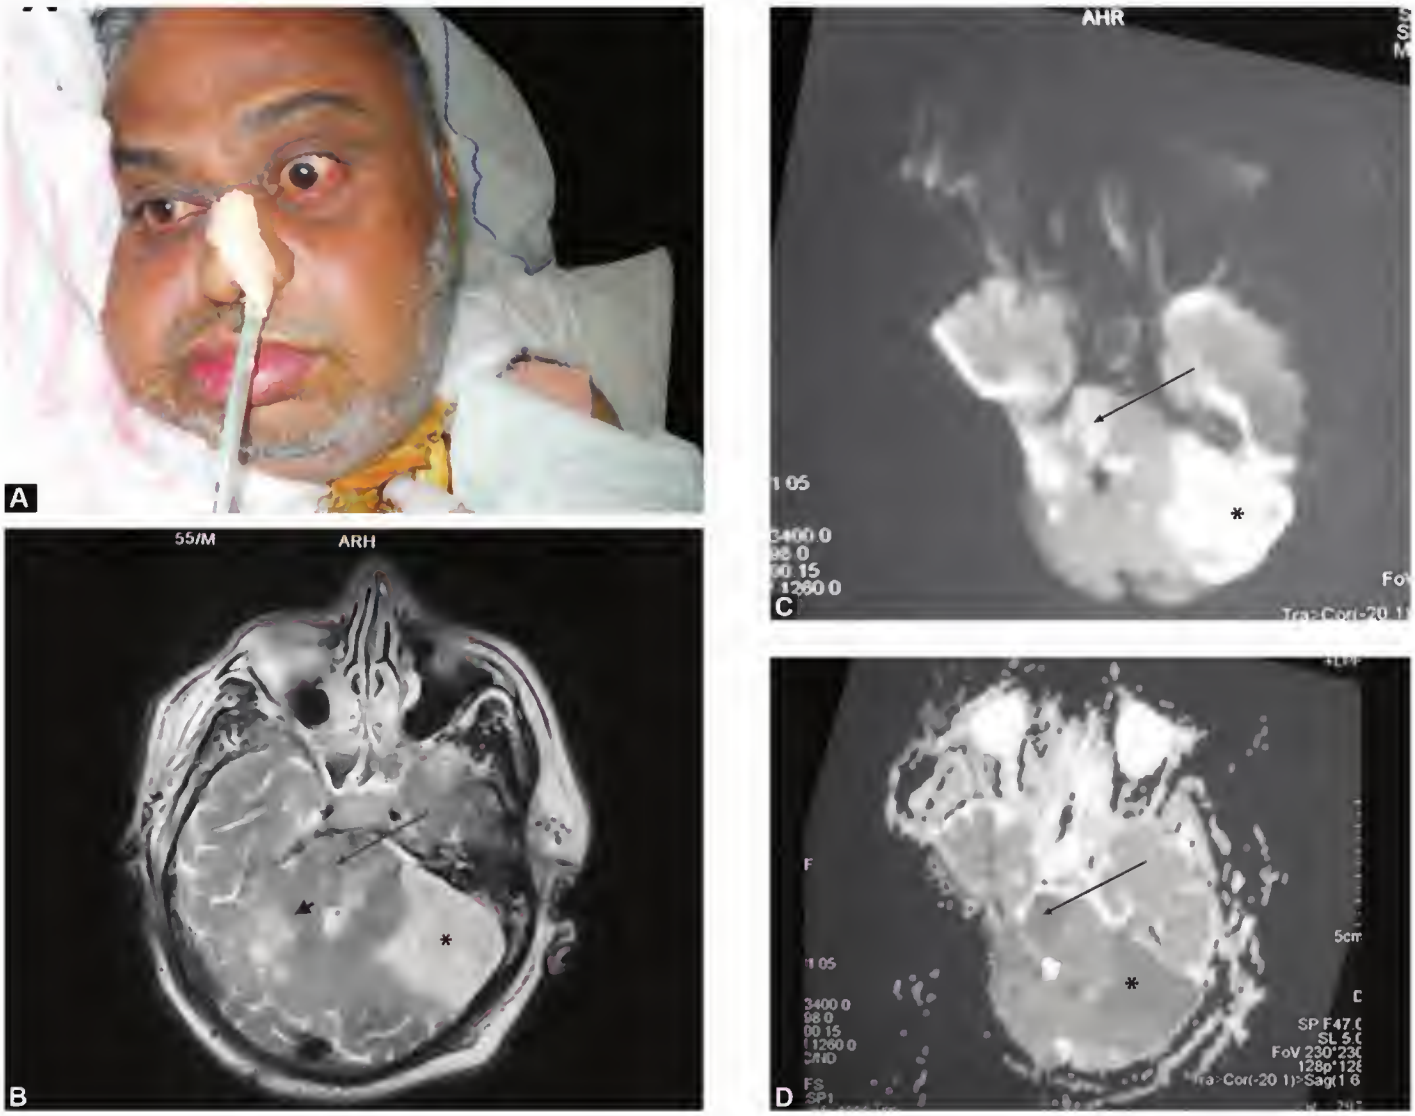
Obtundation
A lesser state of decreased arousal with some responsiveness to touch or voice

Lethargy (somnolence)
Arousal, though diminished, is maintained spontaneously or with repeated light stimulation

Stupor
A state of severely impaired arousal with some responsiveness to vigorous stimuli

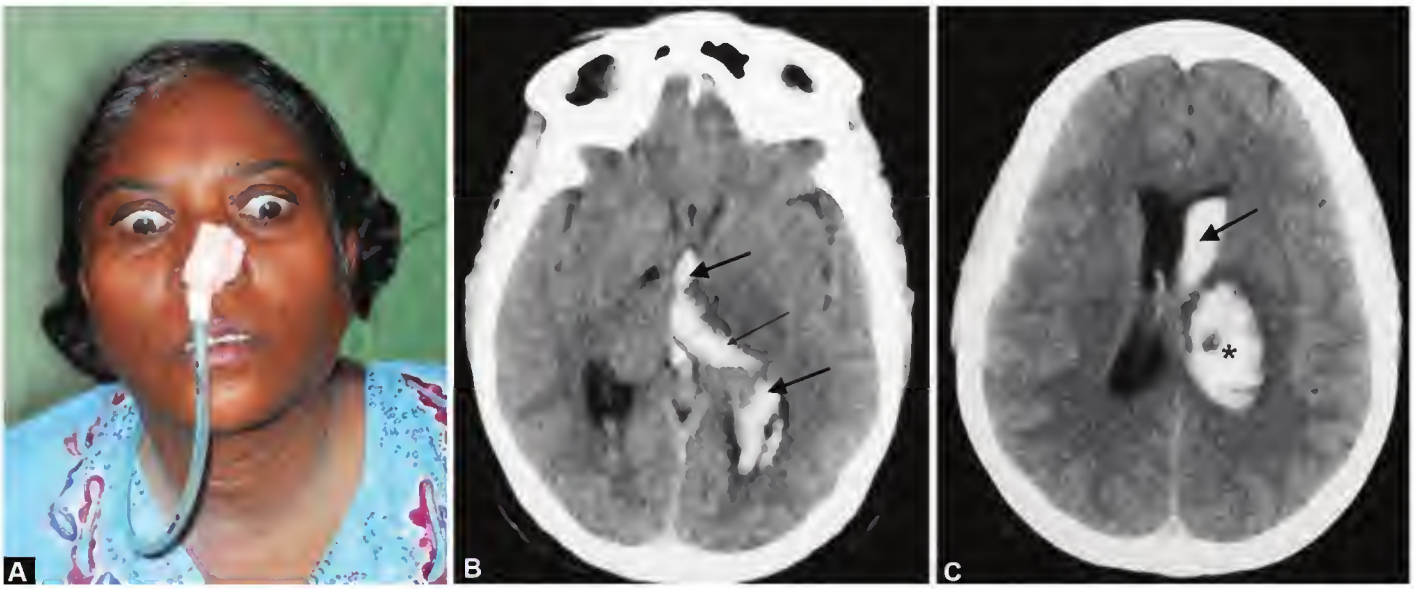
Coma
Total or near total unresponsiveness, i.e., the total absence of awareness of self and environment even when the subject is externally stimulated

Vegetative state
Wakefulness accompanied by lack of cognitive function. The patient opens eyes spontaneously in response to verbal stimuli



Akinetic mutism
Silent, alert appearing immobility with retainment of sleep wake cycles and absent mental and spontaneous motor activity

Apallic syndrome
Absent neocortical function with relatively intact brainstem function



Locked-in syndrome
A state in which weakness of all four limbs is associated with lower cranial nerve paralysis; but, the patient manifests signs of being appropriately aware of himself and his environment and communicates with vertical eye movements

Inattention
A state where a person looks alert or even hyperalert. The eyes are open and the person is looking around, but cannot complete a simple task.

Abulia
A state where the patient is essentially quiet and has complete lack of spontaneity. It is usually associated with bilateral frontal lesions. There is perseveration or repetitive movement

Figures 1A to D: Locked-in state. (A) A patient with weakness all four limbs with lower cranial nerve paralysis. The patient manifests signs of being appropriately aware of himself and his environment and communicates with vertical eye movements. (B) MRI brain (T2 weighted axial image) showing hyperintensity in the pons (arrow). (C) Hyperintensity in right middle cerebellar peduncle (arrow head) and in left cerebellar hemisphere (asterisk). (D) Diffusion weighted images (upper panel right) apparent diffusion coefficient map (lower panel, right) showing acute infarction in pons (arrow) and cerebellum (asterisk).

Figures 2A to C: Clinical photograph showing a delirious patient (A) NCCT head of the same patient showing acute haematoma in the left thalamus (thin arrow) and corona radiate (asterisk) extending into lateral and third ventricles (thick arrow) (B and C).

HISTORY AND GENERAL EXAMINATION

The history has to be obtained from an eyewitness account or from a paramedic who had resuscitated the patient. Recent events or preceding illnesses that lead to the comatose state should be enquired into. A history of trauma, drug or alcohol use is important. Possible ingestion of medications should be evaluated. History regarding any psychiatric illness which might be responsible for coma should also be elicited.

Bedside clinical evaluation should begin with measurement of blood pressure. If blood pressure is elevated, careful evaluation for signs of an acute ischaemic or haemorrhagic stroke, or increased intracranial pressure is indicated. Certain breathing patterns are very classical and facilitate anatomical localisation in a comatose patient (**Figure 3**). Patients with *Cheyne-Stokes breathing* manifest rapid shallow breathing to the point where there is a cessation of breathing and apnoea. Thereafter, there is an abrupt spontaneous return of respirations with deep sighs, and the cycle repeats. This type of pattern is seen in head injury and metabolic conditions. *Biot's breathing*, seen in lesions of medulla oblongata (e.g. head trauma, stroke) refers to an abnormal breathing pattern consisting of rapid, shallow breaths followed by periods of apnoea. This pattern is often confused with *ataxic breathing*. While in Biot's breathing clusters of similar sized breaths occur, in ataxic breathing pattern, the respirations are completely irregular in both rate and rhythm mimicking dysmetria of the extremities. *Kussmaul breathing* is characterised by a deep, rapid breathing rate and is seen in metabolic acidosis. *Apneustic breathing* usually seen in trauma or stroke involving the medulla oblongata is an irregular breathing pattern which is intermixed with irregular periods of apnoea (**Figure 3**). It is important to look for other tell-tale signs of a traumatic injury, an infectious disease process, or an ingestion of drugs leading to the comatose state. Signs of liver cell failure should also be looked for. Odour of the breath (e.g. alcohol ingestion; acetone like in diabetic ketoacidosis DKA, hepatic encephalopathy) can sometimes be helpful.

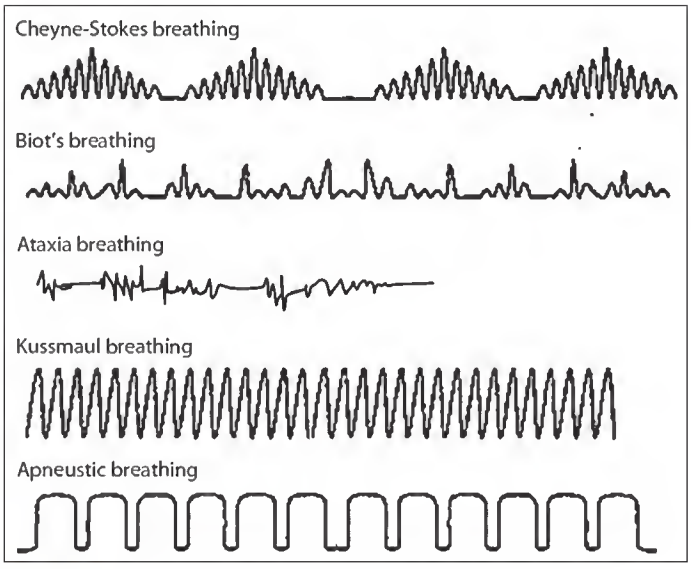


Figure 3: Various breathing patterns and their graphical depiction.

Table 2: Differential Characteristics of State and Causing Sustained Unresponsiveness

Supratentorial mass lesions compressing or displacing the diencephalon or brainstem initiating signs usually of focal cerebral dysfunction
Signs of dysfunction progress rostral to caudal
Neurologic signs at any given time point to one anatomic area (e.g. diencephalon, midbrain-pons, medulla)
Motor signs often asymmetrical
Subtentorial masses
History of preceding brainstem dysfunction
Localising brainstem signs precede or accompany onset of coma and always include oculovestibular abnormality
Cranial nerve palsies usually present
'Bizarre' respiratory patterns common and usually appear at onset
Metabolic Causes
Confusion and stupor commonly precede motor signs
Motor signs are usually symmetrical
Pupillary reactions are usually preserved
Asterixis, myoclonus, tremor, and seizures are common
Acid-base imbalance with hyper- or hypo-ventilation is frequent
Psychiatric Unresponsiveness
Lids close actively
Pupils reactive of dilated (cycloplegics)
Oculocephalics are unpredictable: oculovestibulars physiologic (nystagmus is present)
Motor tone is inconsistent or normal
Eupnoea or hyperventilation is usual
No pathologic reflexes are present
EEG is normal

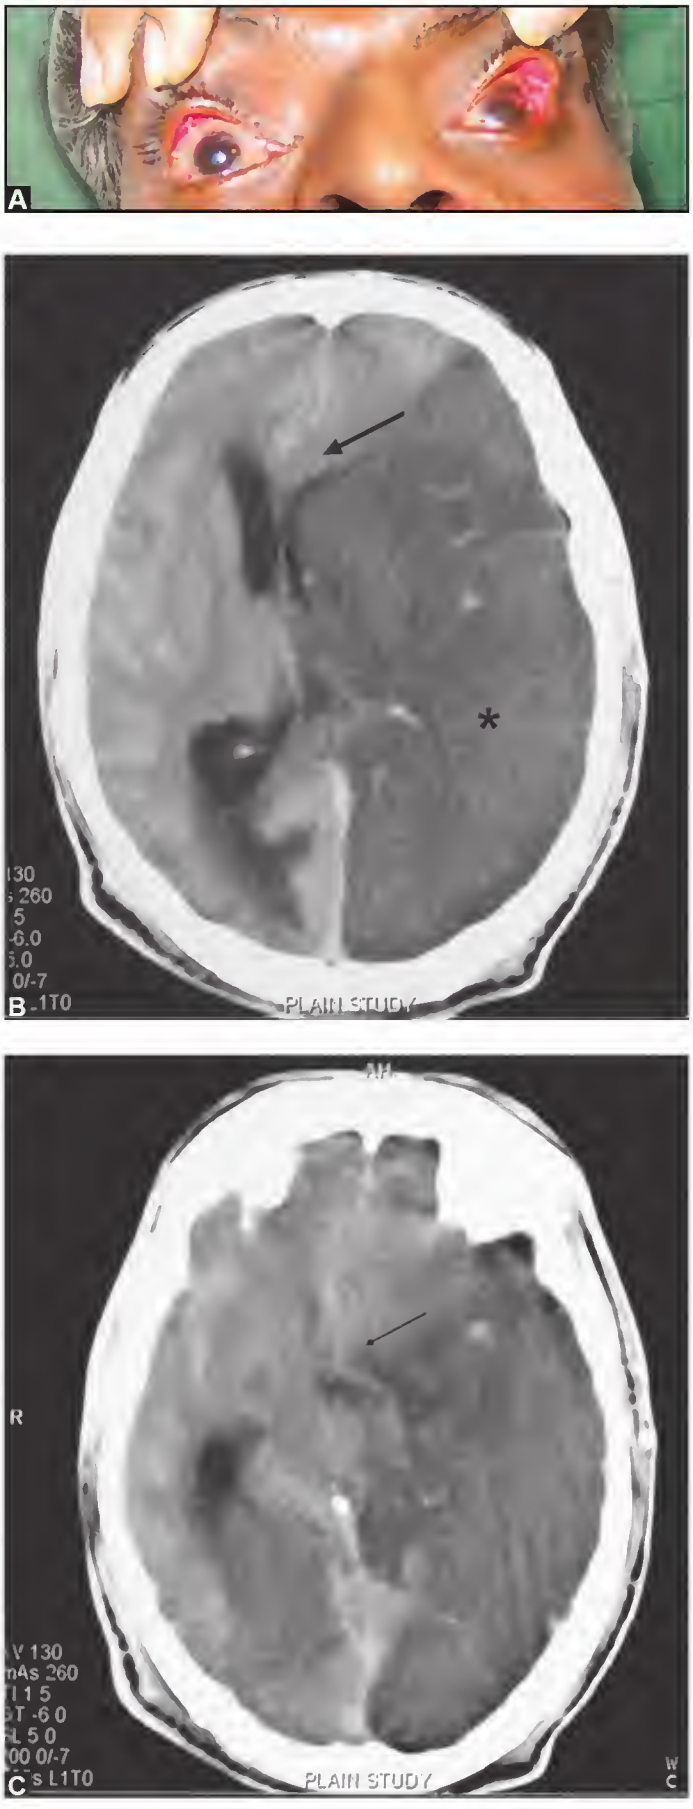
EEG = electroencephalogram.

NEUROLOGIC EXAMINATION IN COMATOSE PATIENTS

The neurologic examination in comatose patients, should include all parts of the traditional neurologic examination except, perhaps, the gait. But there is an emphasis on the level of arousal, the cranial nerve examination, and the motor movements. Examination of the pattern of reflexes is also important. Most importantly, the general principle underlying the neurological examination in a comatose patient is pattern recognition. The first step involves assessing the level of consciousness (**Table 1**), traditionally using the Glasgow coma scale (GCS), which is composed of eye movements, motor movements, and spontaneous language.

The fundoscopic examination gives information about raised intracranial pressure and pathology. Blink test or menace reflex should be done which gives an idea about visual fields. Other aspects of cranial nerve examination include pupils, eye movements, sensory component of Vth cranial nerves and motor component of VIIth cranial nerves and the gag response as part of cranial nerves IXth and Xth.

The pupils tend to be small and reactive and absent corneal oxycephalic reflex indicates metabolic injury. Symmetry of the pupils is very important in differentiating nonstructural versus structural injuries. Midbrain pupils, reflective of midbrain injury, tend to be midposition, fixed, slightly irregular with intact reaction to light. In contrast, small, thin, pin-point pupils that do not react to light are suggestive of pontine injury and can also be seen in opiate intoxication. Asymmetry in the form of unilateral dilatation of the pupil in a comatose patient suggests unilateral third nerve palsy which could be an indication of an uncal herniation, which is essentially a sign that the brain is swelling to the point where the cortex is impinging on the



brainstem and the third cranial nerve as it exits from the brainstem itself; such patients may need urgent neurosurgical intervention (**Figures 4A to C**).

In the examination of eye movements, it is most important to open the eyelids and to see where the eyes are at rest. Any gaze deviation away from the side that is weak is essentially a sign of a hemispheric lesion. If it is towards the side of the hemiparesis, it suggests that the lesion is at the brainstem, specifically in the pons or the cerebellum. If the primary gaze is downwards it suggests that the lesion might be within the midbrain, or perhaps even something pushing down onto the midbrain that is causing the eyes to stay down. Spontaneous eye rolling movements suggest bilateral hemispheric dysfunction as seen in metabolic encephalopathies. *Ocular bobbing* (the eyes, when at rest, dip down and come back to the resting position) and *ocular dipping* (the eyes bounce up and have a slow downward phase) are pathognomonic of pontine injury.

The occurrence of eye movements that are spontaneous and saccadic in motion, and rolling eye movements on opening the eyelids excludes the possibility of the patient being in true coma because saccadic movements involve a level of awareness beyond just a level of arousal.

Due to the oculocephalic reflex, normally the eyes move contralateral to the side of head movement. Absent oculocephalic reflex is an indication of bilateral hemispheric injury. This test should be avoided in patients with suspected neck injury. Oculovestibular reflex, also known as a cold caloric test, is another way to gauge brainstem integrity specifically for pontine and cerebellar function. The test is done by keeping the patient's head end of the bed elevated at 30°, instilling about 60 cc of ice water in each ear with a butterfly catheter and a syringe. The normal response involves a tonic movement of the eyes towards and fast saccades away from the side of stimulation. Bilateral absent fast movements are a sign of bihemispheric injury. An asymmetrical response suggests brainstem dysfunction. A negative response to the caloric test (no eye movements) indicates loss of brainstem integrity. In an awake person or a person who is not comatose, this test induces saccadic movements, nausea, and probably also vomiting.

In the motor examination, asymmetry of the response and assessment of tone helps in localisation. The best way to look for this is to look for spontaneous movements, i.e. sit at the bedside and just watch the patient for some time to see whether or not there is any movement whatsoever. If there are no spontaneous motor movements, the patient may be asked to move a limb on verbal commands, Still, if there is no perceptible movement, then sequentially more noxious stimuli are applied to try and induce a response. If the response elicited is a classical decorticate or decerebrate posturing, it has prognostic significance. Decorticate posturing, indicative of a hemispheric injury and damage to corticospinal tracts, is characterised by adduction and flexion of the arms with wrists and fingers flexed on the chest. The legs are extended and internally rotated with plantar flexion of the feet. Lesions located around the red nucleus cause decerebrate rigidity which is characterised by internal rotation (adduction) and extension of arms, pronation of the wrists and finger flexion. The legs are extended with forced plantar flexion of feet. In severe cases, ophisthotonus may be present.

Figures 4A to C: Clinical photograph showing asymmetry of pupils. (A) NCCT head (axial images) of the same patient showing sub-acute infarct in the left cerebral hemisphere (asterisk) with relative sparing of frontal lobe causing subfalcine herniation arrows (B and C).

DIFFERENTIAL DIAGNOSIS

Causes of coma can be classified as structural, non-structural, toxic or metabolic (**Tables 3 and 4**). Among all patients in coma, one-third have an evident structural lesion. The differential diagnosis tends to be trauma or vascular in origin; meningitis, encephalitis, tumours, or hydrocephalus. Toxic or metabolic injuries include post-cardiac arrest with global hypoxic ischaemic injury exposure to a toxin such as carbon monoxide, drugs and electrolyte disorders. Psychiatric disorders, can present as coma. They can be difficult to differentiate from metabolic causes.

Table 3: Some Causes of Coma

Focal disease
- Trauma (contusion, ICH)
- Non-traumatic ICH
- Ischaemic stroke
- Infection (abscess, subdural empyema, focal encephalitis)
- Tumour
- Demyelination (multiple sclerosis, acute demyelinating encephalomyelitis)

Non-focal disease
- *Trauma (elevated ICP, diffuse axonal injury)*
- *Vascular syndrome*
  - Subarachnoid haemorrhage
  - Aneurysm in posterior fossa with mass effect
  - Hypoxic-ischaemic encephalopathy
  - Stroke (focal strokes with non-focal presentations, posterior fossa infarct with mass effect, hydrocephalus)
  - Hypertensive encephalopathy (including ecclampsia)
- *Infection (meningitis, diffuse encephalitis)*
- *Tumour-related*
  - Tumour (brainstem invasion, posterior fossa mass effect, elevated ICP, hydrocephalus)
  - Paraneoplastic syndromes (brainstem and limbic encephalitis, vasulitis)
  - Toxic and metabolic (**Table 4**)
  - Withdrawal syndromes
  - Nutritional deficiencies (Wernicke's encephalopathy, pellagra)
  - Disordered temperature regulation
- *Seizure (postictal state, non-convulsive status epilepticus)*
- *Others*
  - Basilar migraine
  - TGA
  - TTP
  - Sleep deprivation
  - Situational (i.e. ICU psychosis)
  - Psychiatric (conversion, depression, mania, catatonia)

ICH = Intracranial haemorrhage; ICP = Intracranial pressure; ICU = Intensive care unit; TGA = Transient global amnesia; TTP = Thrombotic thrombocytopaenic purpura.

Table 4: Toxic and Metabolic Causes of Coma and Confusion

Sedatives, hypnotics
- Opiates
- Benzodiazepines, barbiturates, and other sedatives
- Tricyclic anti-depressant agents
- Phenothiazines, butyrophenones

Stimulating exogenous toxins
- Amphetamines, cocaine
- Phencyclidine
- Methylphenidate

Agents causing metabolic acidosis
- Aspirin
- Ethyl alcohol, methanol, ethylene glycol, and other hydrocarbons

Metabolic disorders
- Diabetes mellitus: Hyperglycaemia (diabetic ketoacidosis, hyperosmolar coma), hypoglycaemia
- Thyroid disease (myxoedema, thyroid storm)
- Renal failure (uraemia, dysequilibrium syndrome)
- Electrolyte abnormalities (dehydration and volume contraction, hyponatraemia, hypercalcaemia
- Acid-base disorders
- Hepatic failure: Hyperammonaemia
- Hypoadrenalism
- Hypoxia, hypercarbia
- Hereditary metabolic disorders (i.e. porphyria, carbamoyl-transferase deficiency carrier state)

Withdrawal syndromes
- Alcohol withdrawal
- Benzodiazepine and other sedative withdrawal

Table 5: Approach to the Initial Assessment and Management of Coma

Stabilisation
- Airway control
- Oxygenation and ventilation
- Adequate circulation (includes avoidance of hypotension in stroke)
- Cervical stabilisation

Immediate therapies given to all patients
- Thiamine 100 mg IV
- Dextrose 50%, 50 cc IV (may be held if immediate finger-stick glucose check establishes adequate serum glucose)
- Naloxone 0.4 to 2.0 mg IV (may be repeated)
- Life-threatening conditions to be considered early
- Elevated intracranial pressure: Head CT
- Meningitis, encephalitis, or both: Consider LP, blood cultures
- Myocardial infarction: ECG
- Hypertensive encephalopathy: Early therapy
- Status epilepticus: EEG
- Acute stroke: Consider thrombolytic therapy

IV = Intravenous; CT = Computed tomography; EEG = Electroencephalogram

MANAGEMENT

The approach to the initial assessment and management of patients in coma is depicted in **Table 5**. The specific management depends on the underlying cause. At the time of initial evaluation, it is necessary to assess the ABCs namely, assessing the adequacy of airway; ensuring that the patient's breathing is spontaneous and adequate; and that the circulation to the brain and other organs is adequate.

While carrying out the initial stabilisation and laboratory testing, it is important to treat treatable conditions immediately. Correction of hypoglycaemia and the administration of thiamine can be life saving. Hypoglycaemia suppresses the RAS and leads to a metabolic coma. But this is quickly reversed once the glycaemic levels are restored to normal. It is also important to administer intravenous thiamine to prevent Wernicke's encephalopathy. In the appropriate situation, naloxone for

opiate overdosage or flumazenil for benzodiazepine poisoning, should also be considered.

PROGNOSIS

Coma due to toxic or metabolic causes has a better prognosis than that due to a structural lesion, with the exception that traumatic injury fares better than anoxic injury. In other words, patients who have had cardiac arrest tend to have poorer outcome than patients who had a structural injury secondary to trauma. Clinical signs that are important for prognosis include the motor component of the GCS, the duration of coma (which is really a duration of lack of eye-opening) and other signs of brainstem damage.

Certain electroencephalogram (EEG) patterns are helpful in assessing prognosis in patients with coma. Alpha coma, which looks like a normal alpha rhythm but in an unarousable patient carries a higher mortality rate especially with hypoxic injury or traumatic brain injury. The EEG may be sensitive to external stimuli and may not reflect brainstem function and is influenced by sedative drugs that are routinely used in such patients. Somatosensory evoked potentials can be used for testing the brainstem and are helpful in patients with a traumatic injury or anoxic injury. When measured within 5 to 7 days, bilaterally absent cortical somatosensory evoked potentials are strongly associated with the instance of vegetative state or death. Neuroimaging, especially computed tomography (CT), is useful in differentiating structural lesions but, its overall predictive value is less when compared to electrophysiologic tests or even the clinical examination itself.

In coma due to hypoxic ischaemic injury, patients who have a preserved light reflex, motor response is either flexor or extensor and have spontaneous eye movements have better survival. In head injuries, patients with concussion (defined as a loss of consciousness for less than six hours) and those with a normal CT tend to have a good outcome. When a patient has a loss of consciousness for greater than six hours, axonal shearing or diffuse external injury is likely. Magnetic resonance imaging (MRI) shows changes axonal retraction balls and micro-haemorrhages. Long-term recovery for these patients is very variable. Cognitive deficits, motor and behavioural dysfunction persist, and these patients tend to do poorly as far as functional recovery goes.

3.1 Conventional Radiology

Ashu Seith Bhalla, Ankur Gadodia

INTRODUCTION

Since the discovery of X-rays by Roentgen in 1895, conventional radiology has played a vital role in the diagnosis and management of patients affected by various diseases. Newer imaging techniques, such as ultrasound, computed tomography and magnetic resonance imaging, have reduced the role of conventional radiographs in several clinical scenarios. However, conventional radiology still remains of great value, particularly in diseases of chest, musculoskeletal system, contrast studies of gastrointestinal tract and fistulograms. This is owing to simplicity of the procedure, low cost, easy reproducibility and low radiation dose. Advent of digital radiography has further enhanced the quality and reproducibility of the conventional radiographs. The spectrum of the imaging findings of various pathologies is vast and a full discussion of the same is beyond the scope of this chapter. Hence, a brief summary of the present role of conventional radiology and approach to common diseases classified on an organ system basis is discussed below.

CHEST RADIOLOGY

Chest radiograph is one of the most frequently performed radiological examination constituting about 50% to 60% of the workload of any hospital or imaging centre. The standard chest radiograph is an erect posteroanterior (PA) projection (**Figure 1**). Additional radiographic views and their role is summarised in **Table 1**. Normally there are five different densities, in any radiograph lungs, bones, soft-tissues like heart and diaphragm, fat and muscles. Because of the difference in the coefficient of absorption of the X-rays which depends on the atomic number of the elements and density of the tissues, lungs appear black, bones appear white and soft-tissues have an intermediate density. A schematic approach to analysis of the chest radiograph is given in **Table 2**.

Figure 1: Normal chest radiograph (posteroanterior PA view).

Table 1: Additional Chest Radiographic Views and Their Role

Projection	Role
Lordotic projection	Middle lobe collapse/consolidation, apical opacity obscured by clavicle
Lateral decubitus	Small pleural effusion
Lateral	Localise mediastinal masses, posterior basal consolidation
Expiratory films	Air trapping, small pneumothorax
Anteroposterior	Sick recumbent patient intensive care unit (ICU patients)

Table 2: Suggested Scheme for Viewing the PA Radiograph

Patient information sheet
Technical assessment: Centring, inspiration, exposure
Mediastinum: Trachea, aorta, pulmonary arteries, superior vena cava
Lungs: Lucency, localised/generalised abnormalities, hidden areas
Heart: Position, size, configuration
Hila: Density, shape, position
Bones and soft tissues
Diaphragm: Position, outline
Pleural space

Important Signs in Chest Radiology

1. Silhouette sign

Described by Felson and states that "An intra-thoracic radio-opacity, if in anatomic contact with a border of heart or aorta, will obscure that border. An intra-thoracic lesion not anatomically contiguous with a border or a normal structure will not obliterate that border". This sign is useful in detection and localisation of mediastinal and pulmonary diseases. For example, right middle lobe pathology will obliterate the right heart border (**Figure 2**).

2. Hilum overlay sign

Described by Felson and helps in distinguishing enlarged heart from anterior mediastinal mass. Hilum is seen through the mediastinal mass, whereas with enlarged heart, the hilum is displaced laterally. If the bifurcation of the main pulmonary artery is >1.25 cm medial to the lateral border of the cardiac Silhouette, it is suggestive of a mediastinal mass. If the pulmonary artery arises from the lateral heart border, this favours an enlarged heart.

3. *Air-bronchogram*

Branching, tubular air lucency representing a bronchus or bronchiole passing through airless lung parenchyma produces air bronchogram and is seen in lung disease unlike pleural/mediastinal disease (**Figure 3**).

Figure 2: Silhouette sign. Chest radiograph (PA view) showing lingular lobe consolidation silhouetting the left cardiac border. Diaphragm is not silhouetted by the consolidation.

Figure 3: Air-bronchogram in a patient with pulmonary oedema. Chest radiograph (PA view) demonstrates air within the bronchial tree visible due to surrounding airless lung parenchyma.

Pattern Recognition in Chest Radiology

Felson popularised a pattern recognition approach to lung lesions on the basis of classifying them as either alveolar or interstitial. Important features and causes of the alveolar or interstitial lesions are described in **Table 3**.

Atelectasis/Lung Collapse

Collapse is defined as partial or complete loss of the lung volume. Radiographic appearance depends on degree and mechanism of collapse. Signs of collapse may be considered as direct or indirect (**Table 4**).

Table 3: Features and Aetiology of Basic Lung Patterns as Seen on Chest Radiograph

Patterns	Features	Causes
Airspace/ Alveolar pattern (**Figure 4A**)	Poorly defined nodular lesions (4-10 mm) Coalescence Air-bronchogram	Pulmonary oedema Exudate (pneumonia) Pulmonary haemorrhage Malignancy (bronchioalveolar carcinoma, lymphoma) Aspiration
Interstitial (**Figure 4B**)	Reticular Nodular (well-defined, homogeneous and variable sized) Reticulo-nodular	Interstitial lung disease, e.g. Sarcoidosis Miliary tuberculosis Pneumoconiosis

Figure 4A: Air space (alveolar) pattern. Chest radiograph (PA view) shows homogeneous opacity in left lower zone with ill-defined margins of diaphragm see 4B.

Pulmonary Disease

Infections

Pneumonia: Pneumonia is one of the most frequent causes of morbidity and mortality, and chest radiograph plays an important role in the detection and management of patients with pneumonia. The term lobar pneumonia refers to infection that predominantly involves the alveolar space and thus, produces uniform homogeneous opacification of partial or complete segments of lung and occasionally an entire lobe.

Bronchopneumonia is usually multifocal and infection is centered in distal bronchioles. Radiologically, broncho-pneumonia is characterised by bilateral heterogeneous, scattered alveolar opacities. An air bronchogram is usually absent. *Streptococcus pneumoniae* (common cause of community-acquired pneumonia) causes lobar pneumonia whereas *Staphylococcus aureus* and Gram-negative organisms (causes nosocomial infection) produce bronchopneumonic pattern. *Klebsiella pneumoniae* and *Streptococcus pneumoniae* cause lobar pneumonia with bulging fissures. Round pneumonia is cause by *S. pneumoniae* and *S. aureus*. Viral pneumonia is common in infants and children but unusual in adults and produces interstitial pattern on chest radiographs.

Table 4: Signs of Lung Collapse (Figure 5)

Direct Signs	Indirect Signs
Displacement of interlobar fissure	Elevation of hemidiaphragm
Loss of aeration	Mediastinal displacement
Crowding of vessels and bronchi	Hilar displacement
	Compensatory overinflation

Figure 4B: Interstitial pattern. Chest radiograph (PA view) demonstrates coarse reticulonodular opacities in bilateral lung fields.

Pulmonary tuberculosis: The radiological features in pulmonary tuberculosis have been divided into primary and post-primary or reactivation TB.

Primary tuberculosis: Primary TB has two components: parenchymal lesion and extension of the lesion to the lymph nodes. Enlarged hilar or mediastinal nodes (right paratracheal, subcarinal and aorto-pulmonary window) are the radiological hallmark of this form. It may heal completely or leave a calcified focus. Atelectasis of a lobe or a segment is a frequent finding.

Post-primary tuberculosis: Most common sites are apical and posterior segments of the upper lobes and superior segments of lower lobe. Parenchymal lesions are the hallmark of this form

Figure 5: Left lower lobe collapse in a 20-year-old male. Chest radiograph (PA view) demonstrates wedge-shaped left retrocardiac opacity (arrow) with hyperinflation of the left lung.

of TB (ill-defined patchy opacities, linear striations, subsequently nodular and reticular appearance due to fibrosis). Single or multiple thick-walled cavities are the hallmark of active TB. Bronchiectasis and bronchostenosis are commonly seen in post-primary tuberculosis occur due to cicatrisation and fibrosis. Broncho-stenosis can produce persistent lobar or segmental collapse or obstructive emphysema or consolidation. Pleural effusion is usually small and loculated. Radiological findings in primary TB are detailed in **Table 5**.

Table 5: Radiological Features of Primary and Post-primary Tuberculosis

Primary Tuberculosis	Post-primary Tuberculosis
Parenchymal consolidation	Local exudative lesion
Lymphadenopathy (**Figure 6A**)	Local fibroproductive lesion
Miliary tuberculosis (**Figure 6B**)	Tuberculoma
Tuberculoma	Cavitation
Airway involvement	Bronchogenic spread
Pleural effusion	Miliary tuberculosis (**Figure 6B**)
	Bronchostenosis
	Pleural disease

Bronchogenic carcinoma

Bronchogenic carcinoma produces a wide range of radiological appearances depending on histology (small cell vs non-small cell), location (central vs peripheral) and stage of the disease (**Figures 7A and B**). Usually peripheral bronchogenic carcinoma is seen as an intrapulmonary mass. This may be quite small, an incidental finding on chest radiograph (solitary pulmonary nodule) and poses a diagnostic challenge to the clinician and radiologist. Features that indicate malignancy include: size more than 4 cm; thick-walled (≥16 mm) cavity; associated hilar mass and lobulated, umblicated or shaggy outline (sunburst appearance). Plain radiographs have tremendous limitation in

Figure 6A: Primary tuberculosis in a 12-year-old female. Chest radiograph (PA view) demonstrates right hilar and paratracheal adenopathy.

Figure 6B: Miliary tuberculosis in a 24-year-old male. Chest radiograph (PA view) shows miliary nodules (1-3 mm) involving bilateral lung fields.

detecting early manifestations of malignancy and lesions less than 5 mm are not visualised on conventional radiographs. Massive hilar or mediastinal adenopathy without lung lesion is seen in small cell carcinoma whereas bronchioloalveolar carcinoma presents as solitary spiculated mass or as bilateral, multiple ill-defined opacities resembling pneumonia.

Hilar Diseases

Hilum as seen on chest radiograph comprises of proximal pulmonary artery, major bronchi, pulmonary veins and lymph nodes (**Figure 1**). Lymph nodes are not visualised unless

Figure 7A: Peripheral bronchogenic carcinoma in a 72-year-old male smoker. Chest radiograph (PA view) shows ill-defined spiculated mass in the right upper zone with destruction of anterior end of right 2nd and 3rd ribs.

Figure 7B: Central bronchogenic carcinoma with lung collapse in a 60-year-old male. Chest radiograph (PA view) shows ill-defined spiculated left hilar mass with collapse of the left upper lobe.

enlarged. Hilar enlargement can be due to lymphadenopathy (**Figure 8**) or dilated pulmonary artery. Differential diagnosis of unilateral and bilateral hilar enlargement is mentioned in **Table 6**.

Table 6: Differential Diagnosis of Hilar Enlargement

Unilateral Hilar Enlargement	Bilateral Hilar Enlargement
Lymphadenopathy	Sarcoidosis (**Figure 8**)
Infective (TB, Histoplasma, Mycoplasma)	Lymphoma
Carcinoma lung	Lymphangitis carcinomatosis
Lymphoma	Infective (TB, Histoplasma)
Pulmonary artery	Pulmonary artery dilatation
Pulmonary embolus	Pneumoconiosis (Silicosis)
Aneurysm	
Post-stenotic dilatation	

Figure 8: Sarcoidosis in a 30-year-old female. Chest radiograph (PA view) demonstrates bilateral hilar and right paratracheal adenopathy. Lung fields are normal.

Pleural Diseases

Pleural effusion

Pleural effusion is one of the most common abnormalities of the pleura. The radiographic appearances depend on the quantity of the fluid and posture of the patient. A minimum 75 mL of fluid is required to see the fluid above the dome of diaphragm on the lateral view; and a minimum of 175 mL is needed to obliterate costophrenic angle in upright erect film. Lateral decubitus radiograph can detect 10 to 20 mL of fluid.

Pleural effusion produces a homogeneous opacity with concave border facing the hilum producing characteristic meniscus sign. The upper margin of the opacity extends higher laterally than medially (**Figure 9**). Massive fluid obliterates the hemidiaphragm and cardiac border. Further increase in fluid produces shift of the heart and mediastinum, and even inversion of the hemidiaphragm. Supine radiographs are less sensitive in demonstrating pleural effusion and the signs on a supine radiograph are a veil-like opacity over the lung with well preserved vascular shadows; loss of outline of the ipsilateral hemidiaphragm; blunting of the costophrenic angle; clear demarcation of the lateral lung margin from the chest wall; widening of the paraspinal soft tissues; apparent elevation of the hemidiaphragm and poor visibility of the vessels behind the diaphragm. Absence of air-bronchogram and visualisation of the vessels differentiates pleural effusion from pulmonary oedema and massive pneumonia.

Figure 9: Pleural effusion in a 16-year-old male. Chest radiograph (PA view) demonstrates right pleural effusion. Note the upper margin of the opacity is concave and extends higher laterally than medially.

Pneumothorax

Pneumothorax is defined as the presence of air between parietal and visceral pleura. Radiological features include increased translucency with no intervening vessels, and underlying lung margin demarcated by visceral pleura (**Figure 10**). A small pneumothorax is best seen on expiratory film. Inner margin is usually convex as compared to cysts, bulla or cavities which have concave margin towards the chest wall. Pneumothorax in supine film may show any of these signs; relative translucency, increased sharpness of the adjacent diaphragm or mediastinum, deep and tongue-like costophrenic sulci, depression of the ipsilateral diaphragm and simultaneous visualisation of anterior sulcus and dome of diaphragm.

Mediastinal Diseases

A mediastinal mass has its base towards mediastinum, well-defined margins and produces an obtuse angle with the mediastinum. Air-bronchogram is absent. Boundaries of the mediastinum are shown in **Figure 11** and common differential diagnosis in **Table 7**.

Table 7: Differential Diagnosis of Mediastinal Masses

Anterior	Middle	Posterior
Lymphadenopathy (Lymphoma, TB)	Lymphadenopathy	Neurogenic tumour
	Carcinoma bronchus	Paravertebral abscess
Germ cell tumours	Aortic aneurysm	Dilated oesophagus (Achalasia)
Thymoma	Bronchogenic cyst	

Figure 10: Pneumothorax in a 40-year-old male. Chest radiograph (PA view) shows increased right lung translucency with underlying lung margin demarcated by visceral pleura (arrow).

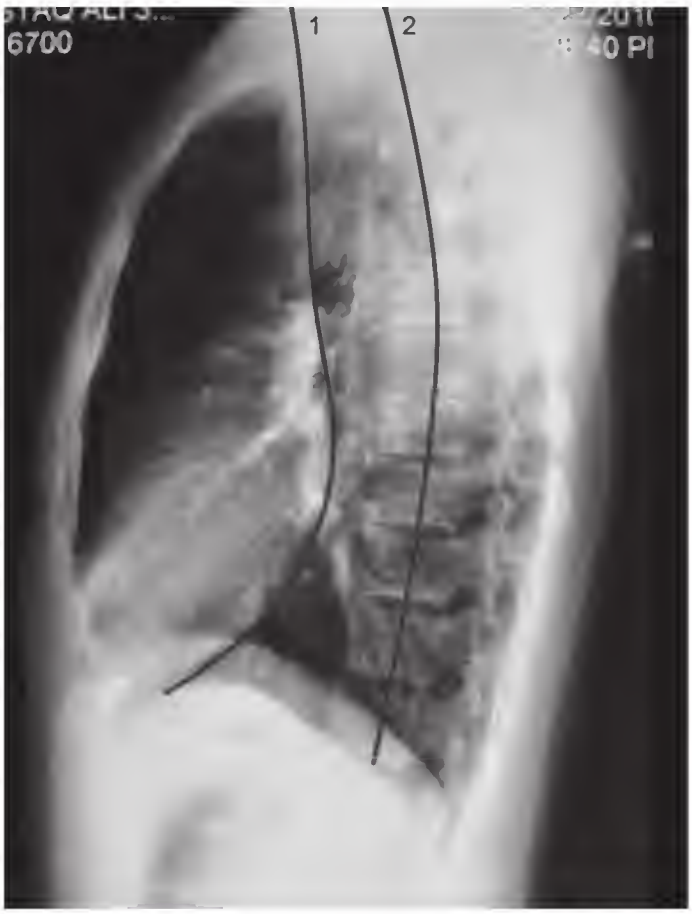

Figure 11: Demarcation of the mediastinum. Line 1 extends along the back of the heart and along anterior margin of the trachea. Line 2 connects a point 1 cm behind the anterior margin of the body of the dorsal vertebrae. Mediastinum anterior to line 1 is anterior mediastinum, between lines 1 and 2 is middle and posterior to line 2 is posterior mediastinum.

CARDIOVASCULAR SYSTEM

Conventional cardiac radiology is supplemented by 2D echo, cardiac CT, catheter angiography or MRI. However, chest radiographs are extremely valuable in demonstration of the cardiac size, contour (individual chambers) and pulmonary vascularity. Chest radiographs are also commonly used to follow the progress of a disease and its treatment. The following five points help in the diagnosis of the acquired or congenital cardiac conditions. These are cardiac size, pulmonary conus, left atrium, aortic knuckle and pulmonary vasculature. Meticulous analysis of the above points gives some indication of the cardiac abnormality in 60% to 65% cases.

The demonstration of the abdominal aorta and its branches was usually done by digital subtraction angiography done through transfemoral route. However now-a-days vascular tree, either arterial or venous is well demonstrated either by CT angiography or MR angiography.

GASTROINTESTINAL SYSTEM

Plain Radiograph

Plain abdominal radiographs are still commonly performed in the clinical setting of acute abdomen or renal colic. A supine abdomen and an erect chest can be regarded as the basic standard radiographs in the work-up of acute abdomen. The erect chest radiograph is superior to the erect abdominal view for the demonstration of pneumoperitoneum (**Figure 12**).

Three to five fluid levels less than 2.5 cm in length may be normally seen in an erect abdominal radiograph, particularly in the right lower quadrant. However, more than two fluid levels in a dilated small bowel (calibre greater than 2.5 cm) are said to be abnormal, and usually indicate paralytic ileus or intestinal

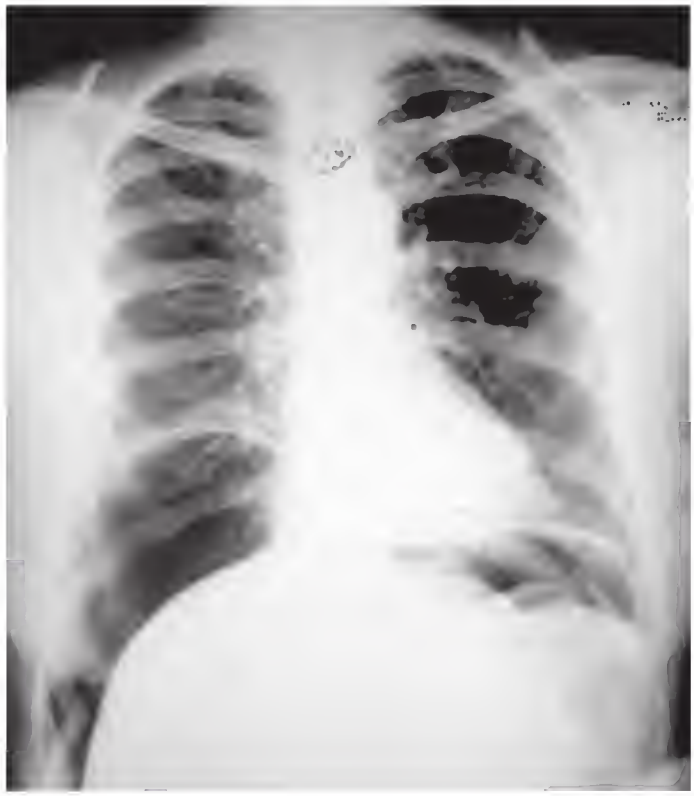

Figure 12: Pneumoperitoneum in a 40-year-old male resulting from perforation of a duodenal ulcer. Chest radiograph (PA view) demonstrates gas under both domes of diaphragm.

obstruction. Demonstration of a zone of transition between dilated and normal/collapsed small bowel is an indicator of mechanical obstruction. Occasionally, plain radiographs can also diagnose the cause of bowel obstruction, like obstructed inguinal hernia, sigmoid volvulus, etc.

Contrast Studies of the Gastrointestinal Tract

The emergence of cross-sectional imaging techniques had a dramatic impact on the imaging of gastrointestinal tract. However, a contrast examination still remains a valuable diagnostic test for evaluating the luminal and subtle mucosal pathologies of the intestinal tract. Barium sulphate, an inert contrast agent comes in a variety of suspensions designed for specific examinations depending on their density and viscosity.

Barium Examinations (Table 8)

1. *Barium swallow:* Barium swallow is the technique of choice for symptoms of the dysphagia, odynophagia, atypical chest pain and gastro-oesophageal reflux. Barium swallow is complementary to endoscopy for oesophagitis and tumours.
2. *Barium meal:* Barium meal is rarely performed with the advent of endoscopy. Barium studies are complementary to endoscopy for most cases of dyspepsia and abdominal pain (peptic ulcer and malignancy). However, they are superior to endoscopy for evaluation of the functional anomalies and submucosal lesions.
3. *Small bowel follow-through:* Indicated in subacute intestinal obstruction, chronic obstruction and inflammatory bowel disease.
4. *Barium enema:* It is used for evaluation of the colonic pathologies. Double contrast study is superior to single contrast for detection of small polypoidal lesions and small ulcerations.
5. *Enteroclysis:* It equires initial placement of a tube in the proximal jejunum prior to barium infusion (**Figure 13**). Enteroclysis is preferred for evaluating subtle mucosal abnormalities, focal small-bowel lesions or to determine the cause of small-bowel obstruction.

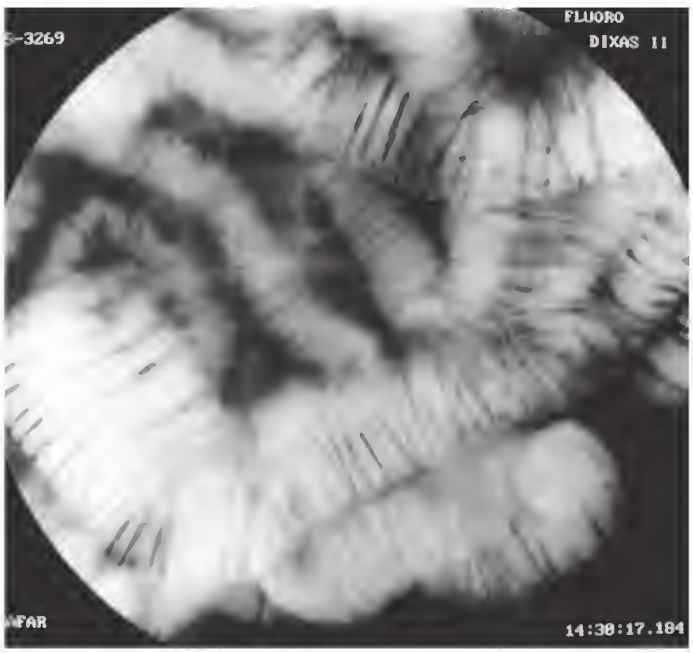

Figure 13: Normal enteroclysis.

Table 8: Contrast Studies of Gastrointestinal Tract: Organs Evaluated and Common Clinical Indications

Contrast Study	Organs Evaluated	Common Clinical Indications
Barium swallow	Oral cavity up to fundus of stomach	Dysphagia, motility disorder (achalasia), carcinoma oesophagus, hiatus hernia, extrinsic compression/ displacement
Barium UGI study	Oesophagus, stomach and duodenum, (single or double contrast techniques)	Epigastric pain, dyspepsia, heart burn, unexplained weight loss, anaemia
Barium meal follow through	Stomach to ileocaecal junction	Tuberculosis, Crohn's disease (**Figure 14**), neoplasm, radiation enteritis, diarrhoea, anaemia/gastrointestinal bleed, partial obstruction
Enteroclysis	Duodenojejunal flexure to ileocaecal junction	Partial small bowel obstruction Crohn's disease-extent, Meckel's diverticulum, malabsorption, tumours of small intestine, occult gastrointestinal bleed
Single contrast barium enema	Colon	Colon obstruction, intussusceptions, fistula, uncooperative/ debilitated patients
Double contrast barium enema	Permits visualisation of mucosal detail	Inflammatory bowel disease (**Figure 15**), polyp

Barium is contraindicated in suspected perforation (causes peritonitis or mediastinitis). Suspected perforation is an indication for use of a water-soluble agent. Post-operative oral

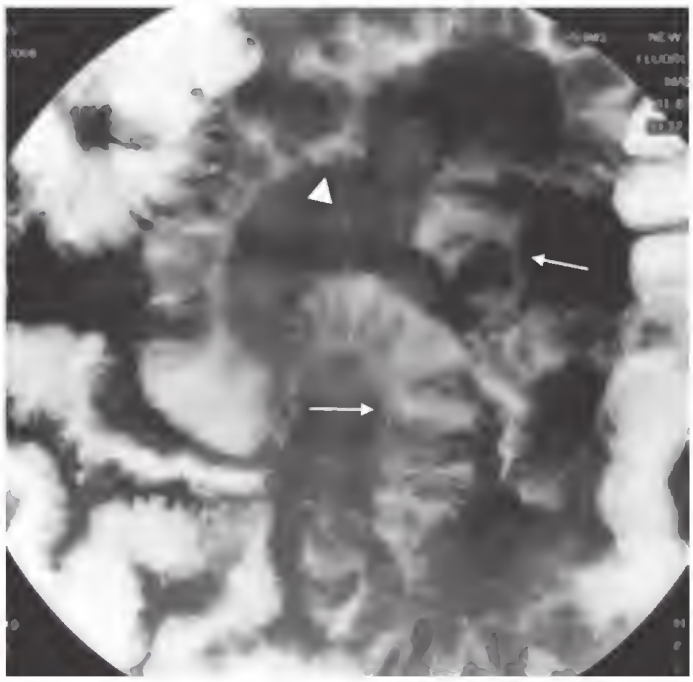

Figure 14: Crohn's disease in a 36-year-old male. Barium meal follow-through shows pseudosacculation involving the jejunum (arrow), longitudinal ulceration involving the mesenteric border (arrowhead).

Figure 15: Ulcerative colitis in a 30-year-old female. Barium enema shows granular mucosal pattern and loss of haustration involving the entire colon.

contrast studies are also done with water soluble agents to look for suspected leaks and patency of anastomosis.

Pattern Recognition in Gastrointestinal Radiology

Following a pattern approach on barium studies facilitates diagnosis of wide spectrum of diseases affecting the alimentary canal (**Table 9**).

Table 9: Features of Basic Patterns as Seen on Contrast Studies of Gastrointestinal Tract

Patterns	Features
Benign stricture	Smooth tapering margin at both ends
Malignant stricture	Irregular, abrupt narrowing, apple core appearance, shouldering at one/ both ends
Extrinsic mass	Intact mucosa, displaced lumen, obtuse angle with luminal surface
Intramural (Submucosal) mass	Intact mucosa, right angle with luminal surface
Mucosal mass	Irregular mucosa with ulcerations, acute angle with luminal surface

Distinction between Small- and Large-bowel Dilatation (Figures 16 and 17)

When a radiograph shows dilated bowel, it is important to determine whether it is small- or large-bowel, or both (**Table 10**).

Table 10: Distinguishing Features between Small- and Large-bowel Obstruction

	Small-bowel Obstruction	Large-bowel Obstruction
Number of loops	More	Less
Distribution of dilated loops	Central	Peripheral
Haustra	Absent	Present
Valvulae conniventes	Seen in jejunum	Absent
Diameter	3-5 cm	≥ 5 cm

Ileocaecal (IC) Tuberculosis

IC TB is the most common form of alimentary tract TB (**Figure 18**). Imaging features of ileocaecal TB are tabulated in **Table 11.**

Figures 16A and B: Small bowel obstruction: Supine (A) and erect (B) radiographs show dilated multiple bowel loops having central position and valvulae conniventes suggestive of small-bowel obstruction. Erect radiograph demonstrates multiple air-fluid levels.

Figure 17: Large-bowel obstruction in a 70-year-old male. Supine radiograph demonstrates gas filled distended large-bowel and caecum. Small-bowel is not dilated due to competent IC valve.

Table 11: Findings of Ileocaecal (IC) Tuberculosis on Barium Examination

Spasm and hypermobility with oedema of the ileocaecal valve
Thickening of an incompetent IC valve with narrowing of terminal ileum (Fleischner sign)
Shallow ulceration
Napkin ring stenoses with a conical, shrunken caecum
Widely open IC valve with fixed and narrowed terminal ileum (Stierlin's sign)
Altered angle of entry of IC junction
Contracted, pulled-up caecum
Skip areas of concentric mural thickening with luminal narrowing in rest of bowel

HEPATOBILIARY SYSTEM

Conventional radiology has no role in the diagnosis of gall-bladder disease. Oral cholecystography has been replaced by ultrasonography, CT and MRI. In liver diseases, ultrasonography, CT, MRI are used to detect focal and diffuse liver diseases. In pancreatic diseases, plain radiograph of abdomen is useful only to demonstrate pancreatic calcification in chronic pancreatitis, but this is also better done using CT. CT, transabdominal and endoluminal ultrasound are most useful in imaging pancreatic pathology and have virtually replaced conventional radiological techniques. Magnetic resonance cholangiopancreaticography shows intra- and extra-hepatic biliary radicals and pancreatic duct and produces images analogous to Endoscopic retrograde cholangiopancreatography ERCP. In majority of cases, ERCP is done for therapeutic purposes only. Similarly percutaneous trans-hepatic cholangiography is no longer used in the diagnosis of biliary obstruction and is used only as a prelude to percutaneous transhepatic biliary drainage.

Figure 18: IC tuberculosis in a 22-year-old male. Barium meal follow-through shows narrowing involving the terminal ileum and IC junction, obtuse angle of entry, contracted caecum and dilatation of terminal ileum.

MUSCULOSKELETAL SYSTEM

Bone and joint radiographs require systematic analysis of bone density, alignment, cortex, medulla, joint space, soft tissue and calcification, and periosteal reaction. The skeletal system may be involved in local (infection, primary tumours) and systemic diseases (endocrine, metabolic marrow pathology, metastatic disease).

Metabolic/Endocrine Disease

Endocrine disorders, such as osteoporosis, osteomalacia, hyperparathyroidism, acromegaly, hyper- or hypo-thyroidism, Cushing's syndrome, pseudohypoparathyroidism, and haemoglobinopathies require skeletal survey. Diseases like hyperparathyroidism and congenital hypothyroidism produce classical radiological changes depending upon the severity. For detection of osteoporosis, bone mineral density by DEXA is the 'gold standard'. Osteomalacia is distinguished from osteoporosis by the presence of looser's zones or insufficiency fractures. Radiological features of common endocrine and metabolic diseases are mentioned in **Table 12**.

Avascular necrosis of the head of femur and other sites is known to occur in steroid therapy, Cushing's syndrome, atherosclerosis, pancreatitis, fat embolism, alcoholism, collagen vascular disease, Caisson's disease, Gaucher's disease and radiation therapy. Radiographs can detect avascular necrosis only late in the course of disease and MRI is the modality of choice for early diagnosis.

Primary Bone Tumours

Broadly bone tumours can be divided into two groups: benign and malignant. Malignant tumours can be primary or secondary (metastatic). Radiographs are the primary imaging modality in diagnosis and characterisation of bone tumours. The

radiographic features that help in characterisation of bone tumours are: site of the lesion (location in the skeleton and in the individual bone); borders (also known as zone of transition); matrix mineralisation (composition of the tumour tissue); pattern of bone destruction (geographic, moth-eaten or permeative); periosteal reaction; adjacent soft tissue, cortical integrity; and multiplicity of the lesions. Benign tumours usually produce well-defined, geographic lytic lesion with sclerotic borders, narrow zone of transition, uninterrupted/solid periosteal reaction, and no soft-tissue mass, whereas malignant lesions demonstrate ill-defined, permeative lytic lesion with wide zone of transition, interrupted periosteal reaction (sunburst/onion skin/Codman triangle) and large soft tissue component.

Table 12: Radiological Features of Common Endocrine and Metabolic Diseases

Osteoporosis	Osteopaenia (prominent in areas of the skeleton rich in trabecular bone, especially in the axial skeleton (vertebrae, pelvis, ribs and sternum) Low-trauma fractures (vertebrae, the distal forearm and the proximal femur)
Hyperparathyroidism (**Figures 19A to C**)	Subperiosteal erosions (radial aspects of the middle phalanges of the index and middle fingers, outer ends of clavicle, symphysis pubis, sacroiliac joints) Intracortical bone resorption Chondrocalcinosis Brown tumours Osteosclerosis (seen in HPT secondary to chronic renal impairment) Metastatic calcification
Rickets (**Figures 20A and B**)	Widening of the growth plate Cupping of the metaphysis Rachitic rosary (expansion of the anterior ends of the ribs) Deformities (genu valgum/varum, coxa vara, Harrison's sulcus, protrusio acetabuli and tri-radiate deformity of the pelvis)
Osteomalacia (**Figure 21**)	Osteopaenia Looser's zones or pseudo-fractures (medial aspect of femoral neck, pubic rami, lateral border of scapula and ribs)
Cushing's disease	Osteoporosis Low-trauma fractures Exuberant callus formation Avascular necrosis of hip

Skeletal Metastasis/Myeloma

Skeletal metastases can be detected by skeletal survey and sensitivity of conventional radiographs in the detection of secondaries in skeletal system is about 60% to 70%. Isotope scanning (99mTc-methyl diphosphonate) is more sensitive but not specific. Osseous secondaries can be osteolytic or osteoblastic. Majority of these are osteolytic; osteoblastic lesions (**Figures 22A and B**) are mainly seen in the carcinoma of the prostate in male and breast malignancy in female. Multiple myeloma produces widespread involvement of the bones having osteopaenia, punched out osteolytic lesions, endosteal scalloping with sparing of the posterior elements and pedicles (Differential diagnosis secondary deposits). The usual sites are spine, skull, ribs, pelvis, long tubular bones and distal ends of the clavicles.

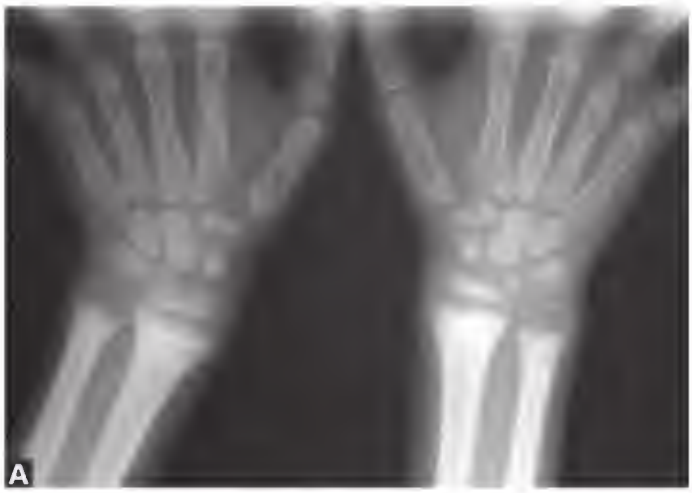

Figure 19A: Primary hyperparathyroidism in a 34-year-old male. Radiograph of hand shows subperiosteal resorption involving the radial margins of the proximal and middle phalanges.

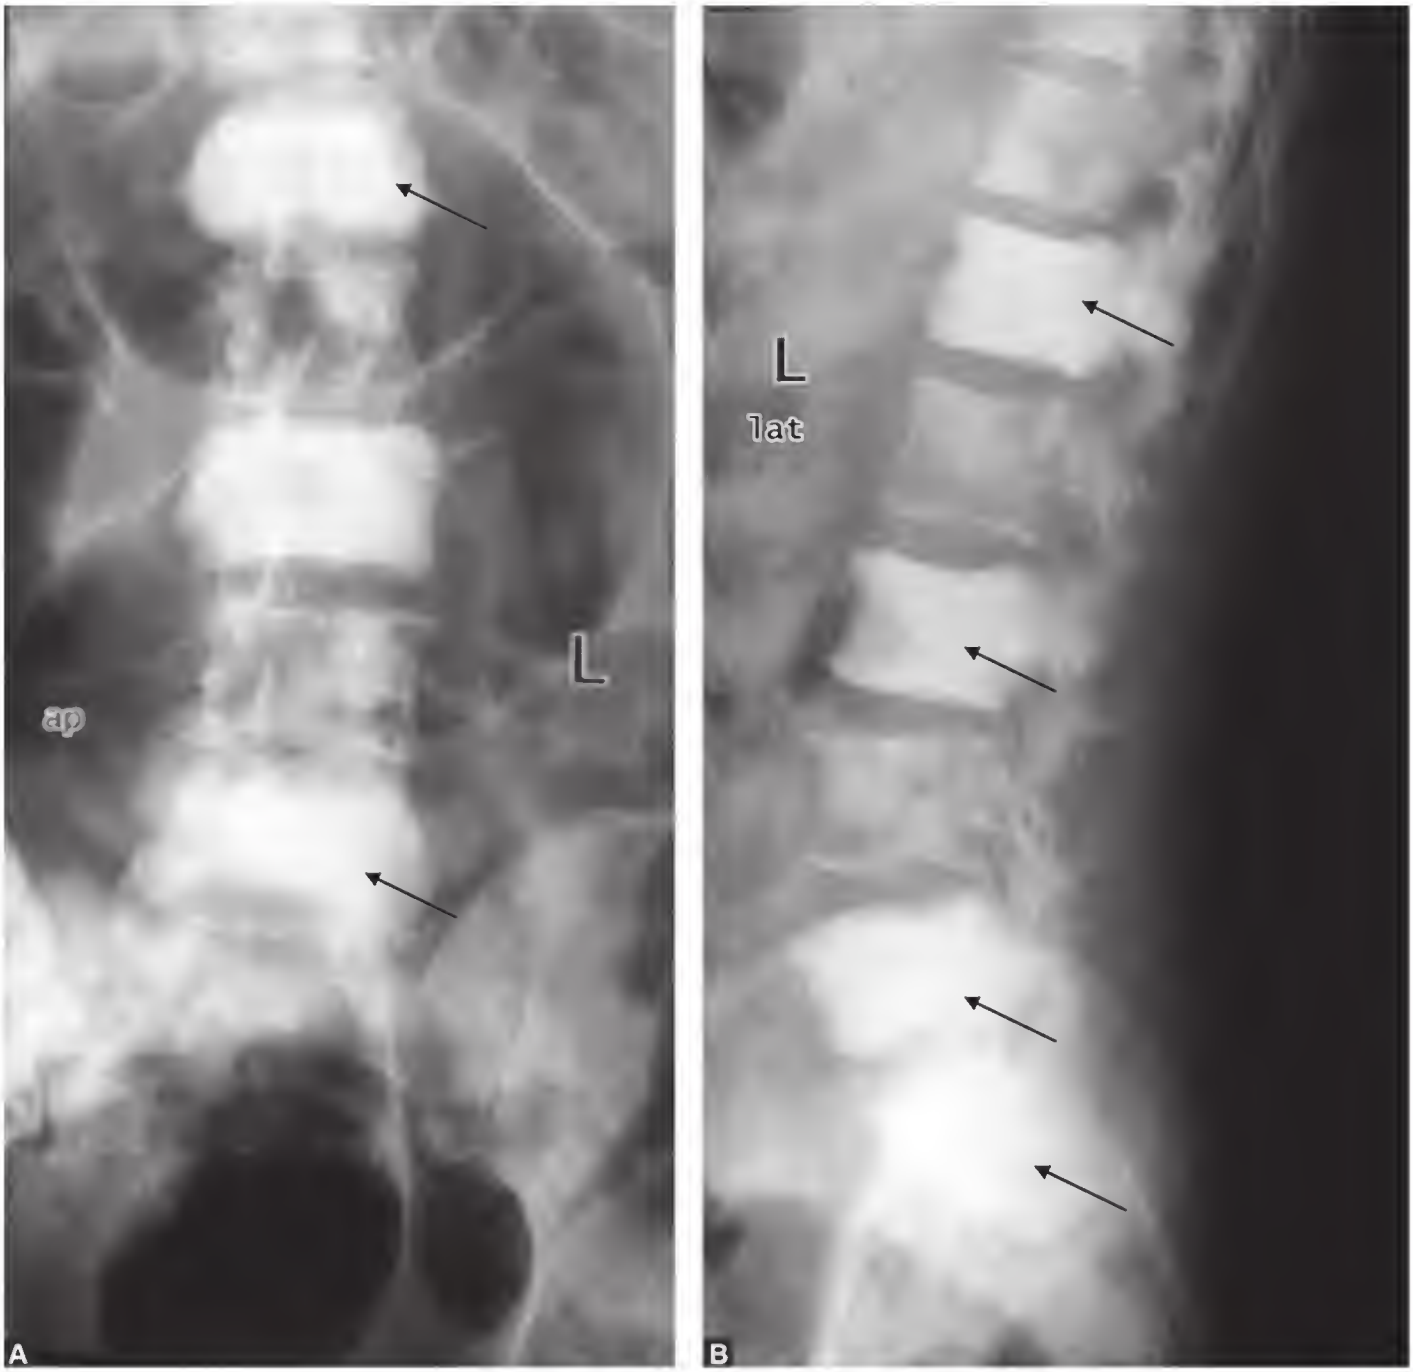
Figure 19B: Radiograph of left hand demonstrates subperiosteal resorption of the proximal and middle phalanx and expansile lytic lesion (brown tumour) involving the middle phalanx of the 4th digit.

Figure 19C: Lateral skull radiograph demonstrates granular texture of the bone (salt and pepper pot appearance) with loss of definition of the both inner and outer table.

Figures 20A and B: Rickets in a 4-year-old male child. (A) Radiograph of bilateral wrist demonstrates diffuse osteopaenia. Growth plate of bilateral radius is widened with metaphyseal cupping, fraying and splaying. (B) Chest radiograph shows widening of the costochondral junction of the ribs suggestive of rachitic rosary.

Figure 21: Osteomalacia in a 48-year-old female. Radiograph of pelvis shows reduced bone density and fuzzy trabecular pattern. Note the presence of Looser's zone (pseudo fracture) involving bilateral pubic rami (arrows).

Arthritis



In rheumatoid arthritis small joints (metacarpophalangeal, metatarsophalangeal and interphalangeal joints) are involved. Imaging features include soft tissue swelling, regional/diffuse osteopaenia, joint space narrowing, central or marginal erosions, subluxation and deformities. In osteoarthritis, predominant features are asymmetrical joint space narrowing, osteophytes, subarticular sclerosis with cystic areas. In ankylosing spondylitis, involvement of the bilateral sacroiliac joint is paramount with ligamentous calcification (paraspinal as well as interspinous ligaments). Disorganised joints, marked sclerosis, subluxation and new bone formation are the classical features of neuropathic joints which occur in syringomyelia, spinal dysraphism, diabetes, leprosy and syphilis.

Osteomyelitis

Osteomyelitis can generally be divided into pyogenic and non-pyogenic types. Radiographs are normal during the initial stage of osteomyelitis and contrast enhanced MRI is the investigation of choice. Later, radiograph demonstrates soft-tissue oedema, loss of fascial planes, osteopaenia, metaphyseal lytic lesion and fluffy periosteal reaction. In infants and adults metaphyseal involvement with epiphyseal extension occurs, whereas in children older than 18 months, metaphyseal involvement predominates. Chronic osteomyelitis on radiograph demonstrates dense involucrum (sheath of periosteal new bone), sequestrum (dead bone), and cloaca (sinus tract). Brodie's abscess caused by *Staphylococcus aureus* is a well-demarcated metaphyseal elongated lytic lesion surrounded by reactive sclerosis.

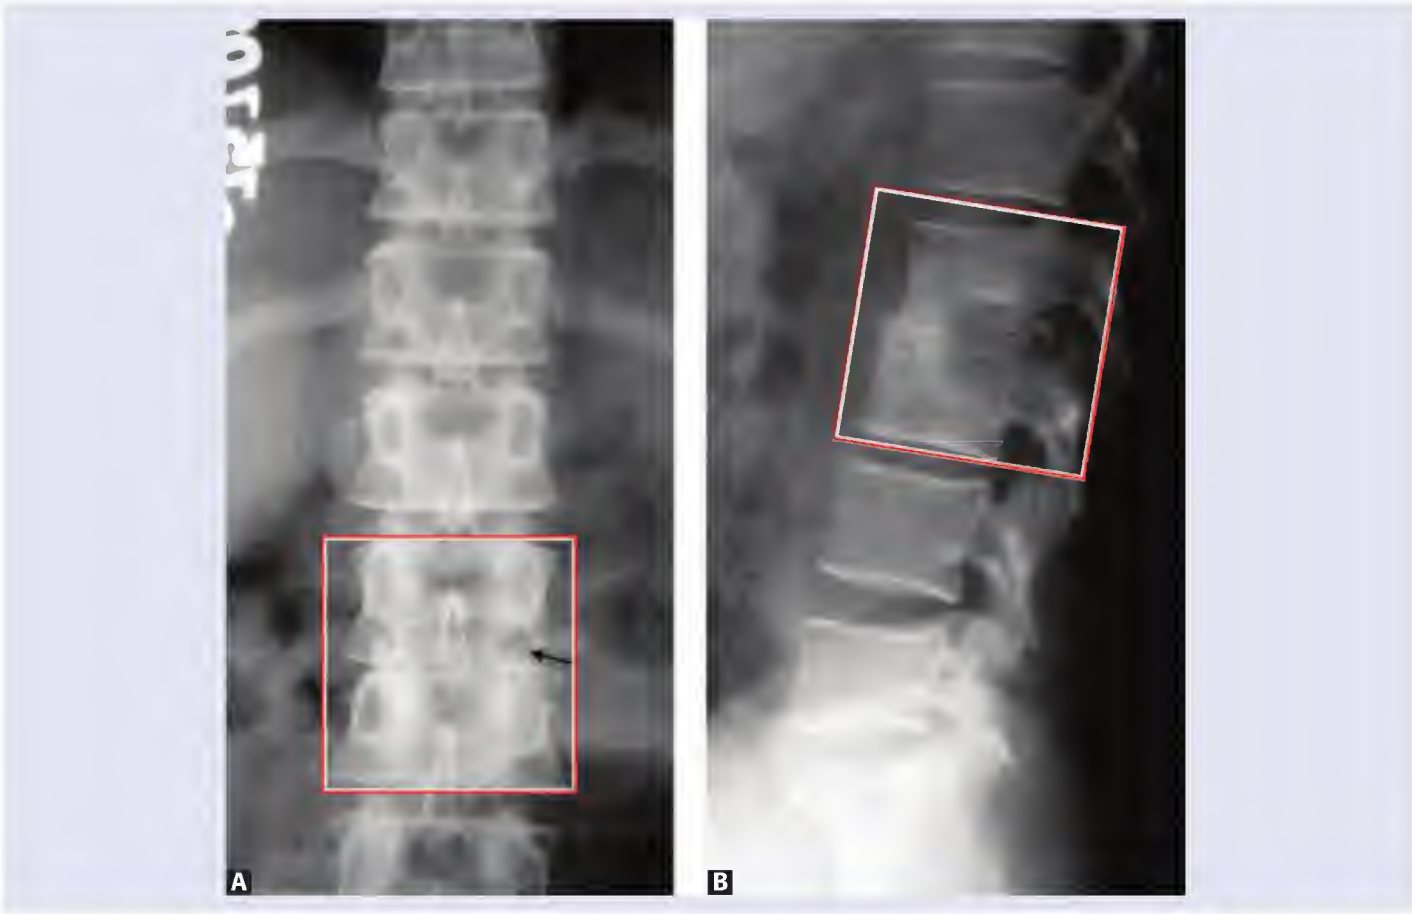
Musculoskeletal Tuberculosis

Musculoskeletal TB accounts for about 1% to 3% of cases of TB (**Table 13**). TB of the spine is the most common form and accounts for approximately 50% of cases. Extra-spinal manifestations are less common. Tuberculous spondylodiscitis has classical appearance of narrowing of the disc with irregularities of the opposing vertebral endplates and paravertebral abscesses (**Figures 23A and B**).

Figures 22A and B: Sclerotic skeletal metastasis in a 72-year-old male with carcinoma prostate. Radiographs of anteroposterior view (A) and lateral view (B) demonstrate sclerosis seen involving the L1, L3, L5 vertebrae and iliac bone.

Table 13: Imaging Features of Musculoskeletal Tuberculosis

Patterns of Involvement	Common Bones/ Joints Involved	Imaging Features
Tuberculous arthritis	Mono-articular involvement (hip and knee–most common)	Narrowing of joint space Peripherally located erosions Juxta-articular osteopaenia
Tuberculous osteomyelitis	Small bones of hand and feet–most common	Poorly defined lytic lesion Periostitis
Tuberculous spondylitis	Upper lumbar/lower thoracic vertebra with involvement of two contiguous vertebrae	Reduction of intervertebral disc spaces End plate irregularities Collapse of vertebrae Paraspinal abscess



GENITOURINARY SYSTEM

Plain Radiography

Plain abdominal radiography is routinely employed in the evaluation of renal calculi and prior to intravenous urography (IVU) to look for stones in the urinary tract.

Intravenous Urography (IVU)

Current role of IVU (**Figure 24**) is in detection of the congenital ureteric and renal anomalies, early changes of renal TB (**Figure 25**) and papillary necrosis (**Figure 26**). It is complementary to retrograde pyelography and CT in detection of the transitional cell carcinoma. IVP is alternative (suboptimal) to CT for evaluation of nearly all aetiologies of haematuria and flank pain (calculi, tumour, infection and trauma).

Figures 23A and B: Pott's Spine in a 22-year-old male patient. Radiographs of spine anteroposterior view (A) and lateral view (B) demonstrate reduction in the disc space of L2-3 vertebrae, end-plate irregularity with lytic lesion involving body of L2-3 vertebra. Findings are suggestive of spondylodisitis.

Figure 24: Normal IVU. Fifteen minutes IVU demonstrates normal contrast excretion. Bilateral kidneys and ureters are normal.

Figure 25: Genito-urinary TB in a 40-year-old male. IVU shows fuzzy papilla involving the left kidney with delayed contrast excretion and contracted bladder (thimble bladder).

Figure 26: Papillary necrosis due to analgesic nephropathy. IVU demonstrates characteristic egg-in-cup cavities. No focal cortical loss is seen.

Micturating Cystourethrogram (MCU)

MCU is very useful in demonstrating vesicoureteric reflux, bladder abnormalities like diverticulum and filling defects. Obstructive lesions in the urethra, like strictures, valves, diverticuli are readily demonstrated.

Retrograde Urethrogram (RGU)

RGU gives excellent anatomical information concerning the distal urethra as far as the distal sphincteric mechanism.

Hysterosalpingography (HSG)

HSG is a radiographic method for evaluation of the endometrial cavity and the fallopian tubes following direct instillation of contrast media. Current indications of the HSG include infertility, recurrent abortions, detection of suspected uterine anomalies and assessment of tubal patency and morphology.

3.2 Ultrasound in Medicine

BS Rama Murthy

Ultrasound (US) has evolved into a first line imaging modality in the investigation of problems encountered in medical practice. Non-invasive cost-effective visualisation of the internal organs without the use of radiation or contrast agents have made US imaging readily accessible even in the remotest regions of our country. The following paragraphs are an attempt to present a few situations in clinical medical practice and the possible US findings which aid in clinching the diagnosis or narrowing the differential diagnosis. US may give vital clues which can help make decisions for further imaging/laboratory investigations.

Apart from grey scale imaging which forms the bulk of basic US usage, one can use Doppler US to assess the vascular status of the organs or regions of pathology. Three-dimensional US gives the ability to view the region of pathology in multiple planes simultaneously.

Special high frequency transducer (the hand-held probe which emits US energy and receives the echoes) design enables the study of superficial structures, such as the thyroid, testes etc. in great detail.

Special transducer design enables intracavitary usage, such as the vaginal, oesophageal, gastroduodenal or rectal routes.

US imaging employs sound waves that are beyond the range of human hearing. Typically 3.0 to 5.0 Megahertz (MHz) is the frequency used for abdominal imaging. Superficial part imaging transducers are capable of producing US of upto 15 MHz. The US energy propogates through the tissues underlying the transducer. The tissue field produces reflections (echoes) which reach the same transducer. These echoes are converted to electrical impulses which after processing produce the image on the monitor. The transducer has an array of piezoelectric crystals which produce US on being deformed by an electric impulse. The reverse process occurs when the echoes reach the transducer.

A region which returns no echoes is termed anechoic. Clear fluid containing structures as urinary bladder, gall bladder and cystic lesions are anechoic. A region which returns echoes similar to the liver is termed isoechoic. We also have the terms hypo- and hyper-echoic signifying solid regions returning lighter or darker echoes relative to the liver respectively.

Like all imaging modalities US interpretations have to be done based on the clinical background.

For the purpose of discussion, the following clinical situations, are discussed:

1. Fever of unknown origin (FUO)
2. Jaundice
3. Hypertension
4. Portal hypertension
5. Stroke/Transient ischaemic attacks
6. Diabetes mellitus.

FEVER OF UNKNOWN ORIGIN (FUO)

Fever under investigation may be due to infection, neoplasia or collagen vascular disease. The US imaging can demonstrate the focus of localised infection as a small liver/kidney abscess or a sub-diaphragmatic abscess (**Figure 1**). It should be emphasised that US is an excellent modality, in demonstrating fluid containing space occupying lesions in solid organs. Extensive tuberculous infection of the peritoneum in its ascitic or plastic forms can be well recognised by US (**Figure 2**). Loculated peritoneal fluid collections traversed by flimsy fibrinous bands are pathognomonic of ascitic form of peritoneal tuberculosis (TB). Omental and mesenteric thickening with adherence seen as 'sandwich sign' is suggestive of plastic form of TB.

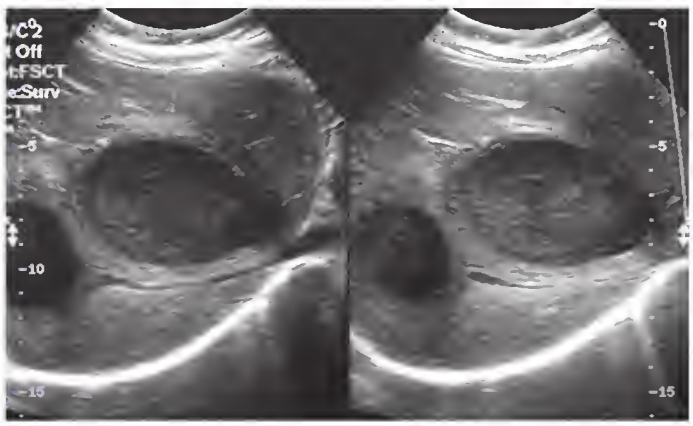

Figure 1: Liver abscesses in case of fever of unknown origin (FUO).

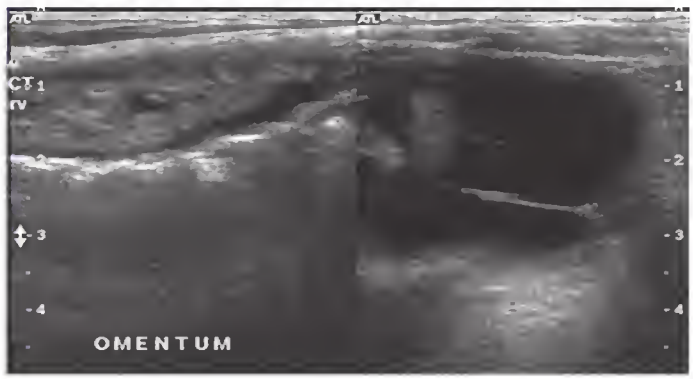

Figure 2: Thickened omentum and loculated fibrinous ascites in peritoneal tuberculosis.

Among neoplasia renal cell carcinoma and lymphoma can present with fever. Abdominal or cervical lymph nodal enlargement can be demonstrated with US (**Figure 3**). Gut wall thickening especially in the ileocaecal region could be due to TB or lymphoma.

Lymphoma is classically hypoechoic with increased vascularity on Doppler examination.

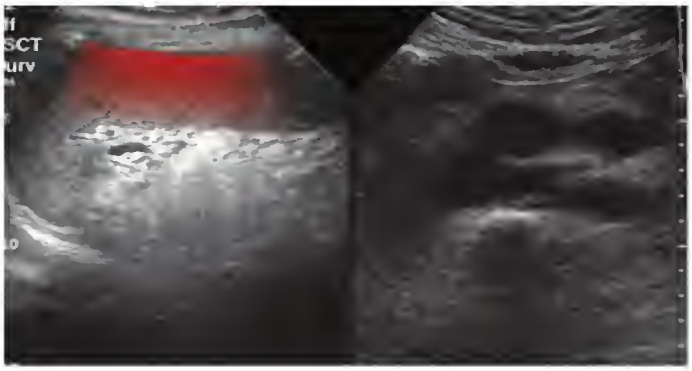

Figure 3: Splenic lesions and juxta-aortic lymph node enlargement in NHL.

JAUNDICE

Jaundice could be due to haemolytic, hepatocellular, cholestatic or obstructive causes. Biliary ductal obstruction at any level results in upstream dilatation. US imaging has a high sensitivity for biliary ductal dilatation and can indeed stratify patients of jaundice into obstructive versus non-obstructive groups. In addition to recognising the presence of obstruction, US also gives information about the level of obstruction and cause of obstruction (**Figures 4A and B**).

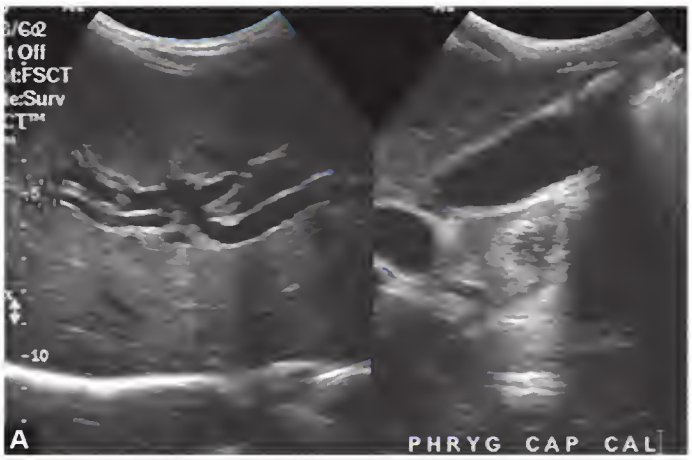

Figure 4A: Intra-hepatic biliary dilatation in a case of common bile duct calculus (**Figure 4B**) also note presence of gall bladder stone in the fundic region.

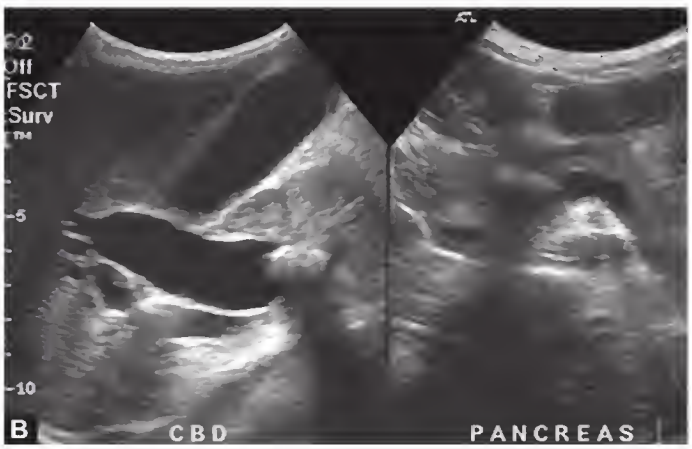

Figure 4B: Calculus in the intra-pancreatic segment of common bile duct. Calculi are typically bright (hyperechoic) with an acoustic shadow.

Normal intra-hepatic biliary ducts beyond the right and left main hepatic ducts are not visualised by US. Dilated intra-hepatic ducts are seen as tubular cystic structures running parallel to the portal radicles and produce the typical 'double barrel' or 'shot gun' appearance.

The normal main bile duct (common hepatic and common bile duct) can be consistently demonstrated by US and is less than 6 mm in caliber. Any diameter above 6 mm in a case with no history of biliary surgery is indicative of dilatation. It must be noted that there could be non-obstructive ectasia as in a choledochal cyst or as in ectasia associated with advancing age. The level of obstruction can be gauged by noting the presence of gallbladder and/or pancreatic duct dilatation. The cause of obstruction may often be demonstrated in the form of a ductal calculus, cholangiocarcinoma, pancreatic mass or a periampullary carcinoma (**Figures 5A and B**). In sclerosing cholangitis and human immunodeficiency virus (HIV) cholangiopathy the main bile duct shows wall thickening.

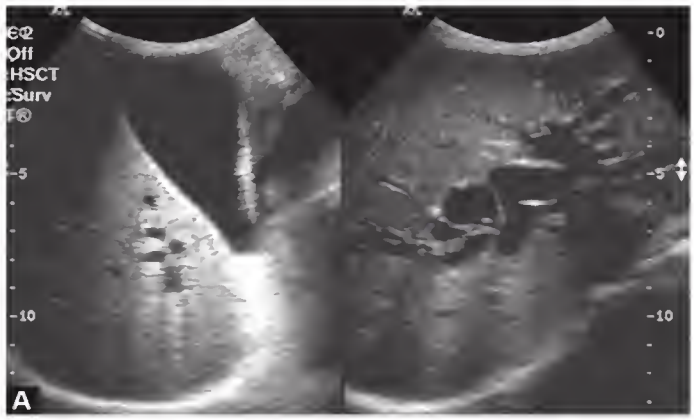

Figure 5A: Intra-hepatic biliary ductal dilatation with gallbladder dilatation in periampullary carcinoma (**Figure 6**).

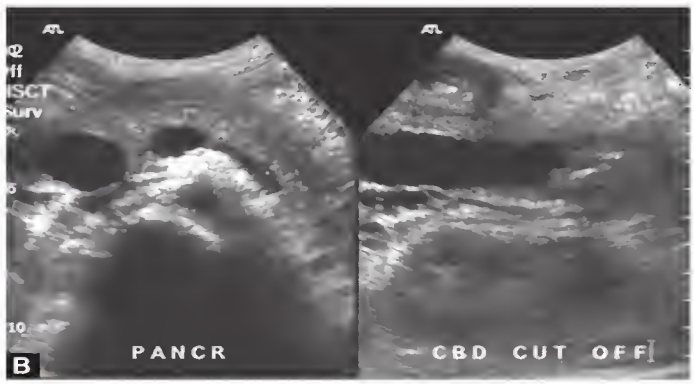

Figure 5B: Terminal CBD cut-off in periampullary carcinoma.

HYPERTENSION

In the setting of hypertension US plays two distinct roles.

1. To look for potential renal or adrenal causes in secondary hypertension.
2. To assess renal status in chronic hypertension.

The renal conditions that can be identified as a possible cause of hypertension include autosomal dominant polycystic renal disease, post-inflammatory renal scarring (focal or global), diabetic nephropathy, acute glomerulonephritis and other parenchymal diseases (**Figures 6 and 7**). These are traditionally

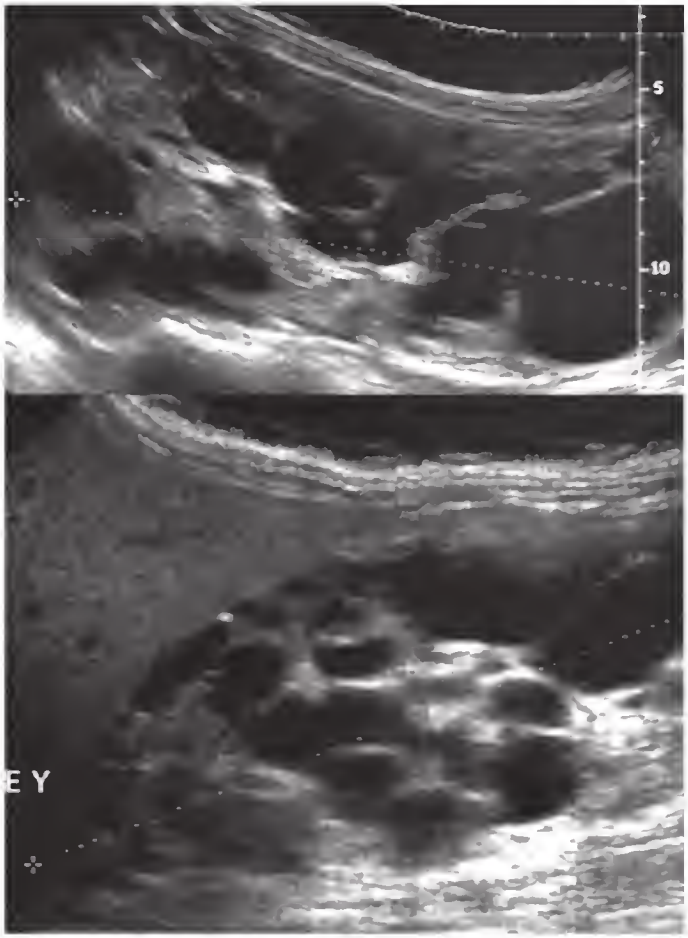

Figure 6: Right and left kidneys replaced by multiple cysts. Note the symmetrical enlargement, in a case of autosomal dominant polycystic kidney disease.

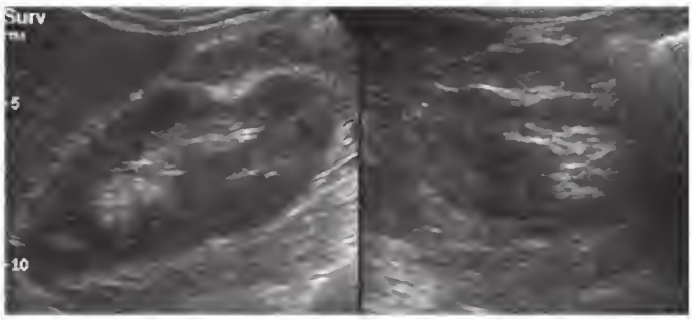

Figure 7: Focal lower pole chronic pyelonephritic scar of the right kidney. Note the presence of focal parenchymal thinning as well as the contour alteration.

classified as renal parenchymal causes and are diagnosed on the basis of B mode imaging.

On the other hand, we have renal vascular cause as in renal artery stenosis (atheromatous plaques or fibromuscular dysplasia).

Duplex Doppler US provides a non-invasive screening technique. The B mode and Doppler findings include:

1. High peak systolic velocity in the stenotic segment (greater than 180 to 200 cm/sec) and an renal artery/aortic ratio (RAR) of 3.5 or more are considered as markers of a haemodynamically significant (greater than 50% diameter reduction) main or accessory renal artery stenosis (**Figure 8A**). The visualisation of the main renal artery is rather dependent on the body habitus, and the operator expertise. Hence, it may not serve its 'screening' role to the expected level.
2. The segmental arteries are consistently seen by colour Doppler and sampling of at least three of them serves as a screening test. In the presence of main renal artery stenosis the intra-renal Doppler spectral waveforms show 'tardus parvus' nature (**Figure 8B**). This means that the systolic velocities are attenuated with a slower acceleration of the slope of the systolic upstroke. Acceleration time greater than 70 milliseconds are indicative of main renal artery haemodynamically significant stenosis.

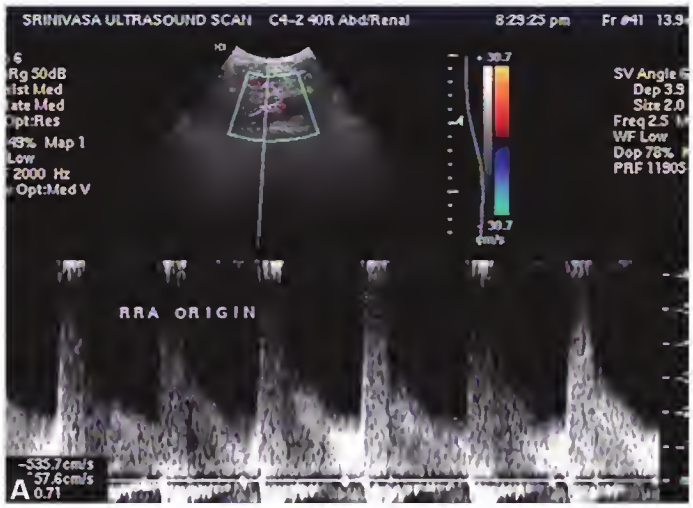

Figure 8A: High systolic velocity in the origin of the right renal artery.

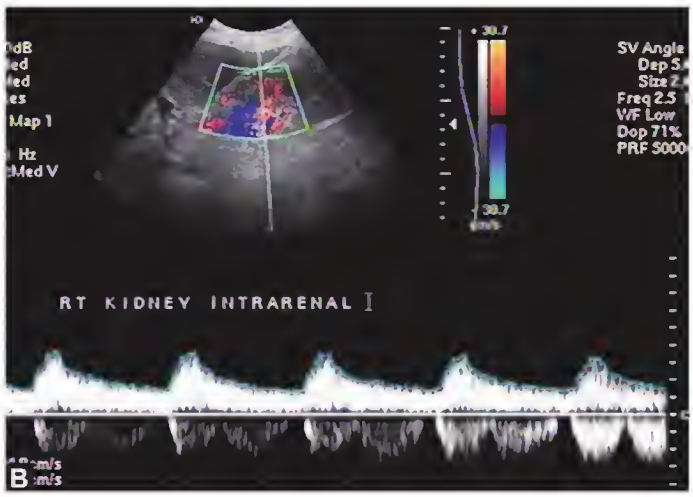

Figure 8B: Tardus parvus intrarenal waveform (segmental artery) in the right kidney of the subject in **Figure 10**.

In addition, the presence of low pulsatility in the intra-renal arteries is indicative of better chance of reversal to normotensive state after stent placement or balloon angioplasty.

Adrenal cause which can be detected by US is a pheochromocytoma or adrenal carcinoma (**Figure 9**).

PORTAL HYPERTENSION

In the clinical setting where portal hypertension is a potential possibility (ascites, splenomegaly, haematemesis, dilated abdominal wall veins), US may help in answering the following questions:

Is Portal Hypertension Present? What Is the Cause?

The splenomesentericoportal venous axis normally shows an inspiratory increase and expiratory decrease in caliber. Decrease or absent respiratory caliber change is a very

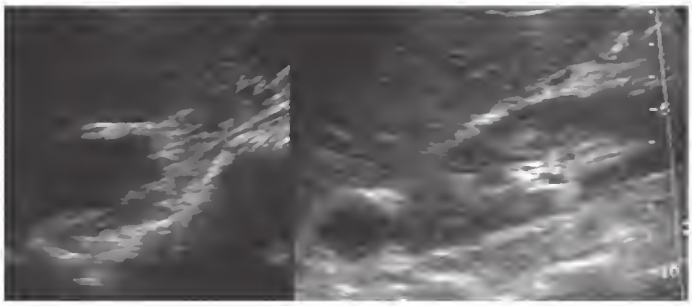

Figure 9: Right adrenal solid mass.

sensitive marker of portal hypertension (**Figure 10**). Upstream dilatation of the splenomesentericoportal venous axis occurs proximal to the site of pathology. For instance, in portal cirrhosis (hepatic cause of portal hypertension) upstream dilatation occurs in the splenic, superior mesenteric and portal veins.

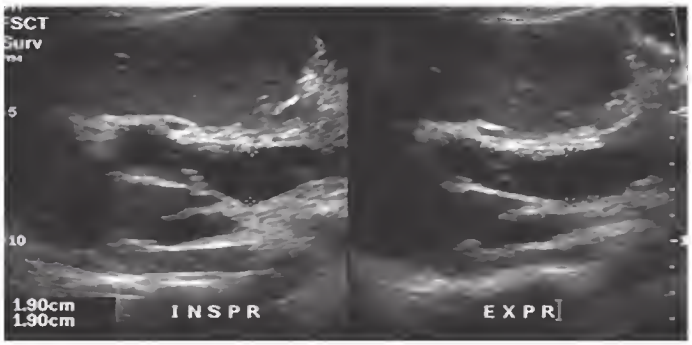

Figure 10: Absent respiratory portal venous caliber change in portal hypertension. Also note portal venous dilatation.

Portal vein is considered dilated when its caliber is more than 1.3 cm. Dilatation of the portal or splenic veins is not as sensitive or specific compared to respiratory caliber change in the diagnosis of portal hypertension. Identification of venous collaterals is a strong confirmatory sign of portal hypertension. Collaterals may be porto-hepatic as in periportal (portal cavernoma) or peri-pancreatic collaterals (**Figure 11**). These collaterals bypass the region of cause of portal hypertension and drain into the portal venous radicals in the liver. In contrast porto-systemic collaterals drain either into the superior vena cava or inferior vena cava territories. Examples of the former include the dilated coronary vein and short gastric collaterals. Examples of the latter include splenorenal or splenoretroperitoneal collaterals and the recanalised umbilical vein.

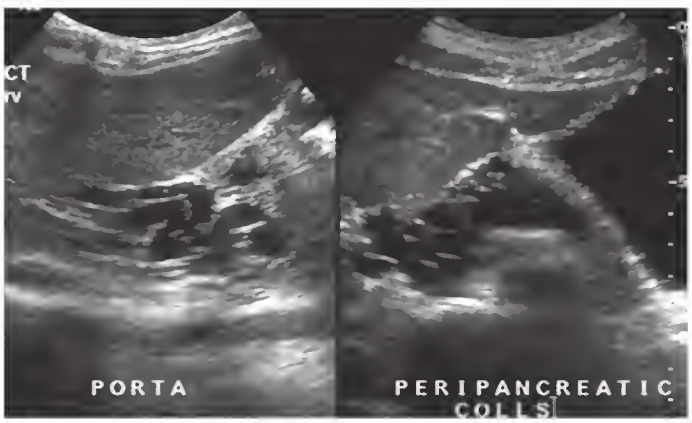

Figure 11: Portal cavernoma and periportal collaterals.

Having obtained as much B mode findings as possible Doppler is used to map the presence and direction of flow in the splenomesentericoportal venous axis and the collaterals. Hepatofugal flow in the portal vein has important clinical implications. This is associated with decreased incidence of variceal bleed but increased incidence of hepatic encephalopathy. Porto-hepatic and porto-systemic collaterals show hepatopetal and hepatofugal flow, respectively.

The cause of portal hypertension in terms of portal venous thrombosis (a portal cavernoma implies portal venous thrombosis in the past), cirrhotic hepatic echopattern or IVC or hepatic vein pathology may be identified.

STROKE/TRANSIENT ISCHAEMIC ATTACKS

Stroke due to atherosclerotic disease is a leading cause of mortality and morbidity. Transient ischaemic attacks are harbingers of stroke. Vast majority of ischaemic strokes are due to emboli. The source of emboli could be from the carotid system or the cardia. It is well documented that the embologenicity in the carotid system increases with the degree of stenosis due to atheromatous plaques. The North American Symptomatic Cartoid Endarterectomy Trial (NASCET) trial has convincingly proved that carotid endarterectomy is more beneficial than medical therapy in symptomatic patients with 70% to 99% internal carotid stenosis. This study has ensured the future of carotid Doppler ultrasound as a screening tool. The indications for carotid Doppler include TIA, stroke, carotid bruit, amaurosis fugax and post-carotid endarterectomy/stenting. The intima medial thickness is being used as a predictor of the possibility of future cerebrovascular or cardiovascular accident.

Carotid Duplex Doppler

Carotid duplex Doppler US enables us to assess the following:

1. *The wall (atheromatous plaque) morphology:* Plaque length, thickness, extent, echogenicity and surface characteristics (**Figures 12 and 13**).
2. *The patent luminal status* is assessed in terms of percentage diameter or area narrowing. This can be done by direct visualisation or by velocity criteria. Velocity criteria include peak systolic ratio, end diastolic velocity and the velocity ratios (ICA/CCA systolic or diastolic ratios). The velocity assessment of stenosis is based on the principle of incremental acceleration of blood flow in the region of stenosis with increasing degree of stenosis.

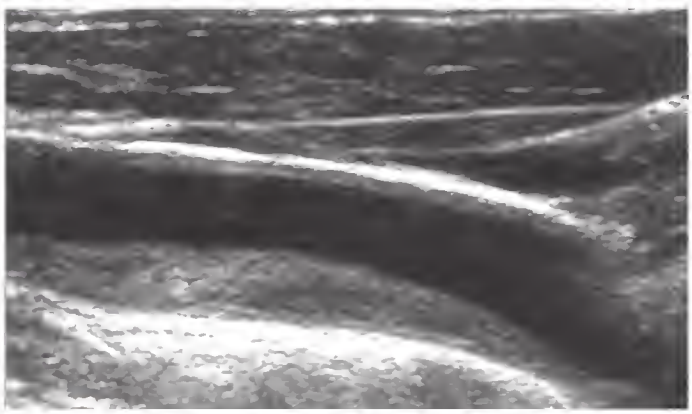

Figure 12: Carotid homogeneous, echogenic, smooth surfaced plaque.

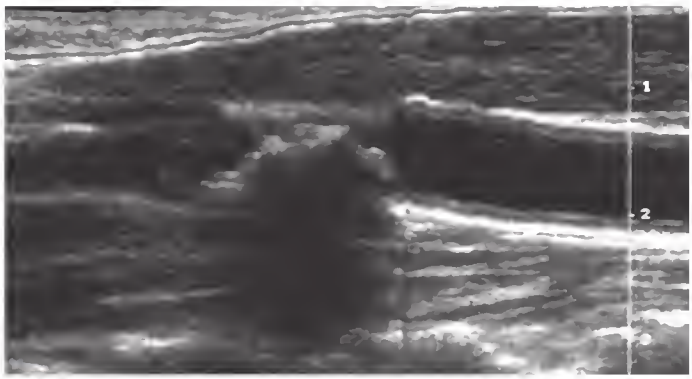

Figure 13: Internal carotid calcific plaque.

Haemodynamically significant stenosis implies more than 50% diameter reduction. Doppler assessment can recognise only haemodynamically significant stenoses.

Carotid duplex Doppler US screening is an excellent non-invasive means of assessing stenosis. Useful information regarding the plaque morphology may be obtained.

DIABETES MELLITUS

US has many roles to play in the context of diabetes mellitus. A few of them may be enumerated below:

1. In terms of aetiology, chronic calcific pancreatitis may be demonstrated. Thinning of pancreatic parenchyma, irregular ductal dilatation and ductular calculi are the defining features (**Figure 14**).
2. In terms of chronic sequelae, we could identify steatotic infiltration of the liver (**Figure 15**), diabetic nephropathy, and steno-occlusive atheromatous disease in the lower limb arterial axis.

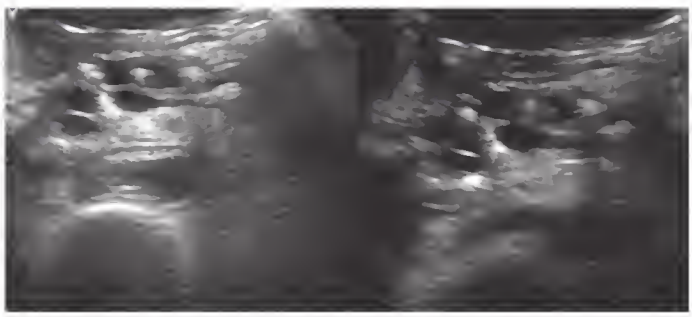

Figure 14: Chronic calcific pancreatitis. Echogenic calculi are seen in the diluted pancreatic duct.

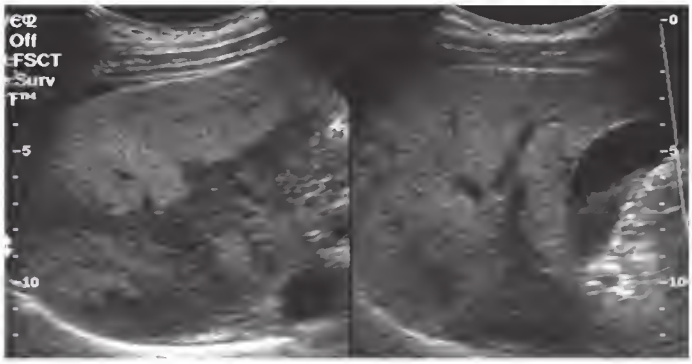

Figure 15: Patchy hepatic steatosis.

3. In terms of infective sequelae, we can identify emphysematous cholecystitis/pyelonephritis.

We will now explore the role of US in the evaluation of various organ systems.

i. *Neonatal brain:* Transfontanellar approach yields coronal and sagittal images of the brain. Hypoxic ischaemic sequelae, intracranial haemorrhage and congenital malformations are assessed and followed-up.

ii. *Neck:* Thyroid, parathyroid, and cervical nodes may be evaluated for enlargement, echopattern and nodules.

iii. *Chest:* US is sensitive for detecting fluid in the pleural cavity. Presence of loculation or fibrinous content may be assessed. Large lung/mediastinal lesions may be characterised as being solid or cystic.

4. *Abdomen*
   (a) Liver: Size may be assessed. The normal liver echopattern is homogeneous. In diffuse liver disorders, the echopattern is altered as happens in cirrhosis. Presence of portal hypertension may be assessed. The strength of US, however; is in its ability to demonstrate space occupying lesions of the liver and characterise them as solid or cystic.

   (b) Biliary system: US can demonstrate the biliary ductal dilatation in obstructive jaundice. The level and cause of obstruction can be determined. Gall bladder disease in terms of calculi, cholecystitis, cholesterolosis and malignancies may be demonstrated.

   (c) Pancreas: Pancreatic swelling and intra- or peri-pancreatic fluid collections in acute pancreatitis and its sequelae may be demonstrated. Ductal dilatation and calculi may be seen in chronic pancreatitis. Pancreatic solid masses may be demonstrated.

   (d) Kidneys: Abnormal location and/or absence of kidneys may be assessed. Obstructive uropathy may be demonstrated. The level of obstruction (pelviureteric or ureterovesical or bladder outflow) may be ascertained. Renal size and the parenchymal echopattern may be evaluated in medical renal disease. Renal artery Doppler may be used to evaluate potential stenosis.

   (e) Adrenals: Adrenal mass lesions may be recognised and described. Adrenal hyperplasia cannot be demonstrated by US.

   (f) Bladder and prostate: Bladder volume, wall thickness and presence of mural polypoid lesions can be assessed. Post-void residue can also be estimated. Prostatic weight and echopattern can be assessed by transrectal ultrasonography.

   (g) Female internal genitalia: Uterine size and presence of fibroids or adenomyosis may be assessed. Ovarian masses can be characterised. Ultrasound has an indispensable role in infertility management. Transvaginal ultrasonography has revolutionised the pelvic imaging.

   (h) Peritoneum: US is very sensitive for fluid in the peritoneal cavity. Further, it can help in characterising

whether the fluid is transudate or exudate. Thickened peritoneum/omentum may be demonstrated as in peritoneal TB or metastasis.

(i) Retroperitoneum: Retroperitoneal lymph node enlargement and their distribution may be evaluated. Retroperitoneal mass lesions may be described.

(j) Abdominal wall: Hernial defects and wall masses can be delineated.

5. *Perineal applications*

Perianal sinuses and fistula can be delineated in terms of extent and length.

6. *Scrotal applications*

Epididymorchitis, torsion, testicular tumours may be recognised.

7. *Musculoskeletal*

Shoulder, wrist, knee, ankle applications.

8. *Orbital and ocular*

Anterior and posterior chamber applications.

DOPPLER ULTRASOUND

1. Carotid and Vertebral

Atheromatous plaque morphology, luminal narrowing and/or occlusion can be demonstrated in cases of transient ischaemic attack or establisted stroke.

2. Transcranial Doppler

It is used to evaluate the Willisian circulation in cases of carotid occlusion. It is also used to evaluate the presence of spasm in subarachnoid haemorrhage.

3. Lower Limb Arterial

Stenosis and/or occlusion can be demonstrated in cases of intermittent claudication, rest pain or gangrene.

4. Upper Limb Arterial

Evaluation of thoracic outlet syndrome and haemodialysis access fistula.

5. Lower Limb Venous

Deep venous thrombosis may be mapped. Incompetency of the valves of the deep veins or communicating veins may be evaluated.

6. Abdominal

Doppler ultrasound contributes to the diagnosis of portal hypertension, renal artery stenosis, renal allograft vascularity, abdominal aortic aneurysm, and mesenteric arterial insufficiency. Evaluation of an abdominal masses for the type of vascularity and main feeder and draining vessels.

INVASIVE APPLICATIONS

US-guided needle placements are now common place procedures. Pleural taps, abscess drainages, renal and other organ biopsies are all done successfully and non-safely under US guidance.

CONTRAST ENHANCED ULTRASONOGRAPHY

Ultrasonography contrast media are microbubbles which when injected enhance the reflectivity of lesions. They have been particularly applied in liver space occupying lesions. Hepatic haemangioma, primary tumour and metastatic lesions have their typical enhancement patterns.

ELASTOGRAPHY/FIBROSCAN

Using US energy, the elastic properties of a tissue (e.g. liver) or a lesion (e.g. breast carcinoma) can be qualitatively or quantitatively assessed. This technique holds promise to distinguish between benign and malignant lesions of the breast. Assessment of the liver for diffuse parechymal diseases (Fibroscan) is another area of promise.

Thus, we have seen a few situations in medical practice where US plays an important role in investigation. However, there are many other situations where US is indicated and where the results have a bearing on the management of the individual case.

3.3 Computed Tomography

Bhavin Jankharia, Nishigandha Burute

INTRODUCTION

The discovery of computed tomography (CT) by Sir Godfrey Hounsfield, Senior Research Scientist in Middlesex, England and South African born Dr Alan Cormack in the 1970s has been a milestone in the history of medical sciences and in the field of radiology. CT literally means writing (graphien) slices (tomos) of the human body with the help of a computation process. CT has not only changed the understanding of many diseases but also impacted the management of various disease processes. Initially, it was called computerised axial tomography (CAT) or computerised tomography, but computed tomography (CT) is currently the preferred name worldwide.

BASIC PRINCIPLES OF COMPUTED TOMOGRAPHY

Working of the CT Scanner

The rays used in a CT scanner are X-rays. The basic principle behind CT is that the internal structure of an object can be reconstructed from multiple projections of the object. The ray projections are formed by scanning a thin cross-section of the body with a narrow X-ray beam and measuring the transmitted radiation with a sensitive radiation detector. The detector adds up the energy of all the transmitted photons. The image is formed by processing of the numerical data from the multiple ray sums by a computer (**Figure 1**).

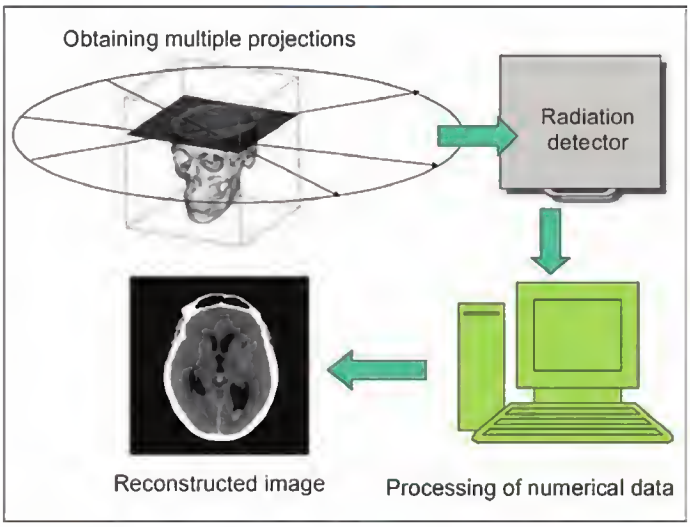

Figure 1: Working of a CT scanner.

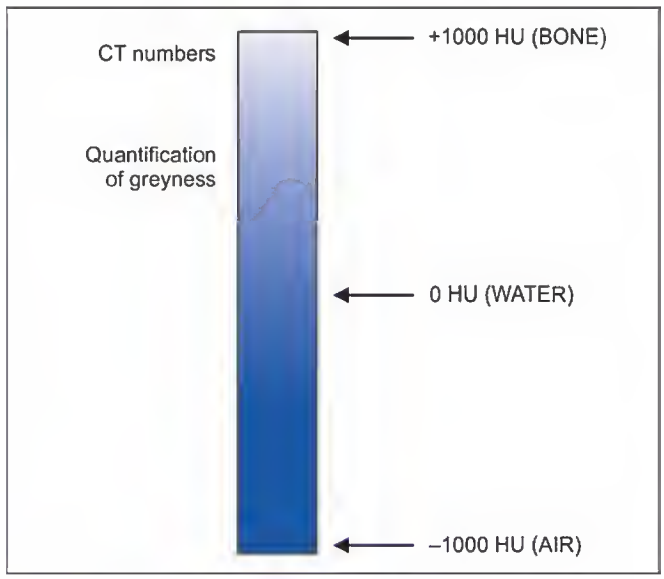
CT Image

The CT image is made up of a number of shades of grey. The grey-scale of a tissue depends upon how much the tissue can attenuate the X-ray beam. The unit of attenuation is called Hounsfield unit (HU) (**Figure 2**). The degree of attenuation of an X-ray beam by a particular tissue depends on its density. Air being the least dense (HU: 1000), it attenuates the beam the least and appears black in colour; water being of medium density (HU: 0), it appears grey; dense cranial bone (upto 2000 HU) appears white on the CT image. The differentiation between normal tissue and pathologies can, thus, be made by observing the difference in their shades of grey.



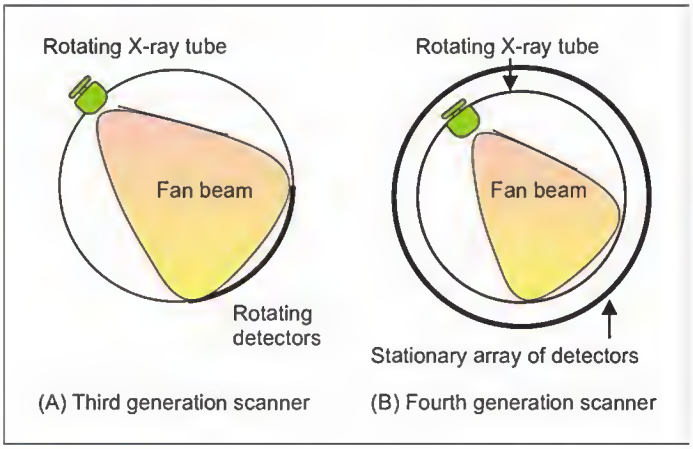


Figure 2: Differentiating tissues with the help of Hounsfield units.

EVOLUTION OF CT SCANNERS

CT scanners have gone through a number of design changes since the technology was first introduced in 1971. The first generation CT scanner used a single pencil beam of X-rays and a single detector and used to take 25 to 30 minutes for a 5-view study of the head. The second generation CT scanner used a fan beam instead of a pencil beam with multiple detectors, with a reduction in the scan time of a head CT to 1 to 2 minutes. The X-ray tube and detector movements were both linear and rotatory (translate-rotate) in the first and second-generation CT scanners. In 1975, third generation CT scanners were introduced in which the translation movement was completely eliminated and only rotation was required with both the X-ray tube and detectors rotating around the patient. A fan beam was used and the unit could produce a head scan in a few seconds (**Figure 3A**). The fourth generation CT scanner used a rotate-fixed configuration of the X-ray tube and detector system, where the detectors formed a ring that completely surrounded the patient. The detectors did not move. The X-ray tube rotated in a circle inside the detector ring (**Figure 3B**). The time required for a CT head, thus, became 1 second.

The advent of spiral/helical CT scanners in 1989 has been considered a major technical advancement in body imaging. It combines continuous gantry rotation with continuous table feed, thus eliminating interscan delay (**Figure 4**). This enables spiral CT acquisition to be much faster than conventional CT. The spiral CT scanner has also matured from a single slice to a 64-slice spiral CT scanner. The development of a dual source multi-slice CT scanner is a recent development, in which two

Figures 3A and B: (A) In a third generation scanner, both the X-ray tube and detectors rotate around the patient. A fan beam is used. (B) A fourth generation scanner has a rotating X-ray tube and a stationary array of detectors. A fan beam is used.

tubes produce 64-slices together. A 256-slice spiral CT scanner is now commercially available.

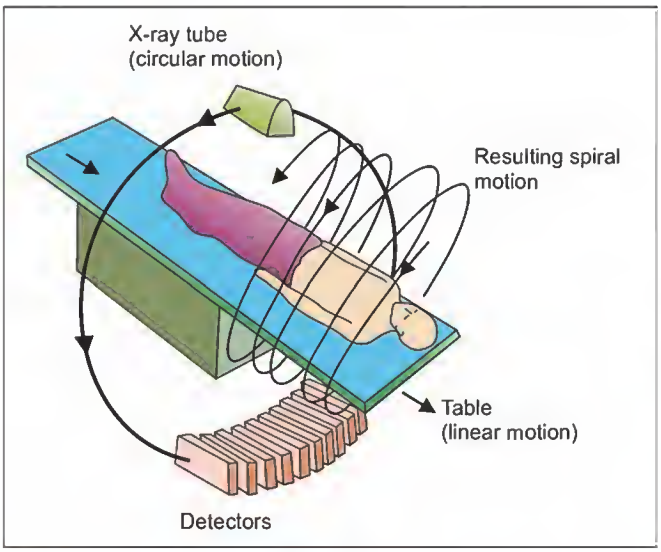

Figure 4: A spiral CT scanner has continuous gantry rotation with continuous table feed resulting in faster image acquisition.

CT CONTRAST MEDIA

Ionic/non-ionic contrast media are used intravenously in appropriate doses for a contrast enhanced CT scan. These opacify blood vessels and in turn the tissues that are supplied by them. The degree of enhancement of a tissue depends on its vascularity and capillary permeability. Thus, contrast media allow better depiction of normal anatomy and help in differentiating normal tissues from disease processes. Contrast media can cause allergic reactions in some individuals. These may range from a simple rash to the rare but fatal anaphylactic reaction.

Contrast media are also used to opacify the bowel loops during abdominal imaging, as they enhance the contrast between bowel loops and the surrounding viscera.

CONTRAINDICATIONS OF CT

X-ray Related

CT utilises X-rays for image production, hence, a CT is contraindicated in the first trimester of pregnancy, which is the period of organogenesis.

Contrast Related

The CT contrast medium is excreted by kidneys; hence, deranged renal function is an absolute contraindication for contrast-enhanced CT. Prior history of a serious reaction to CT contrast agents is also a contraindication.

APPLICATIONS

Due to several recent technical innovations and improvements, new CT applications continue to be added to an already long list of indications. Both positive and negative results of a CT improve the clinician's understanding of the disease and assist him in management decisions.

Head

CT is the modality of choice in head injury patients to look for intracranial bleed, brain contusions and skull fractures (**Figure 5**). It is also useful in acute cerebrovascular stroke to differentiate haemorrhagic from non-haemorrhagic stroke and to detect hypertensive bleeds. It is also helpful in detecting various other intracranial processes, such as granulomas (tuberculomas, neurocysticercosis, etc), hydrocephalous and tumours. CT is the modality of choice for evaluating the bony anatomy of the skull base, temporal bone, cranio-vertebral junction and paranasal sinuses (**Figure 6**). High resolution CT (HRCT) of the temporal bone provides exquisite details of the ear ossicles, middle ear cavity, mastoids and bony labyrinth.

Neck

CT of the neck is used to detect the exact location and spread of various disease processes involving the neck structures, such as the nasopharynx, oropharynx, larynx, cricopharynx, salivary

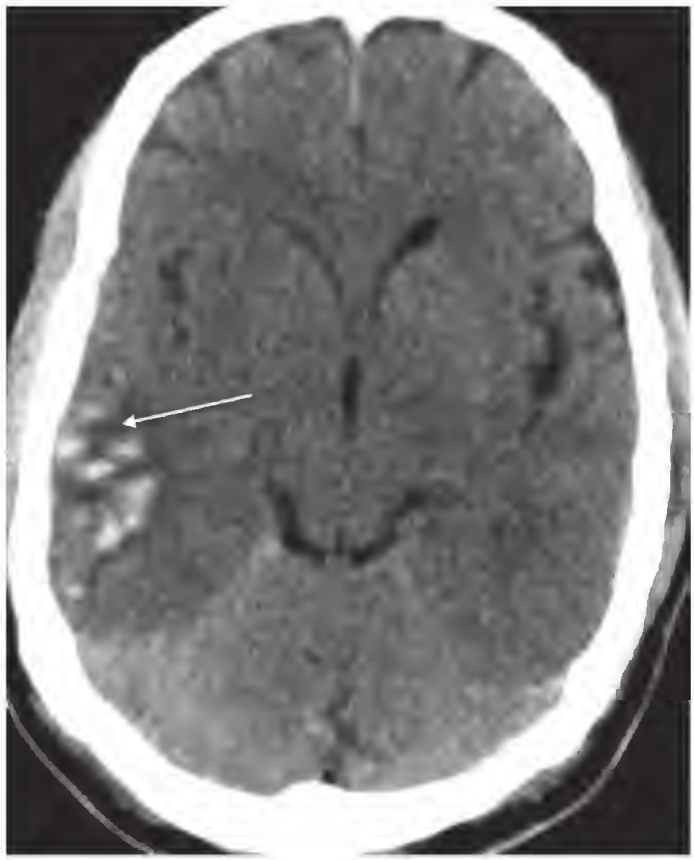

Figure 5: An axial CT of the brain shows haemorrhagic contusion in the right temporal lobe (arrow).

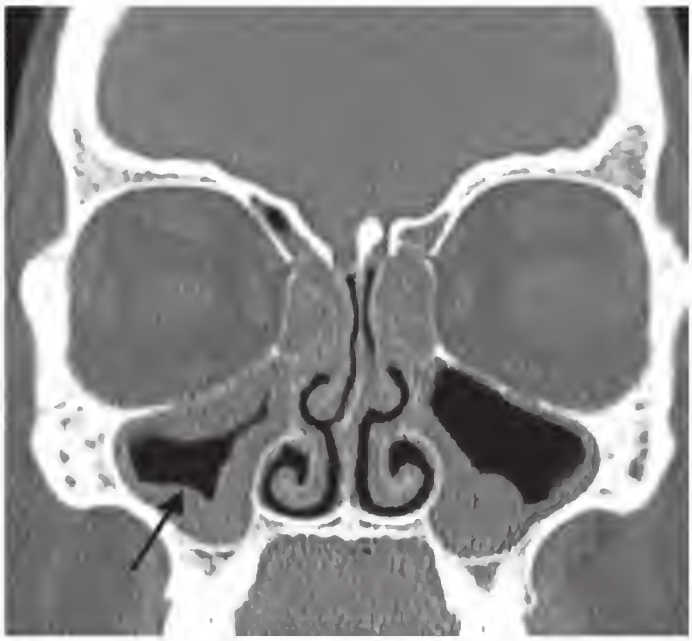

Figure 6: Coronal high resolution CT of the paranasal sinuses shows mucosal thickening (arrow) in the maxillary and ethmoid sinuses.

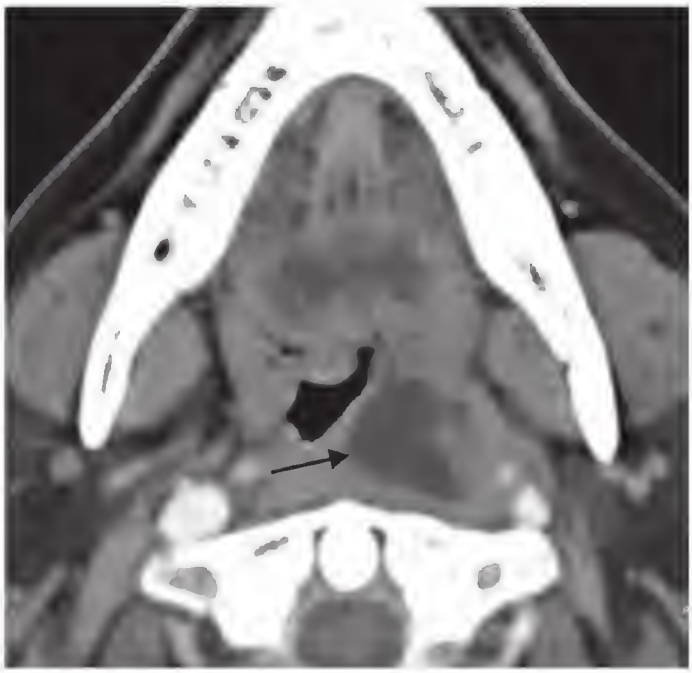

Figure 7: Axial contrast-enhanced CT of the neck shows a retropharyngeal abscess (arrow).

glands, thyroid gland and parapharyngeal space lesions as well as to detect cervical lymphadenopathy (**Figure 7**).

Thorax

CT is the modality of choice for evaluating lung pathologies, such as benign and malignant neoplasms, infections, various interstitial lung diseases (ILDs) and pneumoconiosis. In the pleura, effusions, empyema, pneumothorax and tumours and in the mediastinum, lymphadenopathy and neoplasm are well assessed. HRCT is a technique used for evaluating exquisite details of the lung parenchyma (**Figure 8**). HRCT can detect pathologies, which are not apparent on plain chest radiographs and has changed the management of patient with ILDs and airway pathologies.

Figure 8: HRCT of the lung shows extensive cystic bronchiectasis.

Abdomen

CT is the modality of choice for detecting acute appendicitis, cholecystitis, pancreatitis, acute ureteric colic, and intestinal obstruction with or without perforation (**Figures 9 and 10**). It is also used for the diagnosis, staging and pre-operative planning of various gastro-intestinal and visceral malignancies and benign neoplasms. It is also used for post-operative and post-treatment follow-up of these malignancies.

Vessels

CT angiography, a logical application of spiral technology, is a technique used to produce excellent images of the targetted

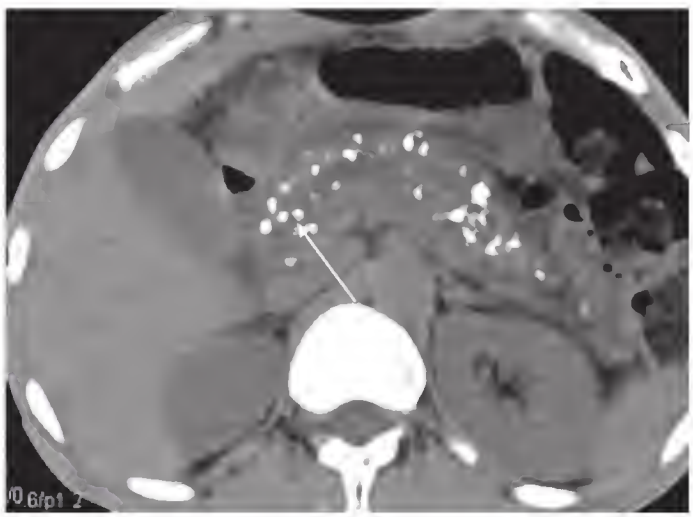

Figure 9: Axial CT of the abdomen shows a bulky pancreas with extensive calcification (arrow), suggesting acute on chronic pancreatitis.

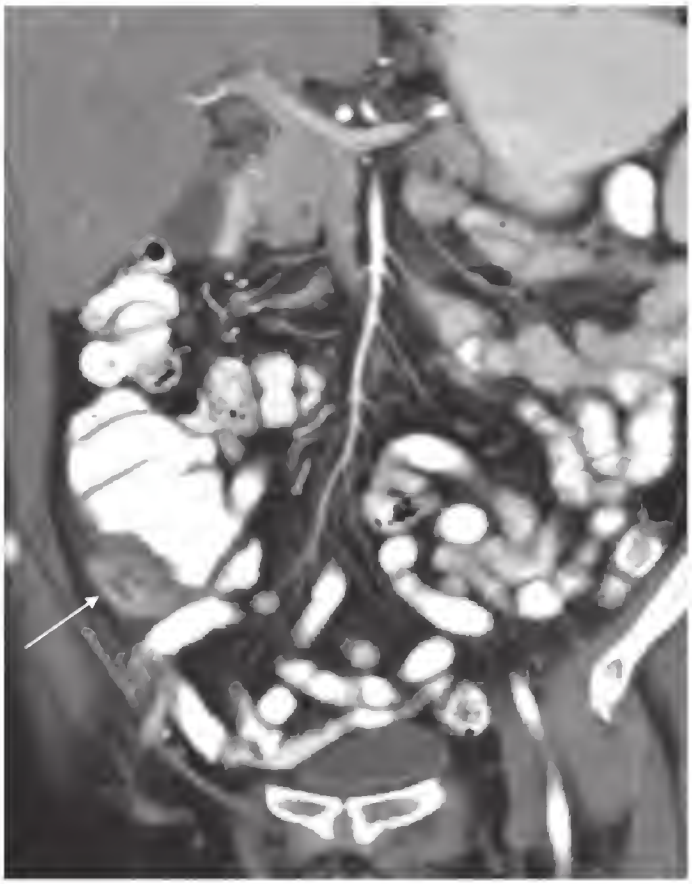

Figure 10: Coronal CT shows acute appendicitis (arrow).

arterial system.The images are displayed as thin collimation axial images or 3D renderings using sophisticated reconstruction techniques, like shaded surface display, maximum intensity projection and multiplanar formats, or can be colour coded using volumetric reconstruction images. Various applications of CT angiography are given in **Table 1**.

Table 1: Applications of CT Angiography

1. Cerebral angiography for detecting lesions of the carotid, vertebral and intracranial vessels, which include stenoses as well as aneurysms and arteriovenous malformation (**Figure 11**).
2. Pulmonary angiography, which is now the 'gold standard' in the evaluation of pulmonary thromboembolism.
3. Aortic angiography for aortic aneurysm, dissections and stenosis (**Figures 12A and B**).
4. Renal angiography for detecting renal artery stenosis.
5. Mesenteric angiography for mesenteric ischaemia.
6. Peripheral angiography for assessing the peripheral circulation of the upper and lower limbs.
7. Portal venography.

Musculoskeletal System

CT is the modality of choice for evaluation of the anatomy and pathology of the skeletal system. It has applications in various congenital anomalies as well as infective, neoplastic and traumatic conditions. The facility of retrospective reconstruction of thin sections and sophisticated 3D evaluation techniques resulting in remarkably high quality multi-planar reformats and shaded rendering is of immense help (**Figure 13**).

Figure 11: Axial cerebral angiography shows the arteries of the circle of Willis.

Figures 12A and B: Aneurysm. Maximum intensity projection (MIP) (A) and volume rendered (VRT) (B) images show a stented descending thoracic aneurysm with another aneurysm in the lower abdominal aorta.

Cardiac CT

Multi-detector CT coronary angiography is emerging as the most reliable non-invasive method for coronary artery disease (CAD) assessment. The newer ultra-fast cardiac CT holds the promise of replacing the standard invasive procedure of conventional coronary angiography as well as nuclear stress thallium, especially in the setting of 'to rule-out'. The standard multi-slice CT that exquisitely produces coronary artery images

Figure 13: Sagittal CT of the spine shows gross osteopaenia and destruction of the L2 vertebral body (arrow).

is a 64-slice CT scanner, but 320-slice and dual-source scanners are now available as well. All scans are gated to the electrocardiogram (ECG) trace, which allows positioning the data acquisition accurately in specific phases (**Figure 14**). Using such modality, one can perform calcium scoring, coronary artery imaging and assess function by reconstructing cine images.

Paediatrics

CT in children is often difficult due to motion artifacts and high respiratory rates. There is often a need to sedate or anaesthetise babies. Multi-slice CT has overcome these problems with sub-second scans and improved image resolution.

Figure 14: Normal cardiac CT angiogram shows the left main (LM), left anterior descending (LAD) and circumflex (CX) arteries.

Trauma

CT provides the high speed of data acquisition needed in trauma patients and to plan triage. CT is the modality of choice in an acute trauma setting for detecting internal bleeding, bone fractures, vascular injuries affecting different systems of the body, and for locating foreign bodies. Vertebral column injuries are well depicted but for spinal cord injures, MRI is the modality of choice. CT is also the modality of choice in patients with metallic implants inside the body, such as metallic rods, plates, fixation screws, etc (**Figure 15**).

Virtual Bronchoscopy and Colonoscopy

Using sophisticated software, it is now possible to get bronchoscopic and colonoscopic views non-invasively. These coloured pictures give better appreciation of the pathology. Virtual bronchoscopy has a role in locating foreign bodies, polyps, tumours, and strictures in the tracheobronchial tree. Virtual colonoscopy is used mainly in screening for polyps, some of which may be pre-malignant lesions.

3D Reconstruction

With the advent of faster scanners, it is possible to achieve 3D images with enhanced spatial and temporal resolution. Multi-planar reconstruction comprises reformatting of a CT image in the axial, coronal and sagittal planes. Multi-planar reconstruction allows better localisation and delineation of structures. Curved planar reconstruction and maximum intensity projection help better visualisation of tubular structures, such as blood vessels and ducts.

Figure 15: Coronal CT of the hip with orthopaedic hardware *in situ*, shows a non-united fracture.

Shaded surface display is useful in the setting of fractures, dislocations and vascular trauma. Volume rendering offers excellent anatomical details, and thus, enhances the visualisation of vessels and is also useful in cardiac imaging.

CT-GUIDED PROCEDURES

Diagnostic Procedures

CT provides an accurate skin entry point and guidance for drainage of intra-abdominal and intra-thoracic collections and abscesses. Under CT guidance, biopsies of mediastinal, pulmonary and intra-abdominal lesions are possible (**Figure 16**).

Figure 16: CT-guided biopsy of an enlarged subcarinal node (black arrow), using an extra-pleural approach (red arrow).

Therapeutic Procedures

Pain management

CT-guided nerve blocks (lumbar sympathectomy, supra-clavicular nerve block) are used for alleviation of pain (**Figure 17**).

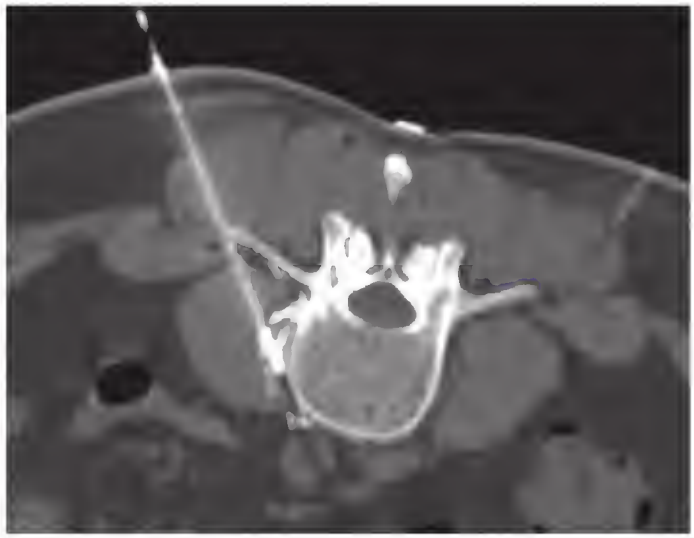

Figure 17: CT-guided lumbar sympathectomy for pain management.

Radiofrequency ablation (RFA)

Radiofrequency ablation of osteoid osteoma and liver and lung malignancies is one of the newer applications of CT.

Vertebroplasty

Transpedicular insertion of a bone biopsy needle in the diseased vertebra under CT guidance, followed by delivery of bone cement into the body of the diseased vertebra is used for management of painful vertebral pathologies.

CT-Guided Radiotherapy Planning

Radiotherapy treatment is usually planned in the axial planes. CT has been extensively investigated as a method of providing pre-treatment data for radiotherapy planning. CT not only provides accurate location and staging of the tumour but also calculates the volume of the tumour to be irradiated using sophisticated software. It is also useful in successive follow-ups.

Liver Volume Estimation in Transplant Patients

CT enables accurate volumetric measurement of a donor liver prior to transplant. This is essential in order to avoid small for size grafts from living donors, which would compromise the outcome of the liver transplant.

POSITRON EMISSION TOMOGRAPHY (PET)/COMPUTED TOMOGRAPHY

The combination PET/CT scanner is a major advancement in imaging technology and patient care. As the name implies, it combines two scanners, the PET scanner, which shows metabolism and the function of cells, and the CT which shows detailed anatomy. The result is that doctors are now able to get highly defined, 3D images inside the human body along with functional information of the same (**Figure 18**).

SAFETY CONCERNS AND RADIATION ISSUES

With the tremendous increase in the use of CT in the past decade, radiation exposure from CT have become a worrisome

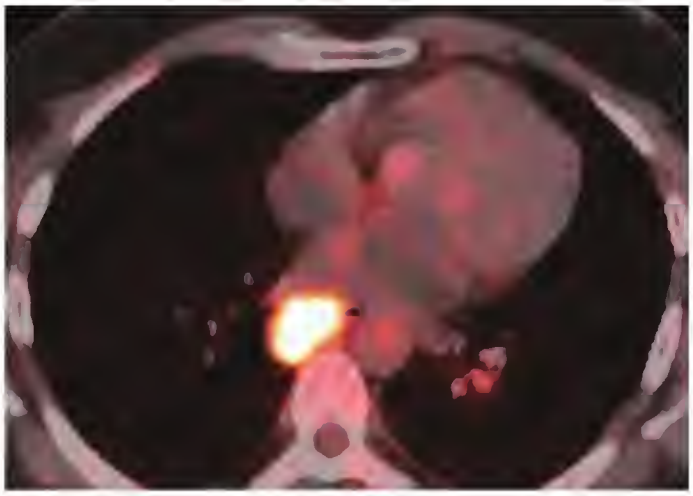

Figure 18: Axial PET/CT shows increased FDG uptake in a subcarinal lymph node.

issue. Recent studies have expressed concern over X-ray-induced cancer risk, especially in children. Proper adjustment of scan parameters, using radiation doses as low as reasonably achievable and avoiding indiscriminate use of this modality are some of the ways suggested for lowering this radiation risk.

CT VERSUS MRI

The soft tissue resolution of CT is not at par with that of MRI, especially in imaging of the brain and spine. However, CT scores in imaging of the lung, bowel and skeletal structures. CT is the modality of choice in acute and trauma settings due to shorter scan times.

CONCLUSION

Although the discovery of CT was a major break-through in the field of diagnostic radiology, the original model has undergone many changes and developments. The list of applications possible on a CT scanner is getting bigger and bigger as newer applications get added. The currently used multi-detector, multi-slice scanners offer sub-second scan times and provide true volumetric data with exquisite 3D renderings. With a large increase in the use of CT, radiation issues are emerging as a matter of concern, and need to appropriately be taken care of.

3.4 MRI in Medicine

Raju Sharma, Ankur Gadodia

INTRODUCTION

Over more than two decades since its clinical inception, magnetic resonance imaging (MRI) has found widespread application in nearly every area of medical practise. MR has had major impact on medical diagnosis and has replaced, many previous 'gold standard' invasive diagnostic procedures with safer and accurate alternative non-invasive imaging.

HISTORY

The phenomenon of nuclear magnetic resonance was discovered by physicists in the 1940s and was first utilised for imaging the human body in the late 1970s. The process of acquiring MR images was first illustrated by Lauterbur in 1973.

BASIC PHYSICS

MRI is based on excitation and detection of electromagnetic energy emitted by protons (H^+). Hydrogen nuclei (1H), possess the strongest magnetic moment and are in high abundance in the human body. Consequently, hydrogen is the most widely used element for MR imaging. On application of electromagnetic radiofrequency pulses, these protons emit signal which is received and converted into an image. The greatest advantage is excellent soft tissue contrast resolution. The physics of MRI is extremely complex and a full discussion of the same is beyond the scope of this chapter and a brief summary of the MR principles are discussed below.

The first step in MRI is application of a strong magnetic field. For this the patient is placed within a large magnet, either permanent or superconductive. The nuclei adopt one of two possible orientations: parallel or antiparallel to the external field. A greater proportion of nuclei align in the parallel direction, so that the net vector of their alignment, and hence net magnetic vector will be in the direction of the external field. Each nucleus spins around the line of the field in a motion known as precession. The frequency of this precession is given by the Larmor equation: $F = \gamma B_0/2\pi$ where F is the precessional frequency, B_0 is the strength of magnetic field, and γ is the gyromagnetic ratio of the nucleus.

The net magnetisation vector from the nuclei inside the magnet in its equilibrium state is static and does not produce a measurable signal. To obtain information from the spins, the direction of the net magnetisation vector has to be altered. This is done by applying a radiofrequency (RF) pulse at the same frequency as the Larmor frequency. The RF pulse causes the net magnetisation vector of the hydrogen atom to turn or flip towards the transverse plane, i.e. a plane at right angles to the direction of the external magnetic field. Following the cessation of the RF pulse, the extra energy is dissipated to the surrounding chemical lattice in a process known as T1 relaxation. In addition, the RF pulse brings the precessing protons in phase, i.e. their spins are now in synchrony. The process of the dephasing which occurs due to inhomogeneities in the nuclear magnetic environment is known as T2 relaxation. The component of the net magnetisation vector in the transverse plane induces a current in the magnetic coils (radiofrequency receiver coils). This current is known as the MR signal and is the basis for formation of an image. By varying the time of application of the signal (time to repetition or TR) or the time to acquiring the RF pulse (time to echo or TE) various image contrasts may be obtained.

Advantages of MRI include lack of ionising radiation, true multiplanar imaging, high soft tissue contrast and spatial resolution.

BASIC MR SEQUENCES

There are two basic MR sequences that are frequently used for MR imaging: spin-echo or gradient-echo techniques. Other sequences are modification of these basic sequences.

Spin Echo (SE) Sequences

Conventional spin echo pulse sequences are used to produce T1, T2 or proton density weighted images and are one of the most basic pulse sequences used in MRI. Spin echo sequences are still considered the gold standard in that the contrast they produce is easily understood and is predictable. Spin echo sequences are versatile, available on all scanners, produce true T2 weighting and are gold standard for image contrast and weighting. Disadvantage includes long scan times.

Fast Spin Echo (FSE) Sequences

Fast spin echo (FSE) is a much faster version of conventional spin echo, but may show different contrast and demonstrate decreased magnetic susceptibility effects. Fat appears bright on both T1W and T2W images, muscles appear darker on T2 weighted images and haemorrhage may be missed on FSE sequences. However, ferromagnetic implants do not show as much artefacts as other sequences. FSE sequences are usually used for brain, spine, joints, extremities and the pelvis. Advantages include short scan times, high resolution imaging and decreased magnetic susceptibility.

Gradient Recalled (GRE) Sequences

GRE images should be called T2* weighted not T2 weighted because of the effects of an imperfect magnetic field. Air pockets (sinuses or intestines), dense bone (skull base), and iron-rich blood breakdown products (methaemoglobin or haemosiderin) all change the main magnetic field in their immediate vicinity, so tissues around such inhomogeneities will experience different magnetic fields. One area where the prominent magnetic susceptibility artefacts on gradient recalled images can be used is in detection of haemorrhage. These sequences are typically shorter than routine sequences, and may yield significant image contrast.

Inversion Recovery (IR) Sequences

Short inversion time

Short tau inversion recovery (STIR) sequence has very low signal from fat but still has high signal from fluids. It is used in the spine and musculoskeletal system to visualise marrow oedema, fractures, avascular necrosis, metastases, etc.

Intermediate inversion time

These are used in paediatric neurology to better visualise gray white matter interface, to look for focal cortical dysplasia, heterotopias, etc.

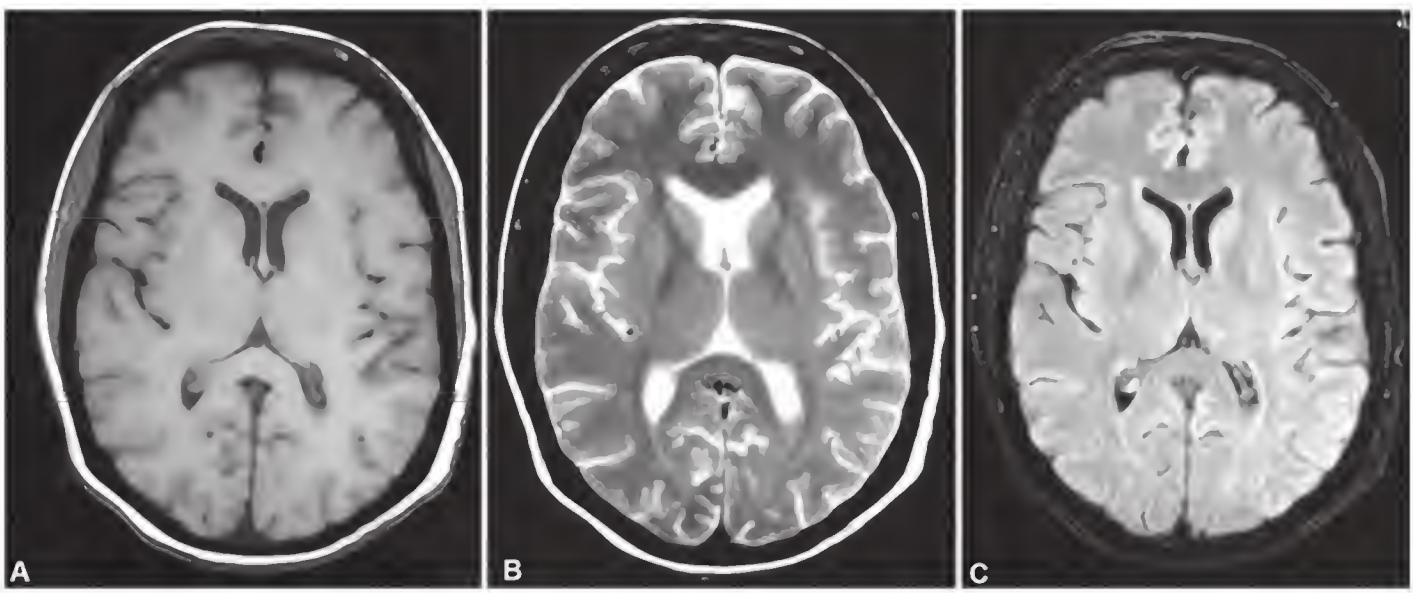
Long inversion time

Fluid attenuation inversion recovery (FLAIR) sequence uses long inversion times (1,800-2,500 ms), depending on field strength, to null the signal from cerebrospinal fluid (CSF). FLAIR is commonly used for neurological imaging to visualise periventricular lesions, white matter lesions. In addition, cortical changes which can also be hard to visualise with T2W sequences are made more prominent (**Figures 1A to C**).

Diffusion Weighted Imaging (DWI)

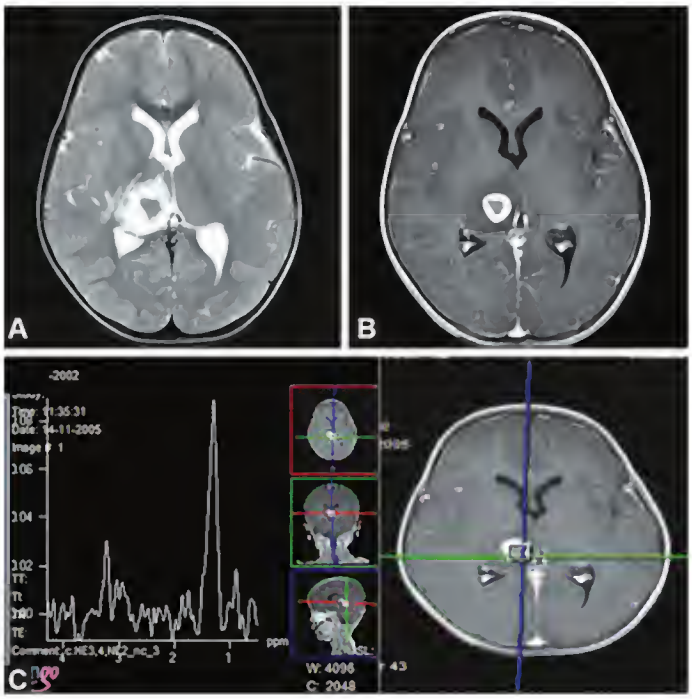
Diffusion is a term used to describe moving molecules due to random thermal motion. In normal tissues extracellular water diffuses randomly whereas in ischaemic tissue, cells swell and absorb water thereby restricting diffusion. DWI should be interpreted in conjunction with apparent diffusion co-efficient (ADC) maps. Bright area on DWI should also be viewed on ADC maps. If the lesions appear bright on ADC, the bright appearance on diffusion can be due to T2 shine through effect rather than true restricted diffusion, whereas lesions which are dark on ADC map represent restricted diffusion. One of the major uses for diffusion-weighted imaging sequence is in the diagnosis of recent stroke where areas of decreased diffusion represent infarction. DWI has also been used in the evaluation of other organs of the body such as liver, breast, kidneys and prostate. Whole body diffusion imaging is used in oncology for delineation of metastatic disease and response to treatment. Infarcts, encephalitis, abscesses, tightly packed tumours, metastases, epidermoid cysts, etc. also show restricted diffusion.

Perfusion Weighted Imaging (PWI)



Perfusion is a measure of the vascular supply to a tissue. Since vascular supply and metabolism are usually related, perfusion can also be used to measure tissue activity. Perfusion imaging utilises a bolus injection of gadolinium administered intravenously during ultrafast T2 or T2* acquisitions. This is used for evaluation of ischaemic disease or metabolic activity of tissues. On the cerebral blood volume (CBV) map, areas of low perfusion appear dark (stroke) whereas areas of higher perfusion appear bright (malignancies). Perfusion-weighted MR imaging has applications in the evaluation of a number of disease states, including cerebral ischaemia and reperfusion, brain tumours, epilepsy, differentiation between radiation necrosis and tumour recurrence and blood flow deficits in Alzheimer's disease.

MR Spectroscopy (MRS)



Spectroscopy provides a frequency spectrum of a given tissue based on the molecular and chemical constituents of that tissue. Spectroscopy has now become routine part of MR imaging to evaluate tissue metabolism. Proton spectroscopy has been used primarily for brain applications (**Figures 2A to C**) and recently for other organs, such as the liver, breast, prostate, and soft tissue. The use of spectroscopy expands the repertoire of anatomical information by providing information on intracellular metabolites. The major metabolites detected in the CNS are N-acetyl aspartate (NAA), a neuronal marker; choline, a marker for cellularity and cell membrane turnover; creatine, a marker for energy metabolism; and lactate, a marker for anaerobic metabolism. In addition to these metabolites, other metabolites that can be assessed include alanine, glutamine, myoinositol, and succinate.

Functional Imaging

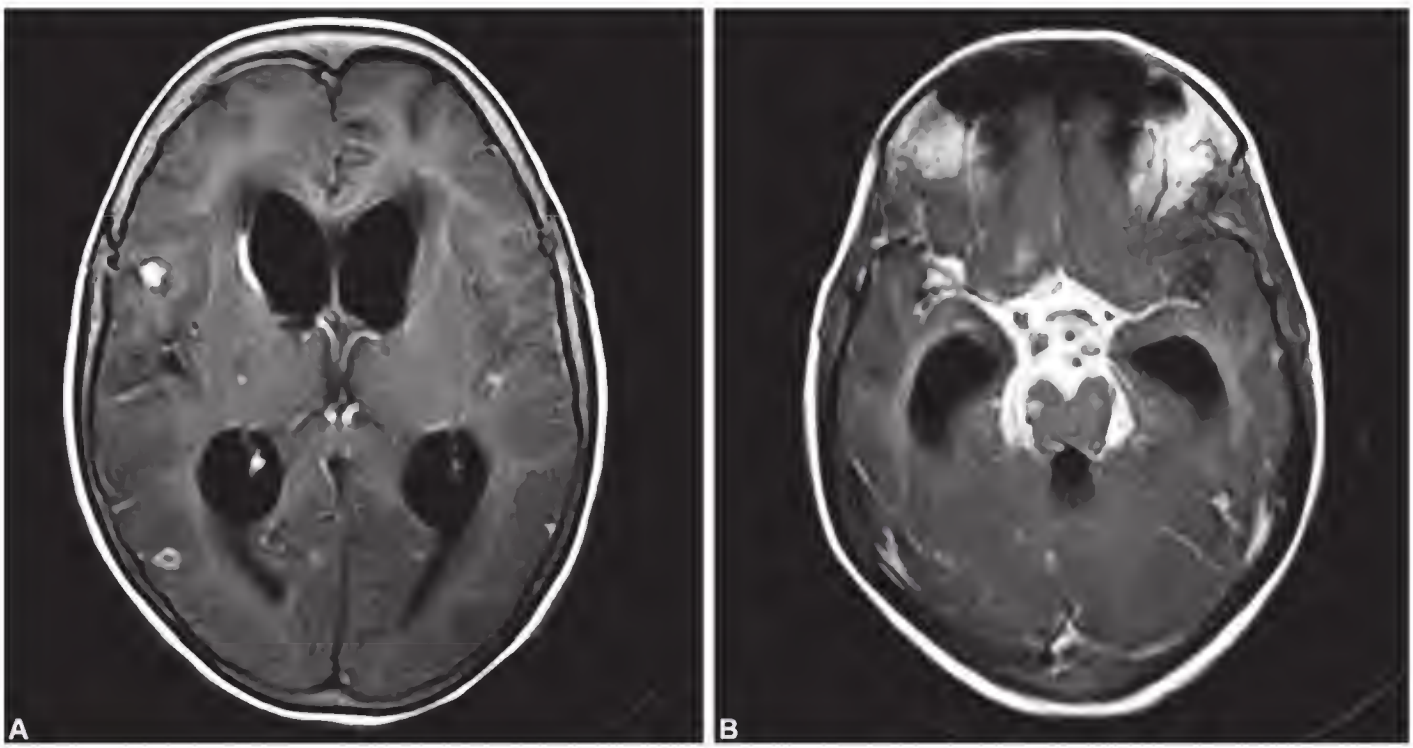
Functional MR imaging (FMRI) is a rapid MR imaging technique that acquires images of the brain during activity or stimulus and at rest. The two sets of images are then subtracted to depict regional cortical blood flow changes in space and time

Figures 1A to C: Axial T1W (A), T2W (B) and FLAIR (C) images of the cerebrum, mid ventricular level. CSF is hypointense on T1W and hyperintense on T2W images. In FLAIR sequence image, static fluid signal is selectively suppressed.

Figures 2A to C: Tuberculoma in a 23-year-old male. Axial T2W image (A) shows hyperintense lesion with central hypointensity seen involving the right thalamus. On post-contrast image (B) thick nodular rim enhancement is seen. Single voxel MR spectroscopy image (C) shows prominent lipid peak. These findings are suggestive of tuberculosis.

during performance of a particular task. An important clinical application of FMRI is presurgical mapping where relation of the functional areas can be defined in relation to mass lesions, thus selecting the appropriate management strategy (surgical versus non-surgical) and avoid damage to vital neural tissues. Other applications involve the understanding of brain functions, evaluation of stroke, epilepsy, pain and cognitive problems.

MR Angiography (MRA)



The principle of MRA is to acquire images where the signal returned from the flowing nuclei is high and the stationary nuclei is low. Thus, contrast between vessel and background tissue is achieved. MRA is used for non-invasive assessment of many vascular abnormalities, including aneurysms, dissection, stenosis, vessel anomalies, and coarctation. In many centers, MRA has emerged as the imaging modality of choice in the evaluation of the thoracic and abdominal aorta, and their major branch vessels, including the carotid, renal, and mesenteric arteries. It is also the modality of choice for getting an overview of all major arteries in diseases like aortoarteritis.

MR Contrast Agents

The most commonly used, clinically approved contrast for MR imaging, is a paramagnetic agent (atoms with unpaired electrons in their outer shells) containing gadolinium, a T_1-shortening agent. Contrast enhancement is extremely useful in evaluation of pathology like neoplasm, infection and inflammation. Gadolinium has the ability to pass through the breaks in the blood-brain barrier and thus is invaluable in imaging the nervous system pathologies (**Figures 3A and B**). In body imaging organs like liver, spleen, pancreas and kidneys enhance immediately after contrast injection and thus, rapid dynamic imaging is recommended for their evaluation.

MR HARDWARE

The hardware of a MRI machine consists typically of a cylindrical superconducting magnet surrounding the patient to generate a large, static magnetic field; gradient coils through which flowing current generates small changes in the magnetic field; radiotransmitter/receiver coils; electronics for radiofrequency transmitting and receiving; and a computer to reconstruct the spatial image from the frequency spectra.

Figures 3A and B: Tuberculoma with meningitis in an 18-year-old male. Axial post-contrast images (A and B) show thick enhancing exudates involving the basal cisterns with mild hydrocephalus. Also, note presence of homogenously ring enhancing lesions involving the right frontal and parietal lobes. These findings are suggestive of tuberculosis.

MR SAFETY AND CONTRAINDICATIONS

Any ferrous containing object is potentially dangerous within the MRI scanning room and patients are always advised to remove all ferromagnetic substances. Hearing aids, jewellery, watches, glasses, prostheses, credit cards and any type of implant should be removed before entering the scanner as they can potentially become a dangerous projectile. Current generation of orthopaedic implants including prosthetic joints, rods, screws, nails, clips, etc. are MR compatible and are not contraindications for MRI although they may significantly degrade image quality.

MR imaging is contraindicated for patients with metal implants or foreign bodies, such as intracranial aneurysm clips, intraorbital metallic foci, cardiac pacemakers, or specific types of cardiac valves. In these instances, these objects may be dislodged or damaged by the magnetic field. MR imaging may also be contraindicated for claustrophobic or uncooperative patients who may not respond to conscious sedation protocols. MRI examination poses almost no risk to the average patient when appropriate safety guidelines are followed.

BASIC CONCEPTS IN MR INTERPRETATION

As mentioned previously, various sequences are used to obtain image contrast. Most pathologies appear dark on T1 and bright on T2 and FLAIR (or STIR) images.

T1- and T2-Weighted Imaging

The selection of TE and TR determines the resulting image contrast. T1- and T2-weighted imaging are the most widely used sequences for soft-tissue delineation of anatomic structures and related pathologic conditions. On T1W images, tissues that have short T1 relaxation times (such as fat) appear as bright signal (**Table 1**). Tissues with long T1 relaxation times (such as cysts, cerebrospinal fluid and oedema) show as dark signal. On T2W images, tissues that have long T2 relaxation times (such as fluids) appear bright.

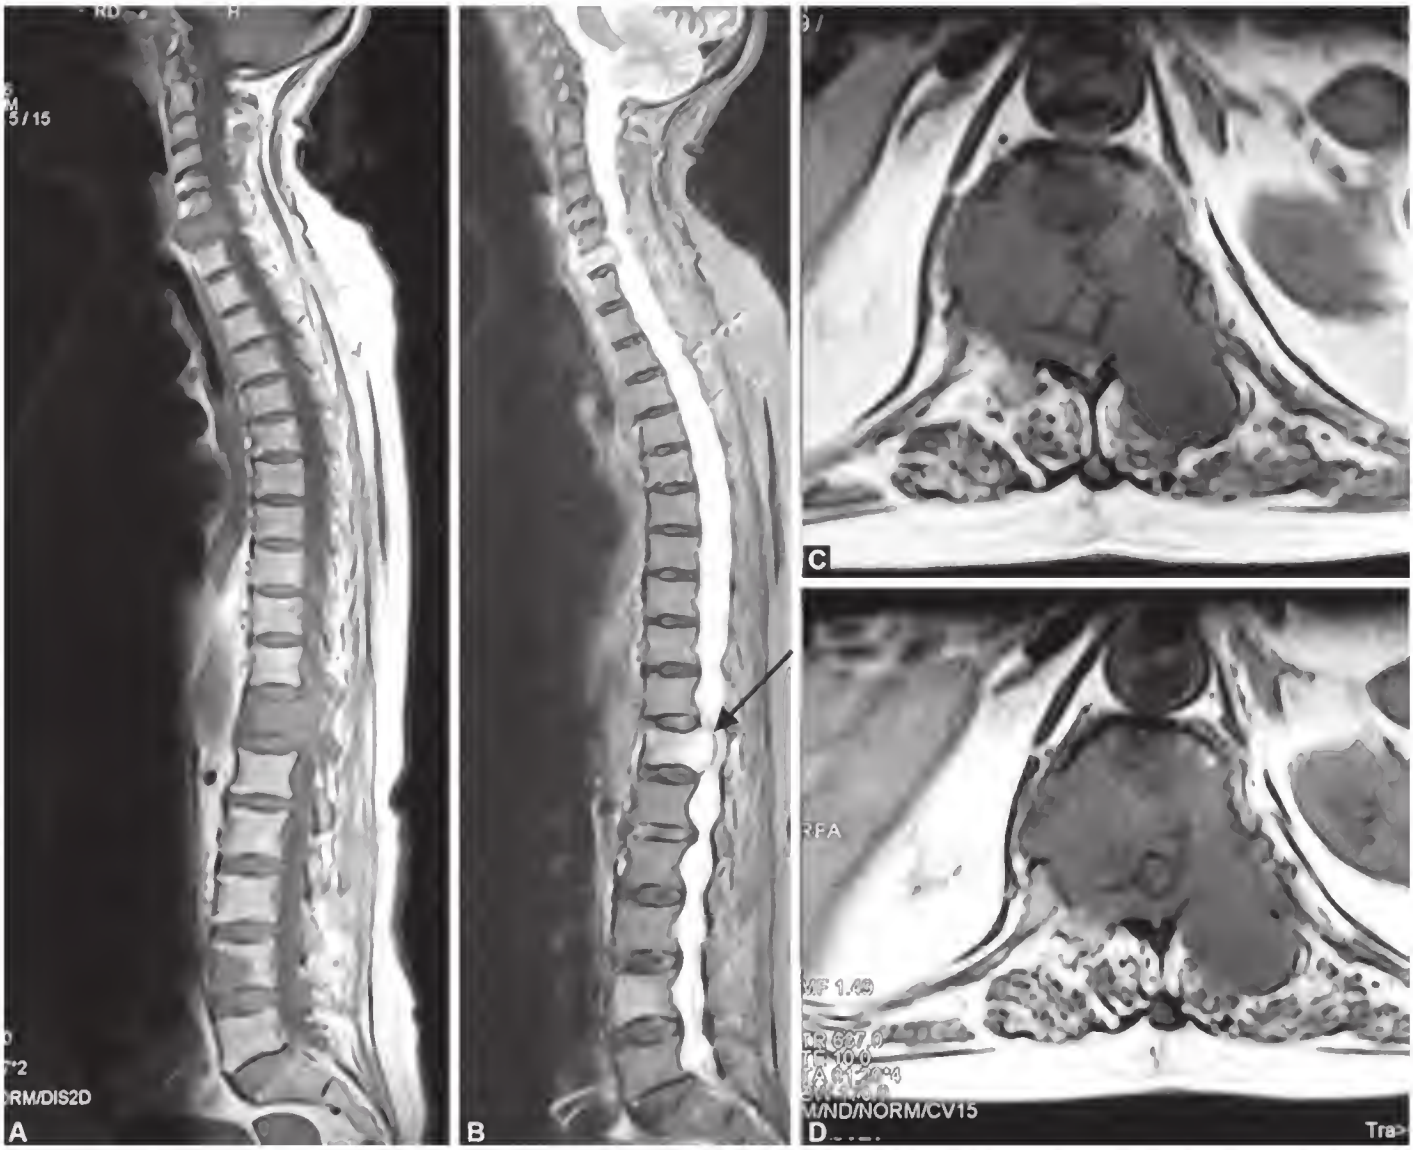
Table 1: Signal Intensities Seen on T1- and T2-W Images

	T1W	T2W
High signal	Fat Fatty marrow Methaemoglobin Slow flowing blood Radiation change Paramagnetic contrast agents Proteinaceous fluid Melanin	High free water (oedema, fluid, bile) Proteinaceous tissue Blood products (oxyhaemoglobin and extracellular methaemoglobin)
Low signal	Collagenous tissue (ligament, tendons) High free water (oedema, fluid, bile) cortical bone, Infection Tumours	Collagenous tissue (ligament, tendons) Cortical bone Bone islands De-oxyhaemoglobin Haemosiderin Calcification
No signal	Air Fast flowing blood Tendons Cortical bone Scar tissue Calcification	Air Fast flowing blood Tendons Cortical bone Scar tissue Calcification

HOW DO YOU DETERMINE THE SEQUENCE FROM THE FILM?

When confronted with a series of MRI images, the first thing to do is identify known areas of fluid, for example, CSF, vitreous chamber, the urinary bladder and renal pelvis. If these areas return a high signal, then the image is T2W. If the fluid is bright and the fat is dark then it is likely to be a fat suppressed T2 image/STIR image. If fat is bright and the fluid is dark then it is likely to be a T1W image. Contrast enhanced scans are usually labelled and are usually T1W sequences with or without fat suppression. Fat in these cases will then be dark and the images are usually compared with the pre-contrast T1W images to ascertain the degree, if any, of enhancement. The way to differentiate a plain scan from a post-contrast study of the brain would be to look at the nasal turbinates on T1W images. Post-contrast studies invariably show enhancement of the turbinates and bright signal.

Second option is to look for the printed TR and TE on the film. T1W images have short TR and TE (TR of the order of under 500-600 ms, while the TE is around 15-20 ms) whereas T2W sequences have longer TR and TE (TR of the order of more than 1,000 ms, TE over 80-100 ms). Inversion time (TI) is in the range of 100-180 ms in STIR and 1,800-2,500 ms in FLAIR images.



CLINICAL APPLICATIONS

Neurological Disease

Brain MR is the most commonly performed MR examination in most institutions. Common indications include – multiple sclerosis, primary tumour assessment and/or metastasis (**Figures 4A to D**), infections tuberculosis, toxoplasmosis, HIV)(**Figures 5A to D**), infarction (cerebral vascular accident vs. transient ischemic attack), haemorrhage, visual disturbances, epilepsy, trauma and unexplained neurological symptoms or deficit. Typically, most pathology appear hyperintense on T2W and hypointense on T1W images, but depending on the lesion morphology, area of involvement (grey matter vs. white matter), associated features (presence/absence of calcification, haemorrhage) and enhancement patterns one can come to a diagnosis. MR contrast agent (gadolinium) is required for assessment of tumours, infection and inflammation. Infectious process such as abscess shows intense thick nodular rim enhancement. Meninges enhance in infections (tuberculosis, pyogenic or viral meningitis) and leptomeningeal tumour spread. Contrast enhanced MR can also ascertain the age of the infarct.

MRI with diffusion (DWI) and perfusion imaging (PWI) has an important established role in identification of hyperacute infarct and ischaemia. An acute infarct shows on DWI as an area of relatively high signal (**Figures 6A to C**). DWI is the most sensitive imaging test available for the diagnosis of hyperacute infarction. Perfusion weighted imaging can also be used to calculate the relative blood supply of the particular volume of the brain. By combining PWI and DWI methods, if PWI is larger than DWI, then the area depicted may represent 'at risk' or penumbral tissue. Evaluation of these tissue characteristics is important for the targeting of therapeutic measures to optimise clinical outcomes. Thus, MR can accurately diagnose hyperacute infarct and identify ischaemic penumbra.

Owing to the relatively poor visualisation of acute haemorrhage, time taken for the performance of examination and logistic problem with monitoring equipment, MR has not been recommended for the initial screening of acute head trauma. It

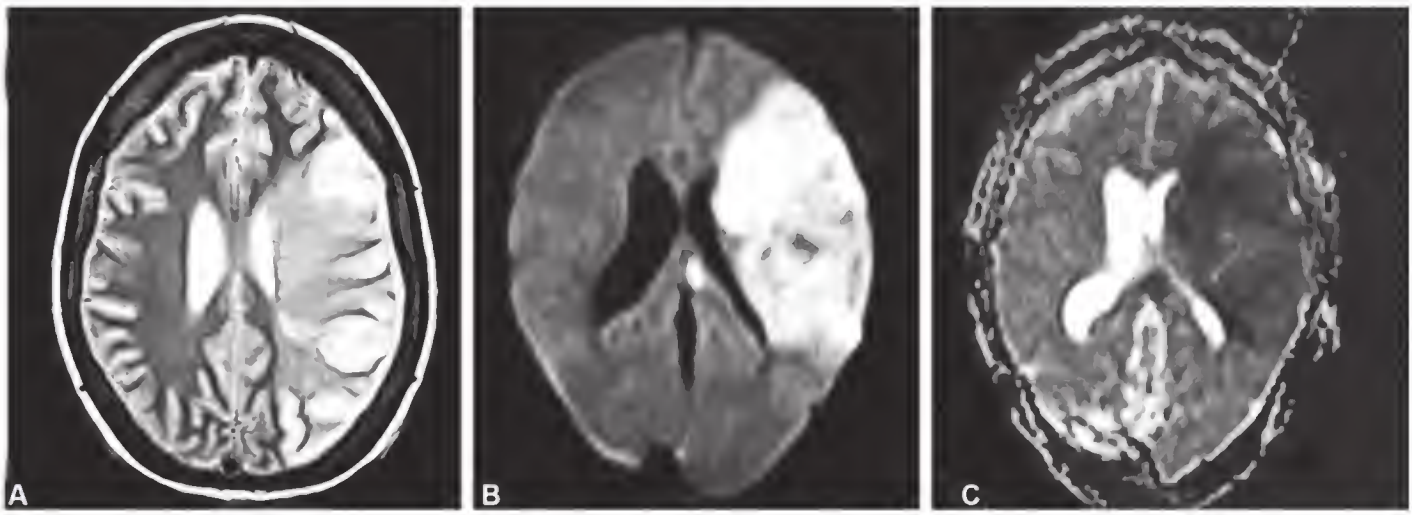
Figures 4A to D: Vertebral metastasis in a 68-year-old female. Sagittal T1W (A), T2W (B) MR images showing altered spinal signal intensity (hyperintense on T2W and hypointense on T1W) involving the bodies of multiple vertebrae. Axial T1W (C and D) MR images showing involvement of the both anterior and posterior elements of the vertebrae associated with soft tissue component extending into the spinal canal causing cord compression. Posterior vertebral margins of the involved vertebrae are showing convex borders (arrow).

is most useful in non-acute situation of otherwise stable patient with an ongoing neurological/ cognitive deficit. In particular, MRI is highly sensitive for detection of diffuse axonal injury.

MRA may be used to image cerebral vessels (vascular stenosis, aneurysms and vascular malformations). Sensitivity is similar to catheter angiography for detection of aneurysm of 3 mm or greater. MRA produces three dimensional images that can be rotated, manipulated on a working station, allowing a highly dedicated examination. MRA may also be useful in certain clinical presentation with a high probability of cerebral aneurysm. A common example is isolated third nerve palsy caused by aneurysm of posterior cerebral artery. MRA has largely replaced conventional arteriographic studies for evaluation of atherosclerotic disease, except in cases of critical stenosis (>70%).

Musculoskeletal Applications

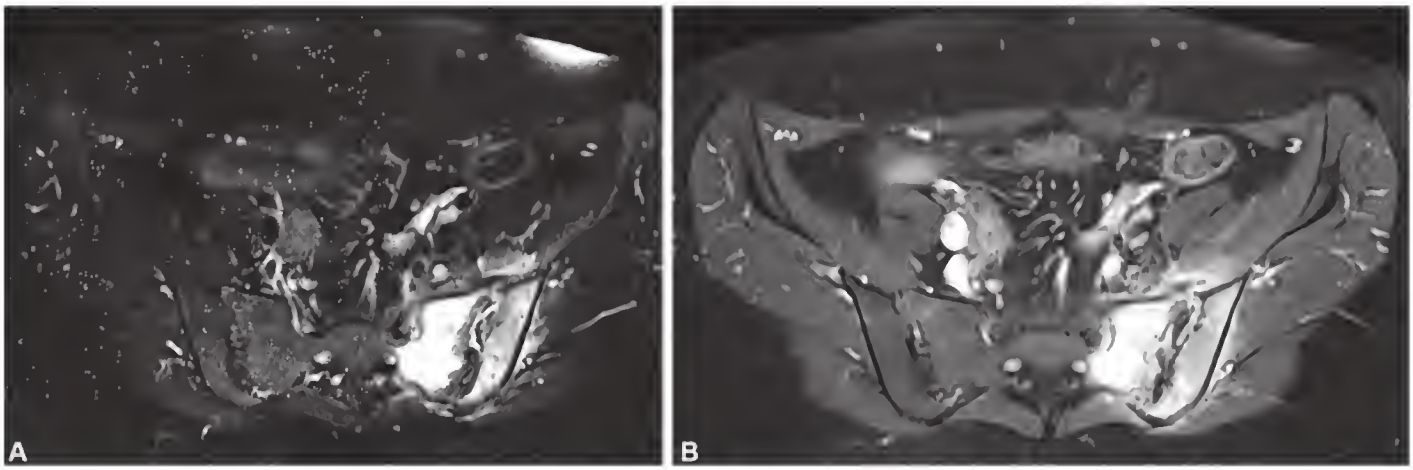
Applications in the musculoskeletal system include evaluation of internal derangement of joints (knee/hip/shoulder), soft tissue injury/inflammation, ligaments and tendons, bone marrow for marrow infiltration, bone infarcts or contusions. In musculoskeletal neoplasms, the role of MR is to demonstrate the extent of the lesion prior to surgery rather than primary characterisation for which plain radiographs are the investigation of choice. MR evaluates compartmental involvement (e.g. extension of bone tumours into soft tissues and joints), skip lesions within the bone marrow and status of neurovascular bundle. Role of intravenous contrast in musculoskeletal system is in evaluation of infection (bone, joint or soft tissues) (**Figures 7A and B**) and evaluation of post-operative spine to differentiate between scar tissue from non-enhancing residual disc.



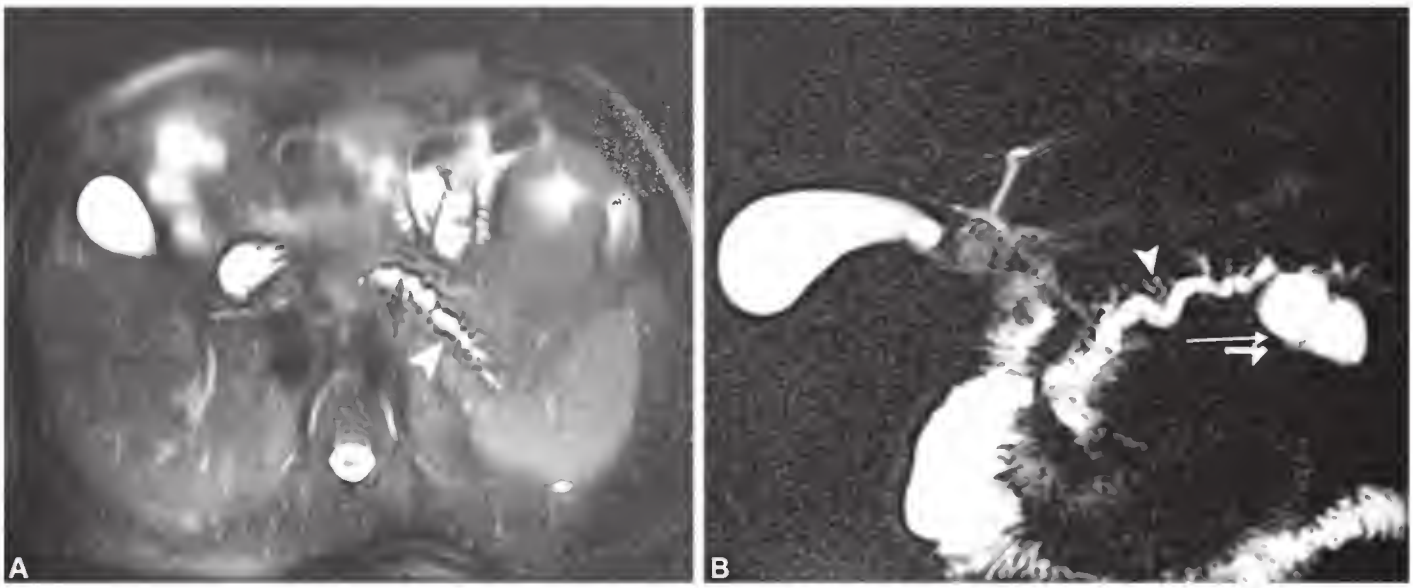
Advanced musculoskeletal MR applications include MR arthrography. In MR arthrography joint cavity is distended by intra-articular injection of dilute gadolinium. It is extremely useful in demonstrating the glenoid and labral tears (shoulder and hip) and in evaluation of the post-operative meniscus.

Hepatobiliary Applications

MRCP uses heavily T2 weighted sequences such as HASTE (half Fourier acquisition with single shot turbo spin echo) or RARE (rapid acquisition with relaxation enhancement) to visualise



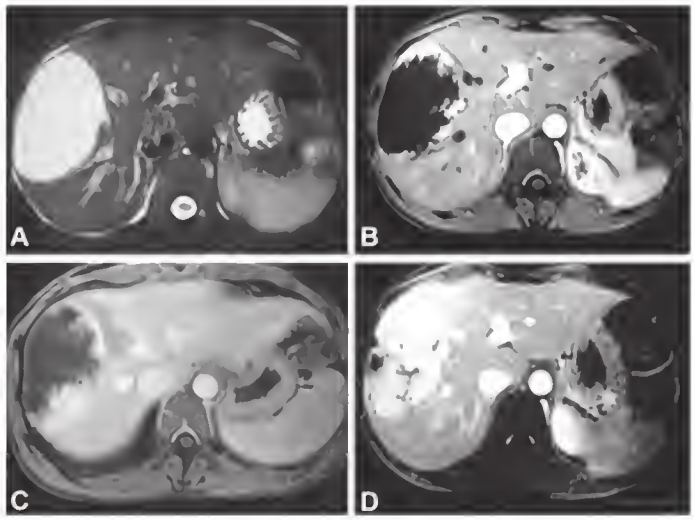
Figures 5A to D: Tubercular spondylodiskitis lumbar spine in a 44-year-old male. Sagittal (A) and Axial T2W (B) image shows hyperintensity and irregularity involving the end plate of two contiguous vertebras, intervening disc with small epidural component. Axial (C) and sagittal (D) post-contrast images demonstrates intense enhancement of two contiguous vertebrae, intervening disc and extradural soft tissue. Also note presence of prevertebral abscess.



Figures 6A to C: Acute infarct in a 60-year-old male. Axial T2W (A) image shows hyperintensity seen involving the left parietotemporal lobes (MCA territory), with mild mass effect. Diffusion weighted (B) image shows hyperintensity and ADC maps (C) show hypointensity in the corresponding area suggestive of restricted diffusion (cytotoxic oedema).

static fluid in the biliary and pancreatic ducts as high signal intensity. The heavy T2 weighting provides very high (bright) signal of static fluid within the biliary and pancreatic ductal systems, while the background tissues have very low (dark) signal (**Figures 8A and B**). These images look analogous to endoscopic retrograde cholangiopancreatography (ERCP) images.

MRCP is now the primary tool in the evaluation of biliary obstruction (calculi, intrinsic and extrinsic masses), intrahepatic bile duct diseases, post-surgical anatomic alterations, and congenital anomalies of the biliary and pancreatic tract. A potential use of MRCP is the demonstration of aberrant bile duct anatomy before cholecystectomy. MRCP is increasingly becoming the initial imaging modality for the biliary system, with ERCP reserved for only therapeutic indications. MRCP can be combined with other sequences for the comprehensive evaluation of the liver, biliary tree and pancreas. In

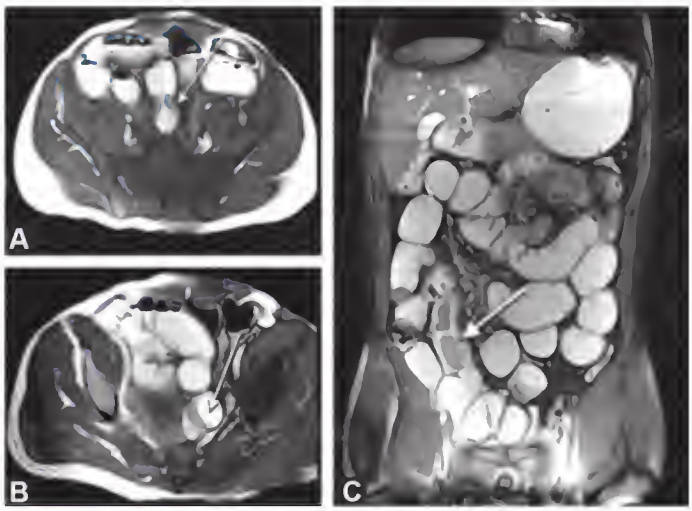


Figures 7A and B: Tubercular arthritis left sacroiliac joint in a 26-year-old female. Axial T2W (A) image shows hyperintensity involving the left sacral ala and the iliac bone, with joint widening and irregularities. Post-contrast (B) T1W image shows intense homogenous enhancement. Findings suggestive of infective sacroillitis.

Figures 8A and B: Chronic pancreatitis in a 37-year-old female. Axial T2W (A) and MRCP projectional (B) images show dilation of the main pancreatic duct (arrowhead) and side branches with a pseudocyst (arrow in B) involving the tail of the pancreas. These findings are suggestive of chronic pancreatitis.

choledocholithiasis/cholelithiasis, calculi appear as dark filling defects within the high-signal-intensity fluid. Benign strictures due to sclerosing cholangitis are multifocal and alternate with slight dilatation or normal-calibre bile ducts, producing a beaded appearance, whereas in malignant obstruction there is abrupt cut-off and eccentric wall thickening. The current limitation of MRCP is its relatively low spatial resolution.

Multiphasic contrast enhanced MR is the investigation of choice for characterisation of focal liver lesions and to look for presence of focal lesion in cirrhotic liver. In cirrhotic livers, MR can be helpful in differentiating between regenerative, dysplastic nodules and hepatocellular carcinoma. Hepatocellular carcinoma enhances in the arterial phase, washes out in the portal venous phase and shows capsular enhancement in delayed phase. On the other hand peripheral nodular discontinuous enhancement of a lesion with delayed fill in is typical of haemangiomas (**Figures 9A to D**). Peripheral arterial phase enhancement and portal venous phase wash out is typical of metastases. MRI is considered a non-invasive diagnostic tool for quantification of iron concentration in haemochromatosis. Liver specific contrast agents (contrast



Figures 9A to D: Liver haemangioma in a 43-year-old female. Axial T2W (A), post-contrast arterial phase (B), venous phase (C) and delayed phase (D) images show a well-defined mass lesion involving the right lobe of the liver. Mass is hyperintense on T2W images. Arterial phase image shows nodular discontinuous peripheral enhancement similar to signal intensity of the aorta. Venous and delayed phases show progressive fill on the contrast in the lesion. Findings are suggestive of liver haemangioma.

agents specific to the hepatobiliary or the reticuloendothelial system) add to the diagnostic capabilities of MR in problem cases.

Gastrointestinal Applications

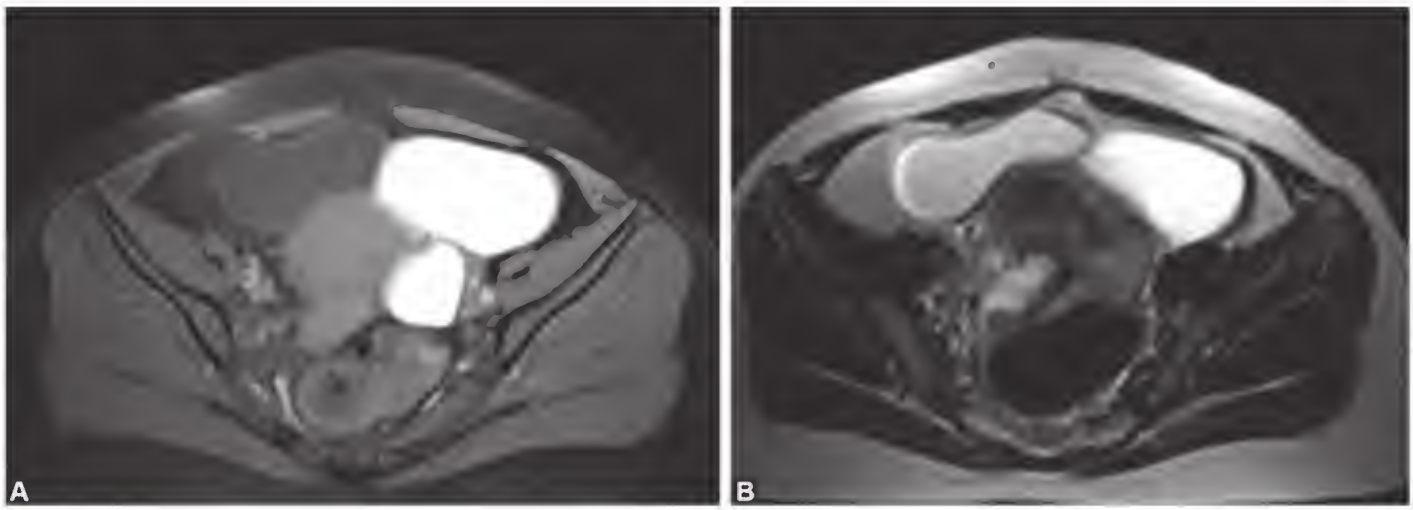
MRI of the bowel has been an under explored field of application for years. High soft tissue contrast resolution, acquisition of multiplanar images and the possibility to obtain functional information make MR a useful imaging technique to evaluate small bowel pathology. Applications include MR enteroclysis, MR colonography and MR virtual colonoscopy. The absence of ionising radiation is an important advantage of MRI examinations because inflammatory diseases such as Crohn's disease (CD) need to be followed up frequently, and are prevalent among young adults. MR enteroclysis (MRE) and MR colonography are emerging techniques for the evaluation (**Figures 10A to C**) of small and large intestinal diseases.

Figures 10A to C: MR Enteroclysis demonstrating tubercular small bowel stricture in a 20-year-old male. Tru-FISP (true fast imaging with steady-state precession) axial (A and B) and coronal (C) images show circumferential short segment wall thickening involving distal illeal loops.

Chest Applications

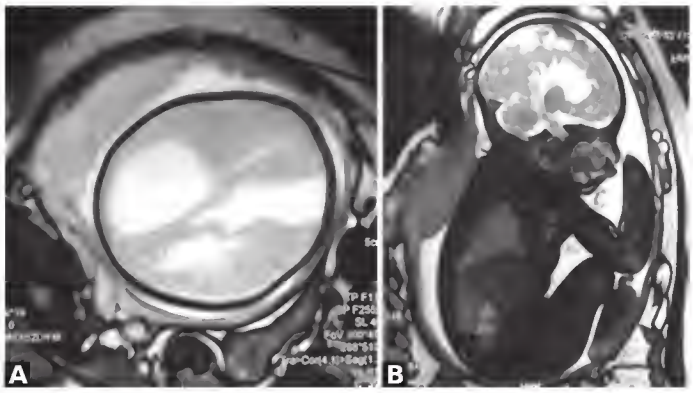
MRI does not substitute CT in the investigation of most thoracic conditions requiring cross-sectional imaging. MRI in chest has poor spatial resolution due to extremely low proton density of normal lung and strong susceptibility artefacts induced by the multiple air—soft tissue interfaces within the lung, and the consequences of cardiac and respiratory movement. The main indications for chest MRI include characterisation of mediastinal lesions that are equivocal on CT, evaluation of superior sulcus tumours, particularly if brachial plexus involvement is suspected and posterior mediastinal masses.

Cardiovascular Applications



Technical advances in MRI have led to increased application of this modality for comprehensive evaluation of cardiovascular diseases. Gradually, MRI has become the 'gold standard' for the assessment of numerous cardiovascular conditions. Important clinical indications of cardiac MRI include heart failure, ischaemic heart disease, myocardial viability, cardiac masses, congenital heart disease, and diseases of the myocardium, pericardium, valves and the entire vascular tree. Cardiac MR for ischaemic heart disease shows higher spatial resolution and sensitivity compared to stress thallium, particularly for subendocardial infarcts. Disadvantages include: longer scanning time, need for general anaesthesia, various contraindications including pacemaker.

Urological Applications



MRI is used as a problem-solving tool in renal imaging, to characterise indeterminate masses on ultrasound and computed tomography. MRI is an alternative to CT and is particularly useful in paediatric or pregnant patients, and in patients with renal insufficiency and when ionising radiation/iodinated contrast is to be avoided. MR urography (MRU) is clinically useful in the evaluation of suspected urinary tract obstruction, haematuria, and congenital anomalies.

Pelvic Applications

These include gynaecological conditions like pelvic pain or pelvic mass, especially to differentiate between uterine and adnexal masses, indeterminate adnexal masses on ultrasound, detection of adenomyosis (blurring and thickening of the junctional zone of uterus on T2 weighted images), differentiation between uterine fibroids and focal adenomyosis (fibroids appear well defined and hypointense on T2 weighted images while focal adenomyosis/adenomyomas appear poorly

Figures 11A and B: Endometriosis in a 24-year-old female. Axial T1W (A) and T2W (B) images show left adenaxal mass lesion. Mass is hyperintense on T1W images and shows mixed intensity (hyperintense upper part and hypointense lower part). These findings are suggestive of endometriosis.

Figures 12A and B: Foetal MR showing corpus callosal agenesis with dorsal interhemispheric cyst at 30 weeks gestation. T2W MR axial (A) and sagittal (B) images show dorsal interhemispheric cyst with absence of corpus callosum and dilatation of occipital horn (colpocephaly).

defined and may show intermediate to hyperintense speckling on T2 weighted images). While both endometriosis and dermoids might appear hyperintense (bright) on T1 and T2 weighted images, endometriosis is identified on T1 fat-saturated images as hyperintense due to haemorrhagic contents (**Figures 11A and B**), while fat in dermoids is suppressed. Another important application is the staging of carcinoma cervix and endometrium.

An important application of MR in the male pelvis includes the early detection of prostatic carcinoma using endorectal coils. Unlike other malignancies, prostatic carcinoma appears hypointense (dark) on T2 weighted images amidst the hyperintense peripheral zone. Early peri-prostatic spread, neurovascular invasion or seminal vesicle invasion is well detected on MR.

Obstetric applications of MR include early detection of foetal anomalies, especially when there is difficulty in sonographic visualisation due to unusual lie of the foetus, complex congenital malformation or insufficient amniotic fluid. Foetal MR is especially beneficial in evaluation of the sonographically occult or indeterminate and complex congenital malformations (**Figures 12A and B**). Foetal MR has an established role in the evaluation of neurological and chest anomalies.

RECENT ADVANCES

MR at 3 Tesla

Imaging at higher field strength (3.0-T MR) provides higher resolution and has already proved superior to 1.5-T systems in neuroradiologic and musculoskeletal applications. In the abdomen, 3.0-T MR imaging is beneficial for hepatic imaging, MRCP, angiography, diffusion-weighted imaging, and colonography.

Figures 13A and B: Takayasu's arteritis in a 16-year-old female. Maximum intensity projections of post-contrast MR angiogram (A) and invert image of A (B) demonstrates the narrowing of the proximal left subclavian artery, infrarenal aorta, bilateral common iliac arteries and left renal artery.

WB-MRI (Whole-Body MRI)

Technical improvements in the MR sequences, the remote movement of the imaging table, and the use of specialised surface coils have rendered whole-body screening with MRI a feasible method. Whole-body magnetic resonance imaging is an accurate, safe and fast technique for the demonstration of disease throughout the entire body. Whole-body MRI is used to depict metastases in disseminated metastasis and lymphoma. Whole-body MR angiography can be very helpful for detecting vascular diseases (atherosclerosis, vasculitis) in different anatomic regions of the body (**Figures 13A and B**).

3.5 Nuclear Imaging

BR Mittal

Nuclear Medicine is a field of medical practice where minute quantities of unsealed radioactive substances, which rely on the process of radioactive decay, are used for diagnosis, therapy and clinical research. These procedures provide supportive service to almost all branches of medicine. This unique ability of imaging and therapy is based on the cellular function and physiology rather than relying on the anatomy. Most diagnostic radionuclides emit gamma rays while radionuclides emitting beta particles are used in therapeutic applications. Radionuclides for use in nuclear medicine are produced either in nuclear reactors or in cyclotrons. The reactor produced radionuclides usually have longer half-lives, whereas those produced in cyclotrons have shorter half-lives. Radioisotopes are also generated by natural decay processes in dedicated generators, e.g. molybdenum/technetium or strontium/rubidium. Radionuclides when combined with other chemical compounds form radiopharmaceuticals which on being administered to the patient, localise to specific organs or cellular receptors. These radiopharmaceuticals emit gamma rays that are detected externally by sophisticated instruments such as gamma camera or PET scanners. This process is unlike diagnostic radiographs where external radiation is passed through the body to form an image.

Gamma camera is the basic equipment in nuclear medicine imaging. The uses of computers in conjunction with cameras provide data and information about the area of body being imaged. Planar studies provide a two-dimensional image whereas tomography provides three dimensional view of physiological and biochemical processes. Tomography is the process of producing a picture of a section through an object. It is performed either by transmitting X-rays through an object (transmission computed tomography, as in CT scanning), by measuring proton density (magnetic resonance imaging) or by tomographically detecting the distribution of radioactivity in a patient (emission computed tomography). The two most widely used emission tomographic studies are Single Photon Emission Computed Tomography (SPECT) and Positron Emission Tomography (PET). The three major categories of emission imaging are projection, longitudinal and transverse section imaging. Longitudinal tomography involves sampling over a limited range of angles and usually involves motion of a detector system parallel to long axis of the body. Transverse section tomography involves rotation of the detector system around the body with slices oriented perpendicular to the patient's long axis. The transaxial data is then rearranged to get coronal, sagittal (slice parallel to the patient's long axis) or oblique algorithms.

SPECT refers to tomography with standard nuclear medicine radiopharmaceuticals that emit single photons upon decay. Though emission tomography was reported by Kuhl and Edwards in 1963, but it was X-ray tomography introduced in 1973 by Hounsfield that had a tremendous impact in diagnostic imaging. Practical application of SPECT came into existence only after the advent of the modern computers and availability of rotating gamma camera system. The most apparent advantage of SPECT is its ability to remove the superimposition encountered in two-dimensional (planar) imaging leading to increased detection of lesions. The end result of the nuclear medicine imaging process is a "dataset" comprising one or more images. Multi-image datasets may be dynamic, representing a time sequence (cine or movie), a cardiac gated time sequence, or a spatial sequence where the gamma camera is moved relative to the patient. The computer provides quantitative information for each of the specific imaging techniques.

Nuclear medicine images can be superimposed, using software or hybrid cameras, on images from other modalities such as computed tomography (CT) or magnetic resonance imaging (MRI) to highlight the part of the body in which the radiopharmaceutical is concentrated. This is called image fusion or co-registration. Presently single photon emission computed tomography/computed tomography (SPECT/CT) and positron emission tomography/computed tomography (PET/CT) equipments are available as single units that are able to perform both imaging studies simultaneously. The fusion imaging technique allows information from two different studies to be correlated and interpreted on one image, leading to more precise information and accurate diagnosis. Nuclear medicine imaging procedures often identify abnormalities very early in the course of a disease, long before some medical problems are apparent with other diagnostic tests. This early detection allows a disease to be treated early in its course when there may be a more successful outcome.

Non-imaging procedures such as thyroid uptake tests, Glomerular filtration rate (GFR) estimations and haematological tests also form part of nuclear medicine. Some of the non-imaging functional studies like clearance studies, dilution techniques are other forms of in vivo diagnostic methods.

Radioimmunoassay constitutes its in vitro application. Radioimmunoassay and radioimmunometric assay were the first methods based on saturation analysis/competitive limited reagent/radiolabelled analyte to measure picomolar concentrations of biomolecules which otherwise is beyond the reach of conventional chemistry. This laid the foundation of modern endocrinology. These assays are also used to measure levels of hormones, vitamins and drugs in a patient's blood.

Beyond diagnosis, nuclear medicine also offers therapeutic applications. However, such applications are limited to a few

diseases like thyrotoxicosis, thyroid cancer, metastatic bone pain, neuroendocrine tumours, rheumatoid arthritis and radio-immunotherapy for some cancers, etc.

HISTORY

The origin of nuclear medicine stems from many scientific discoveries, most notably the discovery of "X-rays" in 1895 and the discovery of radioactivity in 1896 and "artificial radioactivity" in 1934. The first clinical use of artificial radioactivity was carried out in 1937 for the treatment of a patient with leukaemia at the University of California at Berkeley. The most fundamental principle of Nuclear Medicine is the tracer principle, invented by George Hevesy for which he received the Nobel Prize in 1944. Nuclear medicine gained recognition as a medical specialty in 1946 when a thyroid cancer patient's treatment with radioactive iodine caused complete disappearance of the spread of the patient's cancer. Although, the earliest use of Iodine-131 was devoted to therapy of thyroid cancer, its use was later expanded to include imaging of the thyroid gland, quantification of the thyroid function, and therapy for hyperthyroidism. Development of rectilinear scanner by Benedict Cassen and scintillation camera (Anger camera) by Hal O. Anger broadened the discipline of nuclear medicine into a full-fledged medical imaging specialty.

Among many radionuclides that were discovered for medical use, none were as important as the discovery and development of technetium-99m. The development of generator system to produce Technetium-99m in the 1960s became a practical method for medical use. Today, Technetium-99m is the most utilised element in nuclear medicine and is employed in a wide variety of nuclear medicine imaging studies. By the 1970s most organs of the body could be visualised using nuclear medicine procedures. The concept of emission and transmission tomography, later developed into single photon emission computed tomography (SPECT), was introduced by David E. Kuhl and Roy Edwards in the late 1950s. More recent developments in nuclear nedicine include the invention of the PET scanner. Fusion imaging with SPECT and CT was developed by Bruce Hasegawa from University of California San Francisco (UCSF), and the first PET/CT prototype by D.W. Townsend from University of Pittsburg in 1998.

DIAGNOSTIC NUCLEAR MEDICINE IMAGING

A nuclear medicine study involves administration of a radionuclide into the body by intravenous injection, ingestion while combined with food, inhalation as a gas or aerosol (**Tables 1 and 2**). In some studies patient's own blood cells are labelled with a radionuclide (leucocyte and red blood cell scintigraphy). Following administration, the radiotracer is distributed around the body and/or processed differently where disease or pathology is present. Focal increase in radiotracer accumulation results in a 'hot-spot' which represents increased physiological function. In some disease processes a 'cold-spot' may be visualised which represents non-concentration of radiotracer.

Table 1: The Commonly Used Intravenous Radionuclides in Nuclear Medicine

Radionuclide	Symbol	Half-life (T½)	Type of Emission	Energy (Kev) (Photon)
Technetium-99m	Tc99m	6.01 hours	IT	140
Iodine-123	^{123}I	13.2 hours	EC	159
Chromium-51	^{51}Cr	27.7 days	γ	320
Indium-111	^{111}In	2.8 days	EC, γ	171 245
Thallium-201	^{201}Tl	73 hours	EC	69-83* 135 167
Gallium-67	^{67}Ga	3.26 days	EC, γ	93 185 300
Fluorine-18	^{18}F	110 min	β^+	511
Rubidium-82	^{82}Rb	75 sec	β^+	511

*IT = Isomeric transition; EC = Electron capture; γ = Gamma; β^+ = Positron decay; *Mercury X-rays.*

Table 2: The Commonly Used Gaseous/Aerosol Radionuclides in Nuclear Medicine

Radionuclide	Symbol	Half-life (T½)	Type of Emission	Energy (Kev) (Photon)
Xenon-133	^{133}Xe	5.24 days	γ and β^-	81 346 β^-
Krypton-81m	^{81m}Kr	13 sec	IT	190
Technetium-99m DTPA aerosols	Tc99m	6.01 hours	IT	140
Technetium 99m Technegas	Tc99m	6.01 hours	IT	140

γ = Gamma; β^- = Negative decay; IT = Isomeric transition.

CLINICAL APPLICATIONS OF DIAGNOSTIC NUCLEAR MEDICINE

Nuclear Medicine scans may be used to diagnose a number of medical problems. Some of the more frequently performed tests are highlighted below. This is not meant to be exhaustive, and for a more detailed account the reader may refer to the standard nuclear medicine text books, journals and periodicals. Positron Emission Tomography is discussed in a separate chapter of this section.

Endocrine Applications

Thyroid

Thyroid scintigraphy generates one or more images of the thyroid obtained after injection/ingestion of the tracer. Common indications are:

(a) Localisation of ectopic thyroid tissue (i.e. lingual) or to determine whether a suspected thyroglossal duct cyst is the only functioning thyroid tissue present.

(b) To evaluate a neck or substernal mass. Radionuclide scintigraphy may be helpful to confirm if the mass is functioning thyroid tissue.

(c) To assist in evaluation of congenital hypothyroidism.

(d) Differentiation of thyroiditis (i.e. subacute or silent) and factitious hyperthyroidism from Graves' disease and other forms of hyperthyroidism.

(e) Functional evaluation of thyroid nodules and masses (**Figure 1** shows a case of cold nodule of right lobe of thyroid gland).

(f) Distinguishing Graves' disease from toxic nodular goiter, a distinction of significance in determining the amount of Iodine-131 to be given as therapy for hyperthyroidism. (**Figures 2 and 3**).

(g) Post-operative assessment of differentiated thyroid cancer.

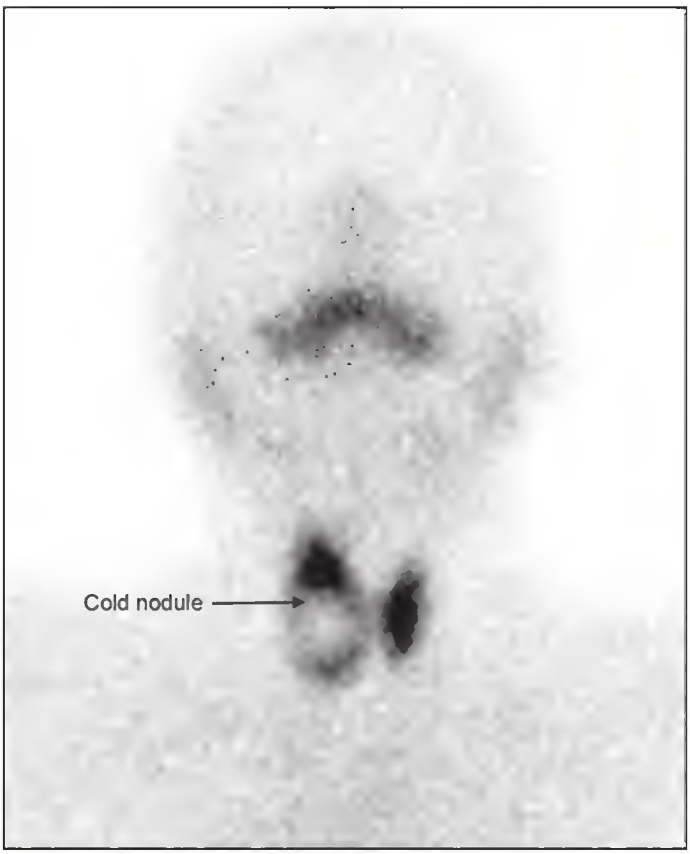
(h) Radioactive iodine uptake (RAIU) for calculating Iodine-131 therapy dose for treating hyperthyroidism.

(i) Perchlorate discharge test for identification of organification defects.

(j) Radioimmunoassay/radioimmunometric assay for measurement of free and total T3, T4 and TSH.

Commonly used radiotracers for thyroid imaging are Tc99m (pertechnetate), Iodine-123 and Iodine-131.

Thyroid evaluation is one of the most frequently performed nuclear medicine procedure. Thyroid scintigraphy plays an extremely important role in the classification of thyroid pathology. The radiation dose to the thyroid is meagre with Technetium-99m, but may be significant with Iodine-131. Hence, lower doses of Iodine-131 are utilised and imaging is not ideal when this radioisotope is used.



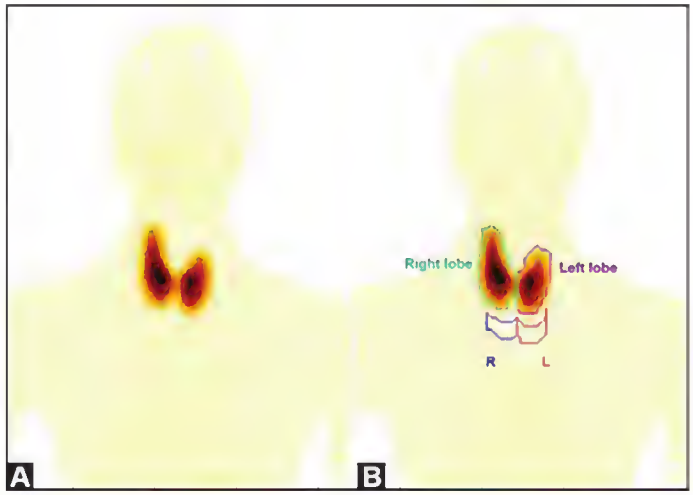


Figure 1: ^{99m}Technetium thyroid scintigraphy showing a non-functional (Cold) nodule in the right lobe of thyroid gland. Rest of the thyroid gland shows homogenous tracer uptake.

Figures 2A and B: ^{99m}Technetium thyroid scintigraphy showing (A) enlarged thyroid gland with increased tracer uptake (B) technetium uptake calculated by drawing ROIs showed 10% uptake (Increased) suggesting hyperthyroidism.

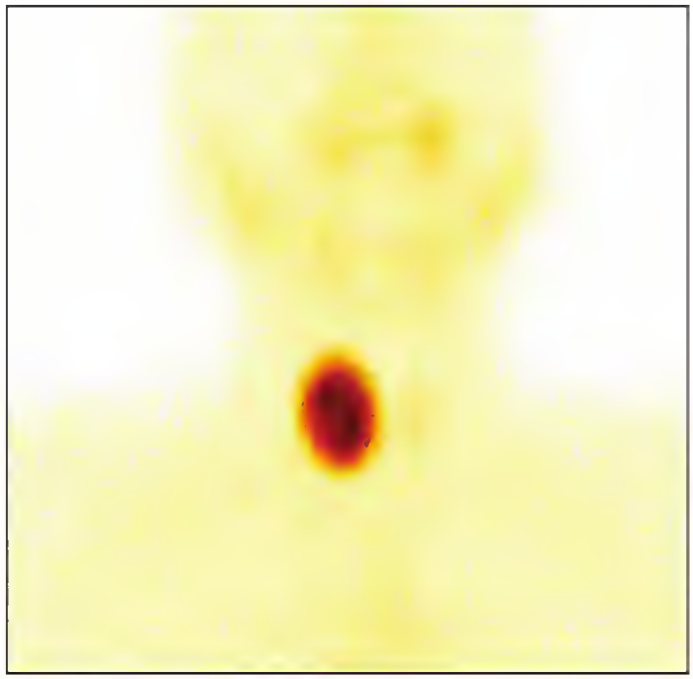

Figure 3: ^{99m}Technetium thyroid scintigraphy showing tracer uptake in a nodule in the right lobe of thyroid gland. Rest of the thyroid gland doesn't show tracer uptake. Findings are consistent with autonomously functioning toxic adenoma.

Parathyroid scintigraphy

(a) Localisation of hyperfunctioning parathyroid tissue (adenomas) in primary hyperparathyroidism and in patients with persistent or recurrent disease.

(b) Gamma probe guided surgery.

Thallium-201 or Tc99m-sestamibi are the tracers employed for parathyroid imaging.

Over 90% of the primary hyperparathyroidism is caused by a single parathyroid adenoma. Most of the parathyroid adenomas are identified by scintigraphy (**Figure 4**) and hence allows limited surgical approach rather than bilateral neck exploration, reducing the morbidity and hospital stay of these patients. Gamma probe guided surgery combined with intra-operative PTH assay has the potential for reduced hospital stay and patient morbidity. Parathyroid scintigraphy has lower specificity in the

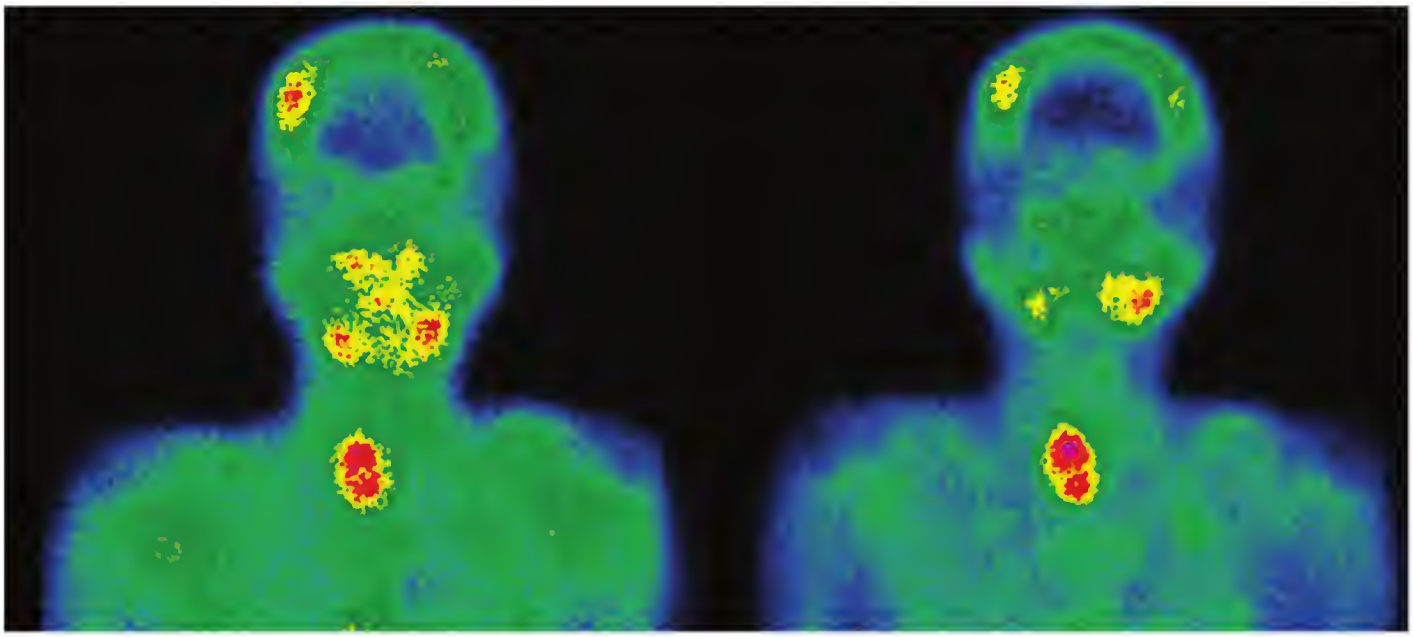

Figure 4: Dual phase Tc99m sestamibi parathyroid scintigraphy shows focal tracer uptake in the region of the right lobe of thyroid. Tracer retention is noted in the lesion at 1 hour. The findings are consistent with large right inferior parathyroid adenoma.

presence of thyroid adenomas. However, the use of subtraction scintigraphy allows reasonable differentiation of thyroid from parathyroid adenomas.

Ultrasonography has high specificity in the diagnosis of parathyroid adenomas but has insufficient sensitivity and inter-observer variability. CT and MRI are also used in the evaluation of parathyroid disorders.

Adrenal medulla

The important tumours of the adrenal medulla are Pheochromocytoma and Neuroblastoma.

The nuclear scan is usually performed with Iodine-123/Iodine-131 labelled Metaiodobenzylguanidine (MIBG). Tc99m HYNICTOC is also used for this.

Iodine-131 MIBG has a specificity of >95% in detection of functioning neuro-endocrine tissue (**Figure 5**) and is mandatory before considering radionuclide therapy with high dose Iodine-131 MIBG. However, sensitivity is lower because of the limited spatial resolution and poor imaging characteristics of Iodine-131. MRI is an excellent modality for the evaluation of adrenal medullary disorders but is incapable of providing the functional status of the lesion. Further, whole body evaluation is possible with scintigraphy.

Adrenal cortex

Scintigraphy is useful in the evaluation of Cushing's syndrome and Conn's syndrome.

Commonly used radiotracer for this is iodine-131 iodocho lestrol/NP-59. With the advent of high resolution cross-sectional imaging like CT and MRI, the role of nuclear medicine in the evaluation of adrenal cortical pathologies has diminished. PET has an extremely important role in the evaluation of adrenal masses and has been shown to exceed CT/MRI in both sensitivity and specificity in evaluation of adrenal masses in known/suspected malignancies.

Genitourinary Applications

Dynamic renal scintigraphy provides information about the blood flow to the kidneys, parenchymal function and drainage from the collecting system. Static cortical scintigraphy is useful in evaluation of relative kidney function and morphological abnormalities. Common indications of renal scintigraphy are:

(a) Diuretic renography for detecting urinary tract obstruction (ureteropelvic or vesicourethral).

(b) Captopril renography to diagnose and prognosticate renovascular hypertension.

(c) Evaluation of kidneys in prenatal Ultrasonography (USG) diagnosis of hydronephrosis.

(d) Renal transplant evaluation.

(e) Measure differential renal function in renal insufficiency.

(f) Renal cortical scintigraphy for detecting pyelonephritis and cortical scars (**Figure 6** shows cortical scars).

(g) Localisation of ectopic kidney and evaluation of anatomical abnomalities.

(h) Radionuclide cystourethrography for vesico-ureteric reflux, (**Figure 7** shows a case of right VUR).

(i) Measurement of GFR/effective renal plasma flow (ERPF).

(j) Detect testicular torsion vs. epididymo-orchitis.

For most purposes the radiotracer used is Tc99m-DTPA or Tc99m-MAG_3 or Tc99m- EC. For anatomical visualisation, the preferred radiotracer is Tc99m-DMSA though sometimes Tc99m-GHA may also be used if DMSA is not available.

Renal scintigraphy has the advantages of providing functional parameters like cortical function and GFR. It plays an extremely important role in the follow-up of patients. The radiation dose delivered by renal scintigraphy is often lower than radiographic procedure like micturating cysto-urethrogram (MCUG) and intravenous pyelograms (IVP). Renal scintigraphy is also less traumatic to the patients.

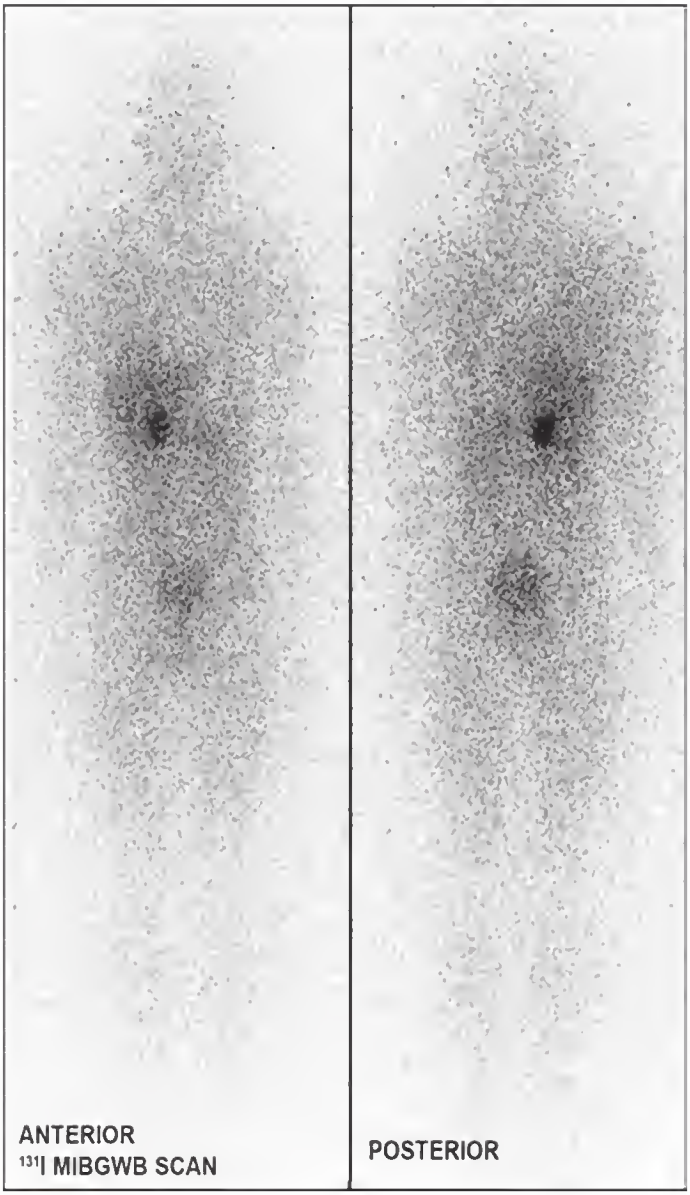

Figure 5: Whole-body ^{131}I MIBG scintigraphy obtained 48 hours after administration of MIBG showing a focus of tracer uptake in the right hypochondrium suggesting a functional neuro-endocrine tumour. The patient had right adrenal pheochromocytoma.

Ultrasonography is an inexpensive initial modality for evaluation of the genito-urinary system. However, operator dependence and inability to differentiate dilated unobstructed systems from obstructed systems mandate further evaluation with scintigraphy. IVP requires bowel preparation and contrast administration and doesn't provide quantitative functional parameters as scintigraphy.

Skeletal System Applications

Bone scintigraphy evaluates the distribution of active bone formation in the body. Whole-body bone scintigraphy produces anterior and posterior planar images of the skeleton, both axial and appendicular. Multiphase bone scintigraphy usually includes blood flow images of the area of region of interest, immediate blood pool static planar images, and delayed images at 3-4 hours. Delayed images may be limited to the areas of interest or may include the whole body (planar or tomographic). Common indications are:

(a) Neoplastic disease: demonstration of skeletal metastasis from various solid malignancies like breast, prostate (**Figure 8** shows a typical case of widespread skeletal metastases).

(b) Early diagnosis of osteomyelitis (**Figure 9**).

(c) Evaluation of diabetic foot for osteomyelitis vs. Charcot's joint.

(d) Evaluation of prosthetic implant for infection or sterile inflammation.

(e) Detection of bone graft viability.

(f) Evaluation of metabolic bone diseases.

(g) Identify occult bone trauma (sports injuries like stress fractures, occult fracture, shin splint).

(h) Diagnosing avascular necrosis of the femoral head.

(i) Evaluate arthritic changes and extent.

(j) Evaluation of chronic regional pain syndrome (CRPS) (Reflex sympathetic dystrophy).

(k) Measure extent of certain tumours and localise sites for biopsy in tumour patients.

(l) Evaluation of otherwise unexplained bone pain, especially low backache.

(m) Identify bone infarcts such as in sickle cell disease.

(n) Distribution of osteoblastic activity before radionuclide therapy for bone pain.

The commonly used radiotracer for bone scan is Tc99m-MDP. Skeletal scintigraphy is extremely sensitive but lacks specificity. With the advent of hybrid scanners, the information obtained from CT is used to increase the specificity of bone scintigraphy. To increase the specificity of bone scintigraphy, a second imaging agent may be used e.g.; positive bone scan patient, in a case of suspected prosthetic infection, may be subjected to labelled WBC scan.

Cardiac Applications

Myocardial perfusion imaging (MPI), multigated radionuclide ventriculography (MUGA), first pass study are the common procedures.

Myocardial perfusion imaging: MPI identifies areas of reduced myocardial blood flow associated with ischaemia or scar. The relative regional distribution of perfusion can be assessed at cardiac stress, rest or both. Imaging can also be performed during acute events such as in the coronary care unit or emergency department. Common indications include:

(a) Diagnosis of physiologically significant coronary artery disease (presence and severity). (**Figure 10** shows a case of ischaemia in the inferolateral wall).

(b) Determine prognosis (risk stratification based on extent and severity of myocardial perfusion abnormalities and left ventricular function.

(c) Differentiate between coronary and non-coronary causes in patients with acute chest pain syndromes seen in the emergency room.

(d) Cardiac risk assessment for patients undergoing major non cardiac surgery.

(e) Differentiate ischaemic from idiopathic cardiomyopathy.

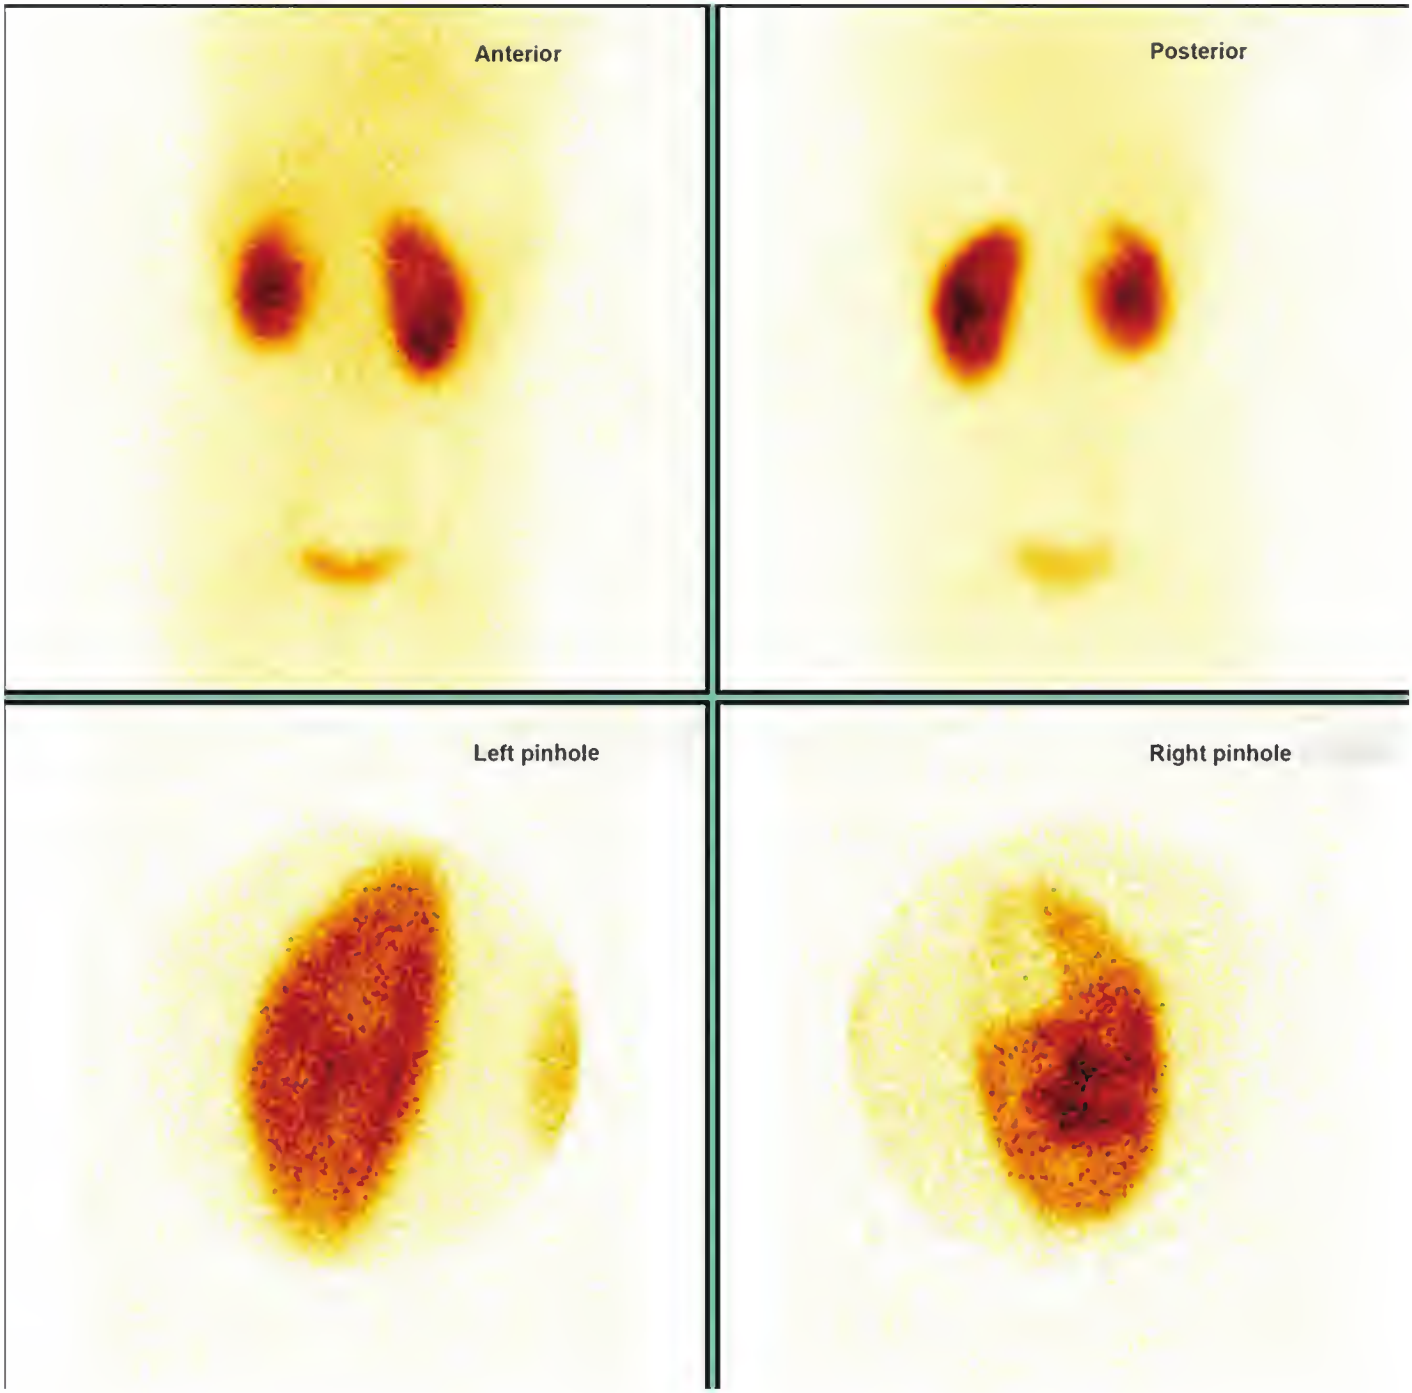

Figure 6: Tc99m DMSA static planar (arterior and posterior) and pinhole images of the kidneys showing smaller right kidney with break in cortical outline in the upper pole of right kidney suggestive of presence of a cortical scar.

(f) Assessment of viable myocardium overlying the infarction to consider revascularisation.

(g) Evaluate the immediate and long-term effects of revascularisation procedures and medical or drug therapy.

Myocardial perfusion imaging is a gate-keeper to invasive coronary angiography. With the advent of CT coronary angiography, there is an increase in the number of equivocal coronary lesion whose physiological significance needs to be evaluated with MPI. MPI, apart from providing information about the perfusion status, also provide various functional parameters like ventricular ejection fraction, systolic and diastolic volumes, myocardial mass and prognostic information. A normal stress MPI has less than 1% risk of contracting any major cardiac event.

Multigated equilibrium radionuclide ventriculography: MUGA is a procedure where patient's red blood cells (RBCs) are radiolabelled and ECG gated cardiac scintigraphy is obtained. Parameters obtained from MUGA include (i) global ventricular ejection fraction, (ii) systolic and diastolic function indices, (iii) regional wall motion, (iv) ventricular volumes, (v) stroke volume ratios. Common indications are:

(a) Evaluation of known or suspected coronary artery disease.

(b) Distinguishing systolic from diastolic causes of congestive heart failure (CHF) in patients with known or suspected CHF.

(c) Measure cardiac toxicity in patients undergoing chemotherapy.

(d) Assessment of ventricular function in patients with valvular heart disease.

(e) Monitoring response to surgery or other therapeutic interventions.

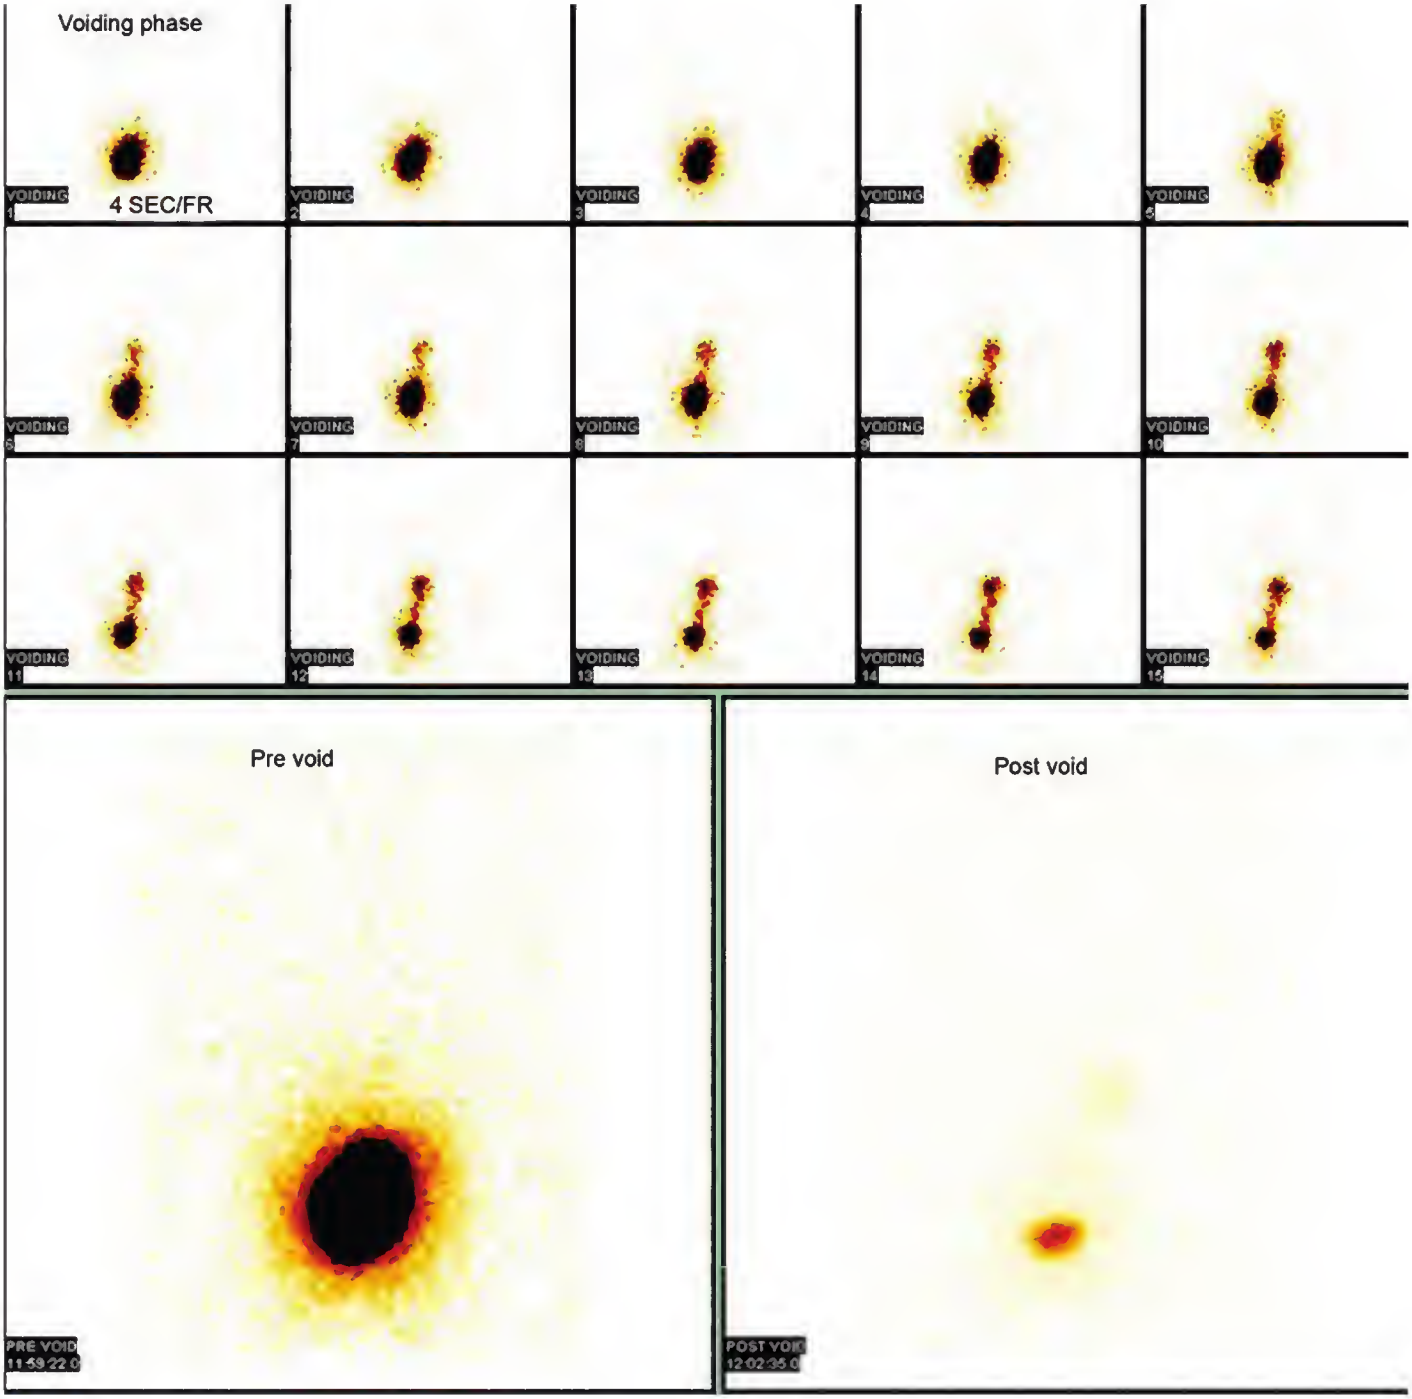

Figure 7: Direct radionuclide cystography (DRCG) study showing left vesico-ureteric reflux. Tracer activity in the urinary bladder is noted refluxing into the left ureter and renal pelvis during the voiding phase of the study.

First pass studies help to identify and quantify shunts and evaluation of right heart failure.

Thallium-201, Tc99m-sestamibi, Tc99m tetrofosmin are the radiotracers for myocardial perfusion imaging. MUGA study is performed with labelled erythrocytes. First pass study to evaluate right heart function or shunts can be performed with any Tc99m labelled tracer.

MUGA study is the current gold standard for the evaluation of LV ejection fraction and is proving indispensable in the evaluation of patients undergoing cardio-toxic chemotherapy.

Pulmonary Applications

Perfusion scintigraphy measures the distribution of pulmonary arterial blood flow. Ventilation scintigraphy records the bronchopulmonary distribution of an inhaled radioactive aerosol within the lungs. Pulmonary lung scintigraphy for pulmonary embolism assesses pulmonary perfusion and often includes ventilation scintigraphy. The most common indications are:

(a) Determination of the likelihood of pulmonary embolism.
(b) Quantify lung ventilation and perfusion as preoperative evaluation.
(c) Evaluation of lung transplantation.
(d) Right-to-left shunt evaluation.
(e) Detect pulmonary complications of AIDS.
(f) Detect inhalation injury in burn patients.

Lung perfusion scan is performed with Tc99m-microspheres of albumin while ventilation scan is performed either with Xenon 133 or with Tc99m-DTPA aerosols/technegas.

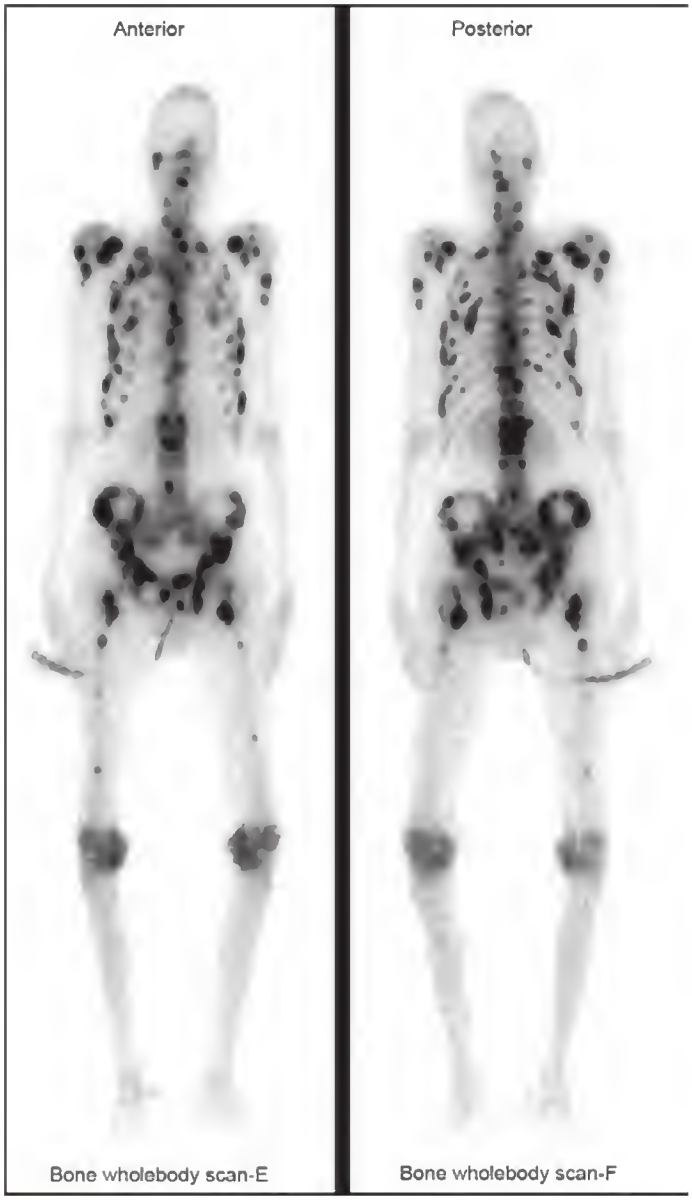

Figure 8: Tc99m-Methylene diphosphonate (MDP) bone scintigraphy showing multiple foci of increased tracer uptake involving several bones. The findings are consistent with widespread skeletal metastasis.

Inspite of the introduction of CT pulmonary angiography, ventilation-perfusion (V/Q) scintigraphy has continued to have important role. V/Q scan delivers far less radiation to the female breast than CT angiography. V/Q scan also serves as a baseline for the evaluation of response to anti-coagulants (**Figure 11**). Of late, the utility of V/Q scintigraphy has also been studied in parenchymal lung disease and asthma. One of the drawbacks of V/Q scan is the large number of indeterminate scans but with the advent of V/Q SPECT, the indeterminate scans have been reduced to <1%. In summary, V/Q SPECT performs equal to CT pulmonary angiography with far less radiation exposure.

Gastrointestinal Applications

Hepatobiliary scintigraphy

Hepatobiliary scintigraphy evaluates hepatocellular function and patency of the biliary system by tracing the production and flow of bile from the liver through the biliary system into the small intestine. Sequential images of the liver, biliary tree and gut are obtained. The common indications are:

(a) Evaluation of suspected acute cholecystitis.
(b) Evaluation of suspected chronic biliary tract disorders.
(c) Determine causes of jaundice and identify obstruction in the biliary passage.
(d) Detection of bile extravasation.
(e) Evaluation of congenital abnormalities of the biliary tree.
(f) Liver and gallbladder scans to evaluate liver and gallbladder function.
(g) Liver (reticulo endothelial cells) scans for cirrhosis, non-cirrhotic portal fibrosis (NCPF), tumours, space occupying lesions, etc.

Scintigraphy suffers from limited anatomical resolution which precludes detection of small lesion and to localise the exact sites of biliary leaks. Some of the studies require many hours to complete.

Gastrointestinal tract motility studies

Gastrointestinal tract motility studies include oesophageal transit, gastro-oesophageal reflux studies, gastric emptying studies, intestinal and colonic transit studies. Gastrointestinal bleeding scans are used to identify bleeding into the bowel.

Gastric emptying and motility: Radionuclide studies of gastric emptying and motility are the most physiologic studies available for studying gastric motor function. The study is noninvasive, uses a physiologic meal (solids with/without liquids), and is quantitative. Serial testing can determine the effectiveness of therapy. Indications for gastric emptying include:

(a) Suspected gastroparesis
(b) Poor diabetic control
(c) Gastro-oesophageal reflux
(d) Following response to therapy for previously documented motility disturbances

Gastric emptying time is the most physiological and the current gold standard for the evaluation of gastric emptying. However, various parameters like the content of the food, acceptability of food to local population, etc. create variations and each centre needs to standardise the procedure.

Meckel's diverticulum scintigraphy and gastrointestinal bleeding: The indication for a Meckel's scan is to localise ectopic gastric mucosa in a Meckel's diverticulum as the source of unexplained gastrointestinal bleeding (**Figure 12**). Scintigraphy may be false negative in active bleeding and in those without adequate gastric mucosa in the diverticulum.

Gastrointestinal bleeding scintigraphy is performed in patients suspected of active gastrointestinal bleeding using Tc99m labelled red blood cells (RBCs). Sites of active bleeding are identified by the accumulation and movement of labelled red blood cells within the bowel lumen (**Figure 13**). Tc99m labelled red blood cells scintigraphy is the most sensitive of all the available investigations in the evaluation of gastrointestinal bleeding. Unlike invasive angiography, scintigraphy is non-invasive, allows follow-up of patients for 24 hours, provides prognostic information and is not associated with risks of contrast administration and renal injury.

Neurologic Applications

Brain perfusion scintigraphy reflects regional cerebral perfusion. Useful in:

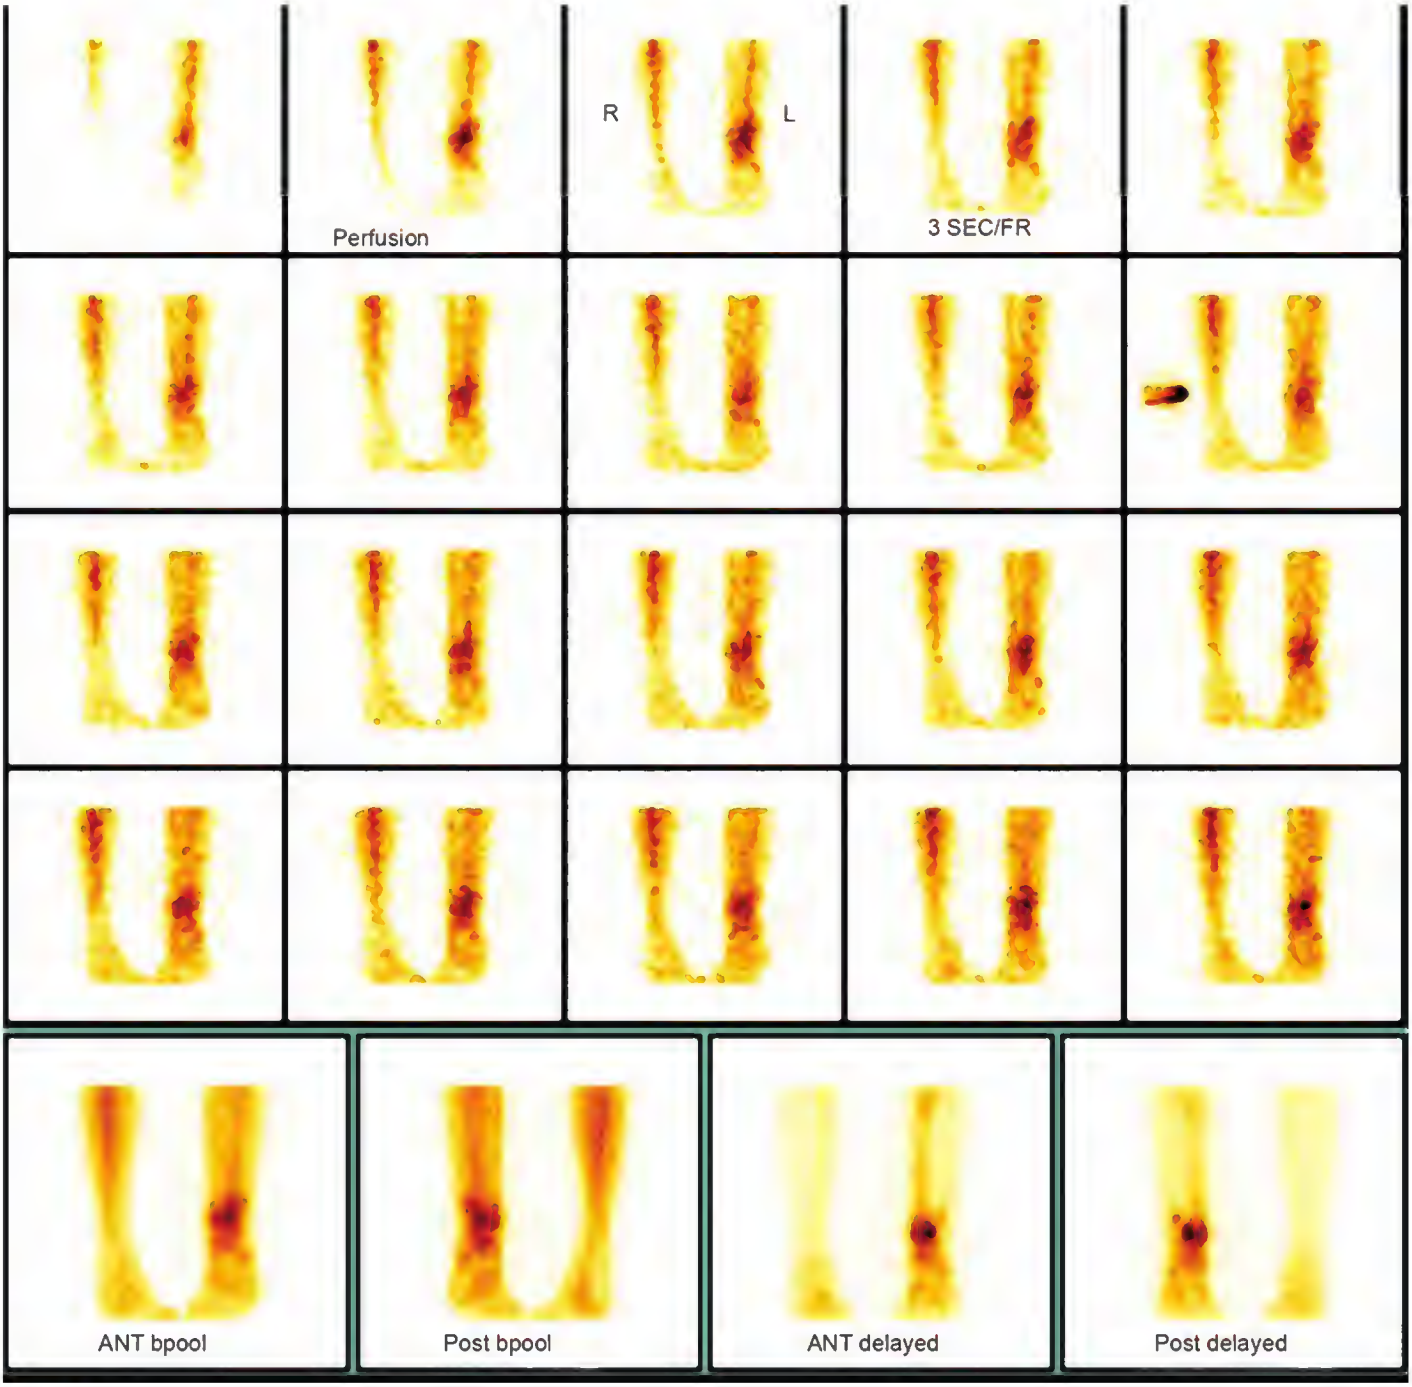

Figure 9: Three-phase MDP bone scintigraphy images of the legs showing increased blood flow and soft tissue pooling of tracer around the lower part of left tibia. Bone phase image acquired at 3 hours shows increased tracer uptake in the same region. The findings are suggestive of active bony infection and inflammation.

(a) Detection and evaluation of cerebrovascular disease.
(b) Evaluating post concussion syndrome.
(c) Evaluation of patients with suspected dementia (Alzheimer's disease, multi-infarct dementia, AIDS dementia).
(d) Presurgical localisation of epileptic foci (ictal and inter-ictal scan).
(e) Evaluation of suspected brain trauma.
(f) Assess brain blood flow in patients suspected of brain death.
(g) Evaluation of patients for carotid surgery.
(h) Evaluation of brain tumours (**Figure 14**) especially follow-up after surgery/radiotherapy.
(i) Cerebrospinal fluid studies for CSF leaks, hydrocephalous, shunt patency, etc.

The commonly used radiotracer for brain perfusion imaging is Tc99m-HMPAO, Tc99m-ECD. Brain tumour imaging may be performed with Tc99m-sestamibi/GHA or Thallium-201. CSF studies are performed with Tc99m-DTPA. The utility of scintigraphy has diminished with the advent of conventional high resolution imaging modalities. Functional disorders like seizures, psychiatric illness are identified with SPECT even when morphological imaging modalities are normal.

Oncologic Applications

(a) Bone scan to evaluate primary bone tumours and to detect skeletal metastases from other malignancies.
(b) Scintimammography (breast scan) to accurately detect and locate cancerous tissue in the breasts.

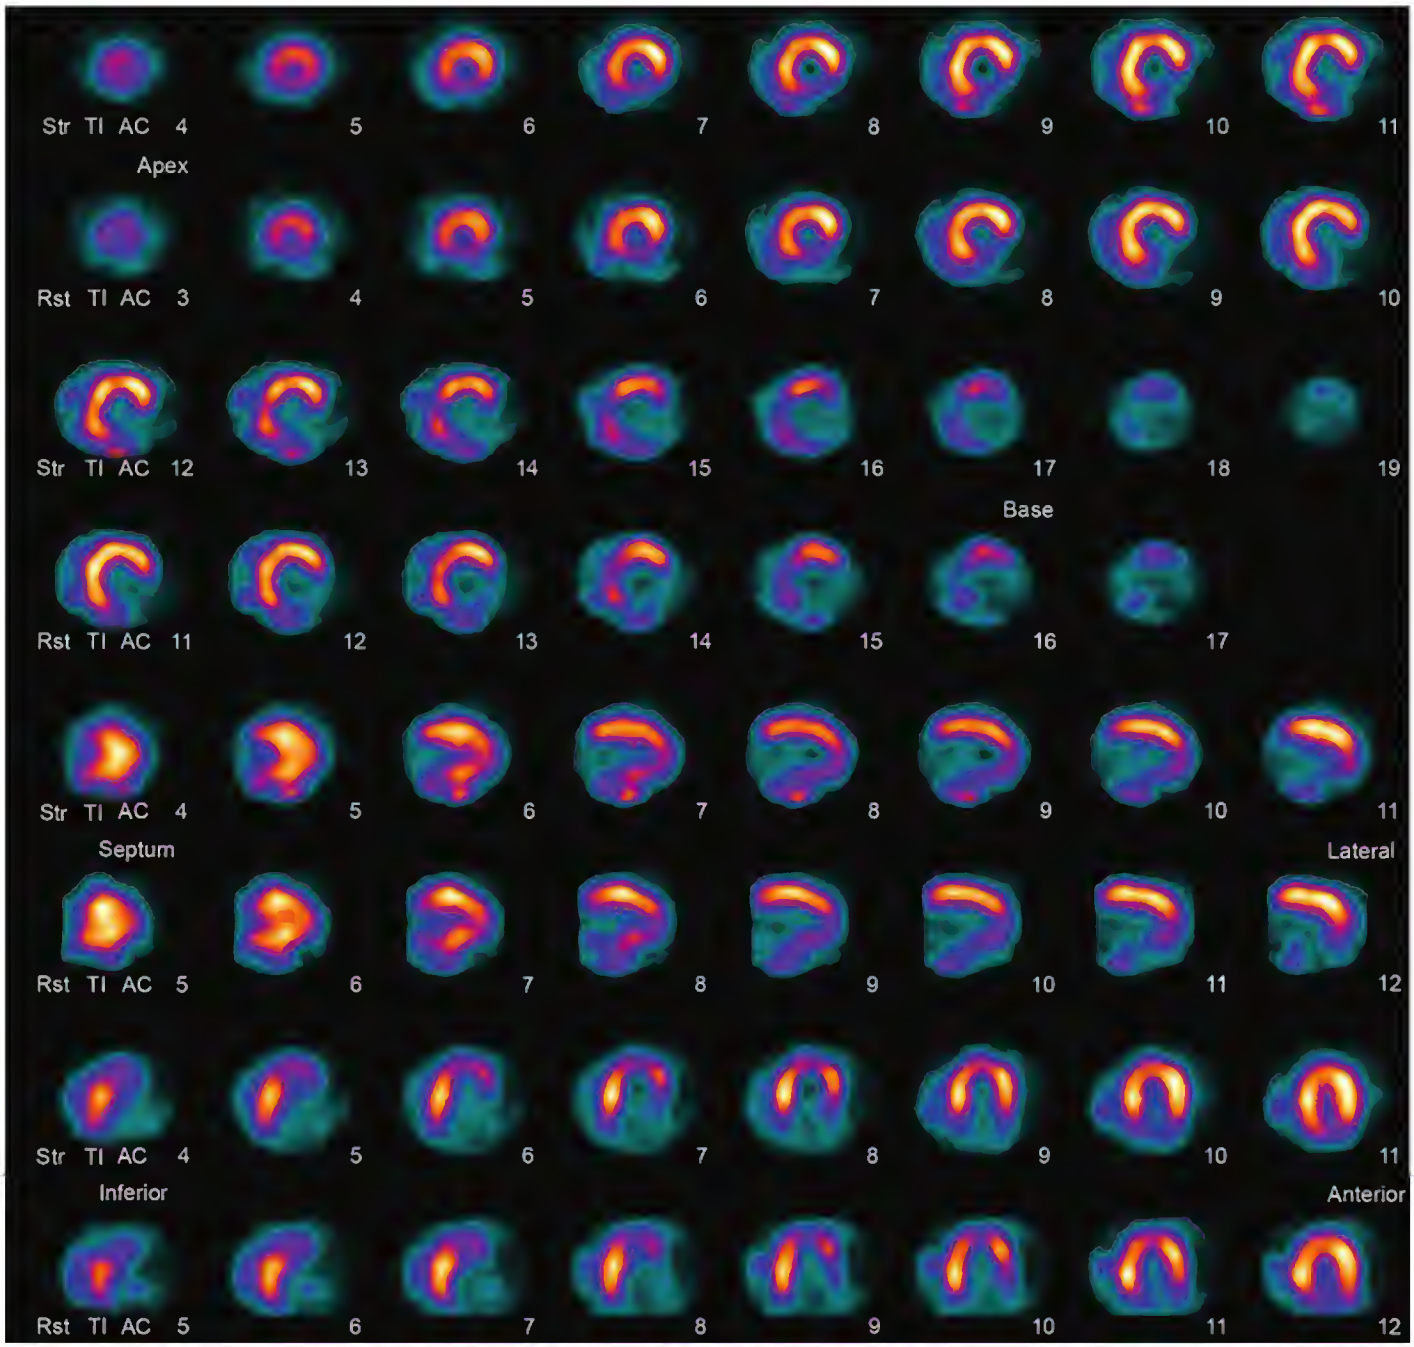

Figure 10: Myocardial perfusion scintigraphy (MPS) performed at stress and rest with Tc99m-Tetrofosmin. Matched stress and rest images [short axis (SA)], vertical long axis (VLA), horizontal long axis (HLA) show impaired tracer uptake in anterior septum and infero-lateral wall of the left ventricular myocardium indicative of stress induced ischaemia.

(c) Sentinel lymph node mapping to localise the lymph nodes before surgery in patients with breast cancer or melanoma.

(d) MIBG and Octreotide scans for neuroendocrine tumours, based on cellular receptors or functions.

(e) Radio-immunoscintigraphy: These imaging tests use monoclonal antibodies. When combined with a radioactive tracer, they are quite useful for detecting various tumours, especially those in the ovaries, colon or prostate.

(f) Gallium scans to evaluate certain types of tumours. Determines the presence or spread of cancer in various parts of the body.

(g) PET/CT scans for initial staging, therapy monitoring and follow-up.

PET/CT has overcome many limitations of routine nuclear medicine procedures like the limited spatial resolution, sensitivity and quantification.

Other Applications

(a) Infection/inflammation detection using gallium-67/labelled leucocytes/ labelled ciprofloxacin.

(b) Venography for deep venous thrombosis (DVT).

(c) Lymphoscintigraphy.

(d) Salivary scintigraphy.

(e) Dacryo-scintigraphy.

(f) Spleen scan.

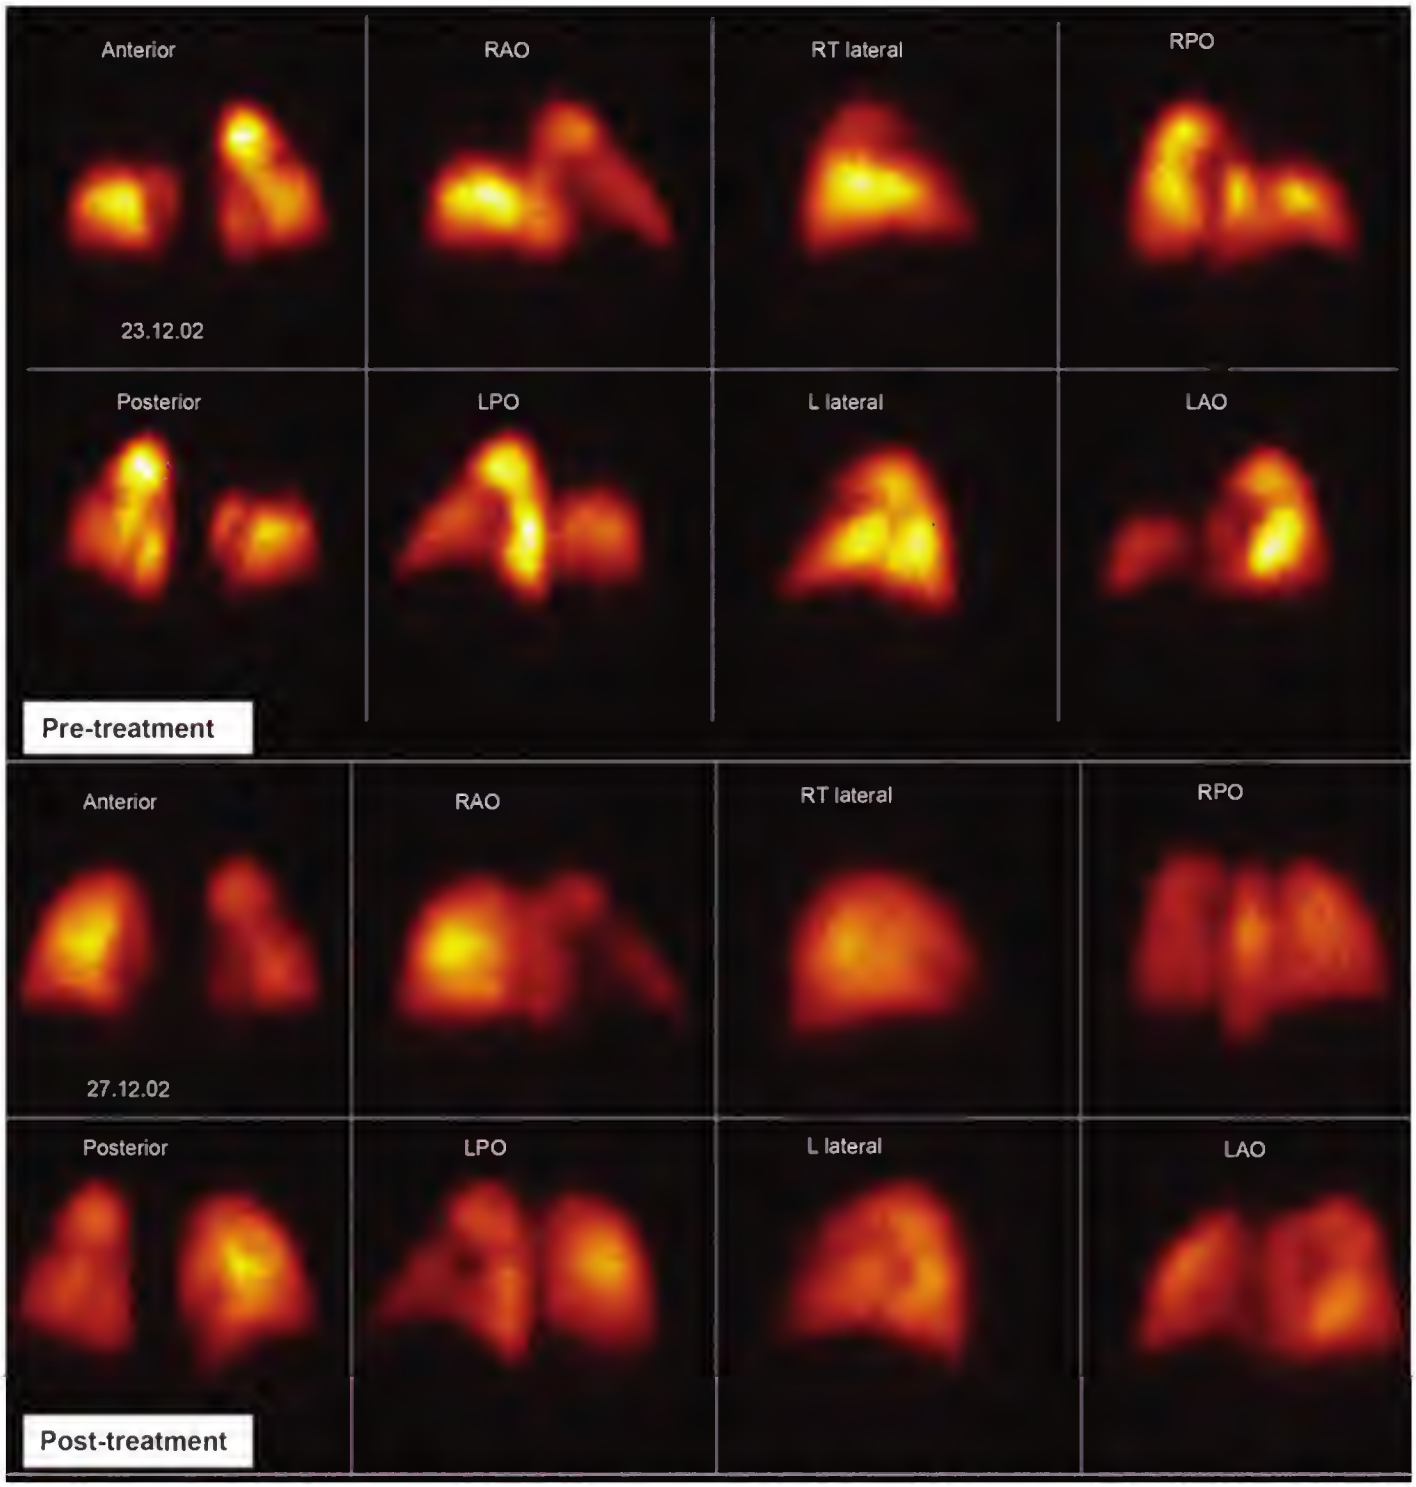

Figure 11: Lung perfusion scintigraphy performed with Tc99m-MAA (macro-aggregated albumin) showing improvement in the follow-up study. Initial perfusion study shows large perfusion defect in the right lung. Follow-up study after treatment with heparin shows restoration of perfusion to the right lung. A small wedge shaped defect in the left lung also improved.

THERAPEUTIC NUCLEAR MEDICINE

Radionuclides are also used for therapy of malignant and non-malignant conditions (**Table 3**). With the use of suitable radio-pharmaceuticals targeted therapy is also possible. In nuclear medicine therapy, the radiation treatment dose is also administered internally (e.g. intravenous or oral routes) rather from an external radiation source as in radiotherapy. The ionising radiation emitted by therapeutic radionuclides travels only a short distance, thereby minimising unwanted side-effects and damage to non-involved organs or nearby structures. Most nuclear medicine therapies can be performed as outpatient procedures since there are few side-effects from the treatment and the radiation exposure to the general public can be kept within a safe limit. Nuclear medicine therapies include:

(a) Radioactive Iodine (I-131) for hyperthyroidism and thyroid cancer.

(b) Iodine-131 MIBG (metaiodobenzylguanidine) for neuro-endocrine tumours.

(c) Palliative therapy for metastatic bone pain using Phosphorus-32 or Samarium-153 or Strontium-89.

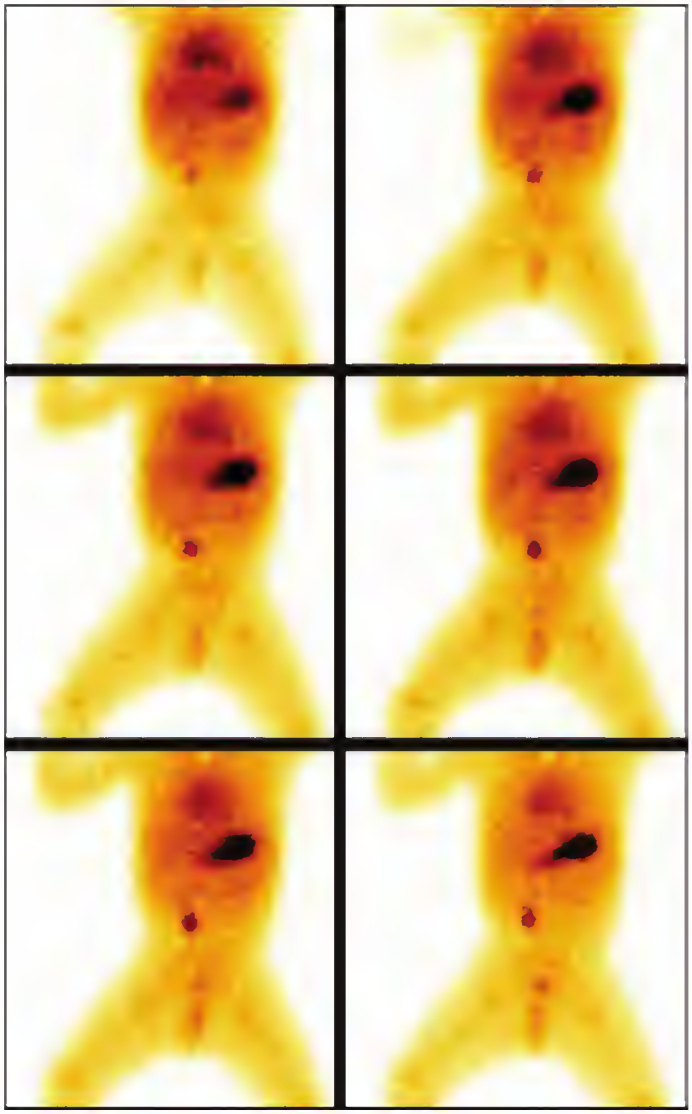

Figure 12: ^{99m}Technetium Meckel's scintigraphy. Multiple static images after intravenous tracer injection shows a focus of tracer uptake in the right iliac fossa. The focus appears alongwith the stomach and shows increasing activity as the study progresses. The findings suggest presence of heterotopic gastric mucosa (Meckel's diverticulum).

(d) Phosphorus -32 for polycythemia rubera vera.

(e) Radionuclides (Yttrium-90, Erbium-169, Rhenium-186) for various arthritis like rheumatoid, psoriatic, haemophilic, etc. (Radiosynoviorthesis).

(f) Iodine-131/Rhenium-186 lipoidal or yttrium-90 theraspheres intra-arterial therapy for hepatocellular carcinoma.

(g) Lutetium-177 peptide therapy for various neuroendocrine tumours.

(h) Radioimmunotherapy - Yttrium-90 Ibritumomab Tiuxetan (Zevalin) and Iodine-131 Tositumomab (Bexxar) for low grade refractory lymphomas.

Nuclear medicine can also guide the choice and extent of surgery not only by demonstrating metastases to the liver, lungs and bones but also by demonstrating tumour limits and involvement of sentinel nodes by probe guided surgery. Nuclear techniques also portray biodistribution and pharmacodynamics/pharmacokinetics of conventional drugs; predict therapeutic abilities of non-radioactive biomolecules and the therapy effects of gene therapy using reporter probes. They also give early indications about the efficacy and or toxic effects of a treatment plan, e.g. PET that provides information about tumour response to a particular chemotherapy schedule; drug resistance in a tumour and cardiotoxicity during adriamycin therapy.

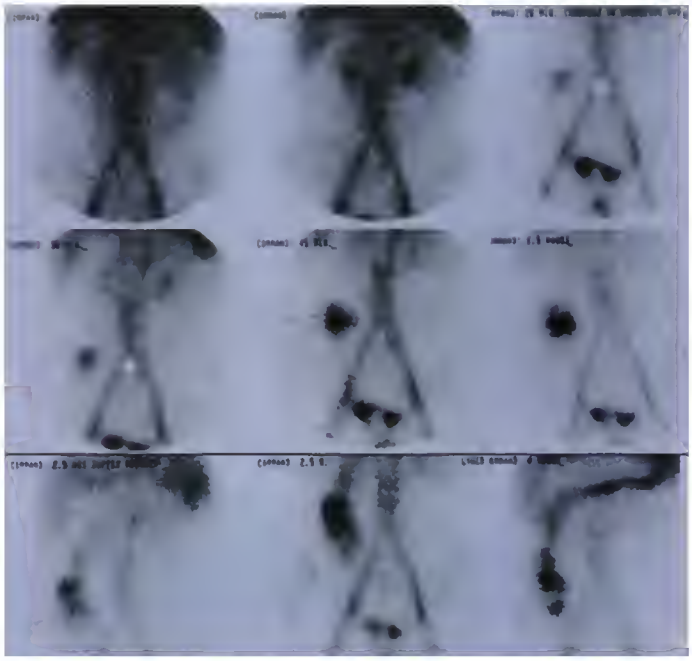

Figure 13: Tc99m labelled RBC gastrointestinal bleed scintigraphy. Multiple static images acquired shows abnormal tracer extravasation in the right iliac fossa. Further imaging reveals further bleeding and antegrade peristalsis into the transverse colon and splenic flexure.

Table 3: The Most Commonly Used Radionuclides for Therapy in Nuclear Medicine

Radionuclide	Symbol	Half-life (T½)	Type of Emission	Beta Energy (Max) (Mev)
Phosphorus-32	^{32}P	14.26 days	β^-	1.71
Strontium-89	^{89}Sr	50.5 days	β^-	1.492
Iodine-131	^{131}I	8.02 days	β^-	0.606
Yttrium-90	^{90}Y	2.67 days	β^-	2.3
Erbium-169	^{169}Er	9.5 days	β^-	0.34
Rhenium-186	^{186}Re	3.72 days	β^- and γ	1.071 0.93
Samarium-153	^{153}Sm	46.7 hours	β^- and γ	0.809 0.707 0.637
Lutetium-177	^{177}Lu	6.65 days	β^- and γ	0.176 0.384 0.497

γ= Gamma; β^-= Negative decay

SAFETY OF NUCLEAR MEDICINE

Nuclear medicine procedures are one of the safest diagnostic imaging examinations available. A patient only receives an extremely small amount of a radiopharmaceutical, just enough to provide sufficient diagnostic information. It results in low radiation exposure, acceptable for diagnostic examinations. Thus, the radiation risk is very low compared with the potential benefits. There are no known long-term adverse effects from such low-dose exposure. Allergic reactions to radiopharmaceuticals are extremely rare and are usually mild.

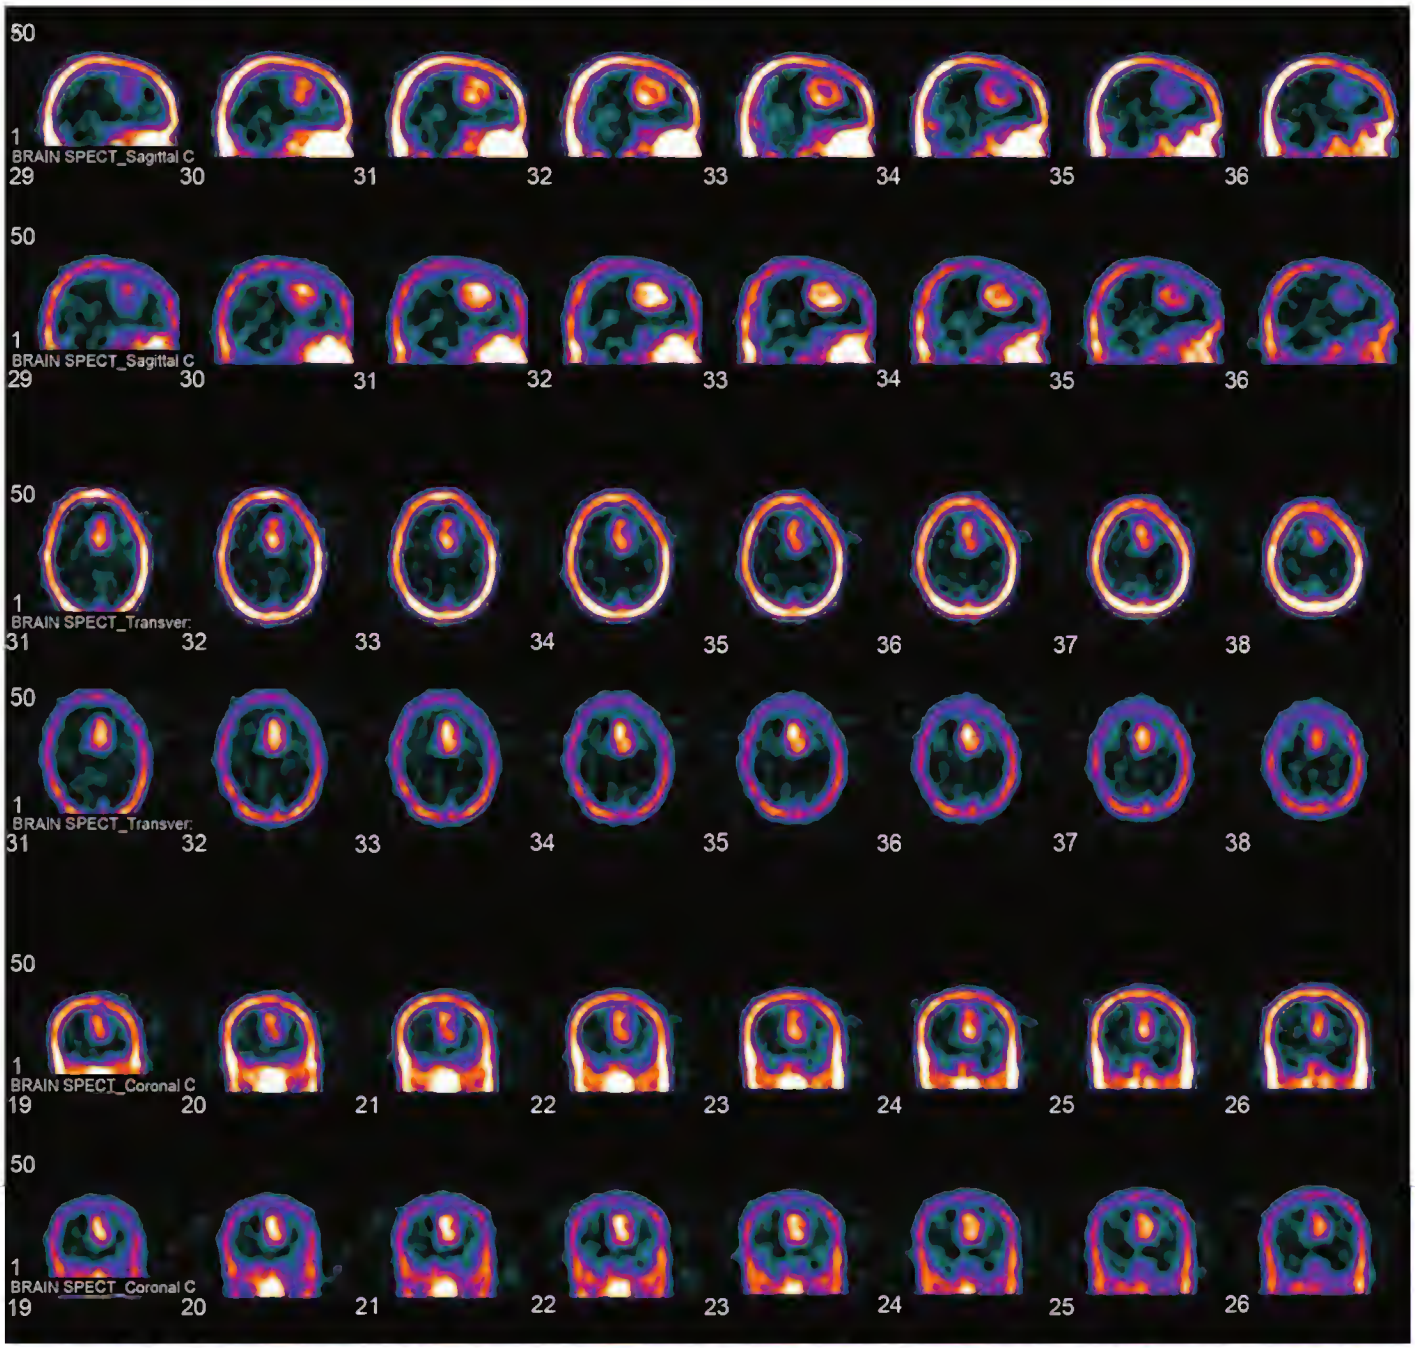

Figure 14: Tc99m-GHA brain tumour imaging focal tracer uptake is noted in the right frontal region. The patient has high grade glioma. The uptake in the scalp is physiological.

Women should always inform, if there is any possibility that they are pregnant or if they are breastfeeding their baby.

Radiation Dose

The amount of radiation from diagnostic nuclear medicine procedures is kept within a safe limit and follows the ALARA (As Low As Reasonably Achievable) principle. The radiation dose from nuclear medicine imaging varies greatly depending on the type of study. The effective radiation dose can be lower than or compatible to the annual background radiation dose. The amount of radiation from a nuclear medicine procedure is comparable to, or often times less than, that of a diagnostic X-ray except that the dose is delivered internally rather than from an external source such as an X-ray machine. The radiation dose from a nuclear medicine investigation is expressed as an effective dose with units of sievert (usually given in milli sieverts, mSv). The effective dose resulting from an investigation is influenced by the amount of radioactivity administered in megabecquerel (MBq), the physical properties of the radiopharmaceutical used, its distribution in the body and its rate of clearance from the body.

3.6 Positron Emission Tomography

Rakesh Kumar, Varun Shandal

INTRODUCTION

Positron emission tomography (PET) is a functional diagnostic imaging technique which can study metabolism of various biological processes like glucose, amino acid, phospholipids, receptors, etc. James Robertson and his associates in 1961 built the first single-plane PET.

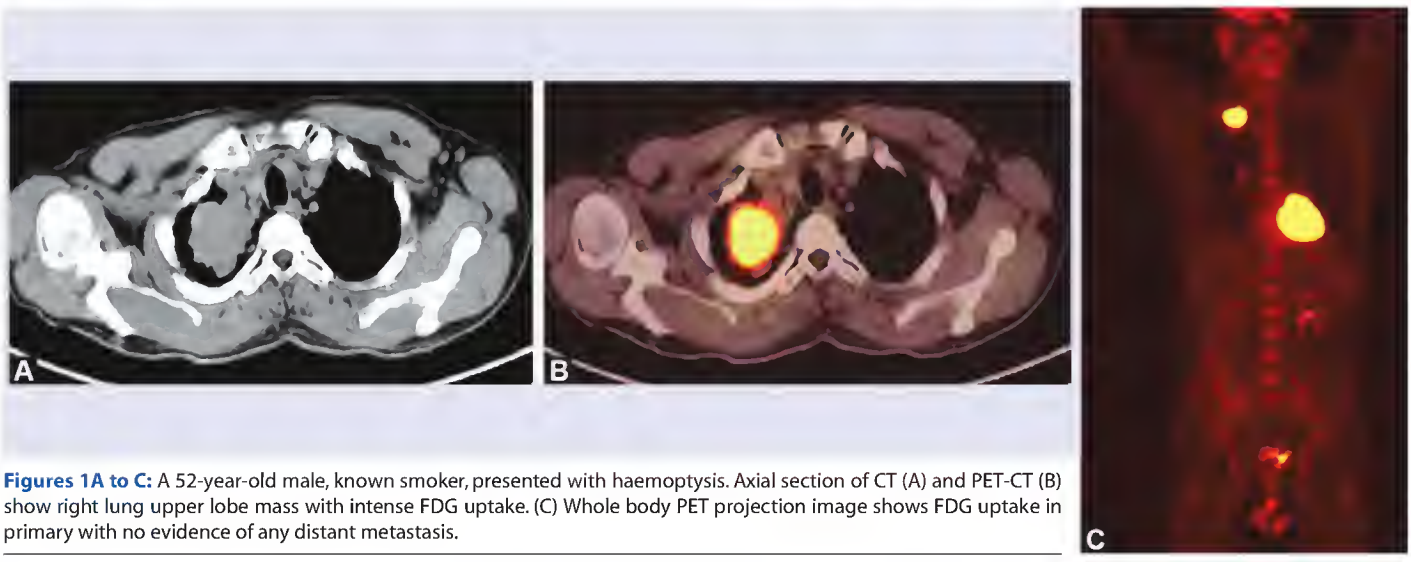
Combined PET and computed tomography (CT) has better specificity and sensitivity than either PET or CT alone, as it can provide the functional and morphological details of the tissue to be studied with better localisation, all-in-one procedure. Although many radiotracers are used for PET and PET-CT but the most widely used radiotracer is Fluorine18-fluorodeoxyglucose (^{18}F-FDG) which is an analogue of glucose. Since the neoplastic processes, infection foci, etc. have increased metabolism of glucose, resulting in higher FDG accumulation which makes their visualisation better with PET-CT. For interpreting the images accurately, the knowledge of normal physiological distribution of FDG is must. Tissues with higher metabolic rate such as skeletal muscles, gut, brown fat, glandular breast, bone marrow, spleen, lymphoid tissues and urinary tract (normal excretion) accumulate more FDG which may sometimes interfere with image interpretation. There is a better quantitative way for evaluating the images by measuring standardised uptake value (SUV) which directly correlates with FDG metabolism in the tissue. PET-CT is the one of the latest functional imaging modality with wide clinical applications in the fields of oncology, infectious diseases, cardiology and neurology. As it is still in the early stages of development, its applicability in other disease conditions are still being explored. The major drawbacks of the PET-CT are the limited availability, its high cost and sometime difficult differentiation between infection and malignancy. In the following section major approved uses of the PET scan are discussed in brief.

PET-CT IN ONCOLOGY

The PET-CT imaging has revolutionised the approach and management of cancer patients. It has proven benefit in all stages of cancer, starting from detection of the lesion, its characterisation, determining the extent of the tumour, initial staging, evaluating the therapy response and detecting the recurrence of the disease. It has been also found useful for monitoring the treatment response, re-staging of disease as well as prognostication of various cancers.

Diagnosis

Solitary pulmonary nodule (SPN) and bronchogenic carcinoma



PET-CT provides additional functional information and is useful as a non-invasive diagnostic test for SPN that differentiates benign lesions from the malignant ones (**Figures 1A to C**). PET-CT has low sensitivity in detecting low-grade tumours, like bronchoalveolar carcinoma and bronchial carcinoid.

Breast carcinoma

In breast cancer patients, mammography is the most readily used imaging technique for the diagnosis of primary tumour but it has lower sensitivity in women with radiographically dense breasts and patients with breast implants. PET-CT is found to be useful in patients with dense breasts and patients with breast implants (**Figures 2A to C**). PET has also been found to be useful in detecting additional primary in contralateral breast in known breast cancer patients. However, magnetic resonance imaging (MRI) remains the gold standard for this purpose.

Other malignancies

PET-CT has the ability to differentiate pancreatic cancer from benign lesions like cystic lesions, especially in patients with chronic pancreatitis. It has a higher accuracy of 94% in detecting

Figures 1A to C: A 52-year-old male, known smoker, presented with haemoptysis. Axial section of CT (A) and PET-CT (B) show right lung upper lobe mass with intense FDG uptake. (C) Whole body PET projection image shows FDG uptake in primary with no evidence of any distant metastasis.

malignancy in cystic lesions than conventional CT (accuracy 80%). The ^{18}F-DOPA whole-body PET-CT is highly sensitive and specific for the detection of pheochromocytomas and paragangliomas and helps in detecting metastasis from malignant pheochromocytomas, especially when used after negative metaiodo-benzyl guanidine (MIBG) study. The FDG-PET has excellent diagnostic performance in differentiating adrenal lesions detected on CT or MRI in patients with known malignancies. PET-CT also has high diagnostic value in endometrial carcinoma and gall bladder mass, but in rest of the cancers it has less or no value for the purpose of diagnosis.

Initial Staging

Initial staging refers to assessing the extent of malignant neoplasms and in differentiating localised from disseminated disease.

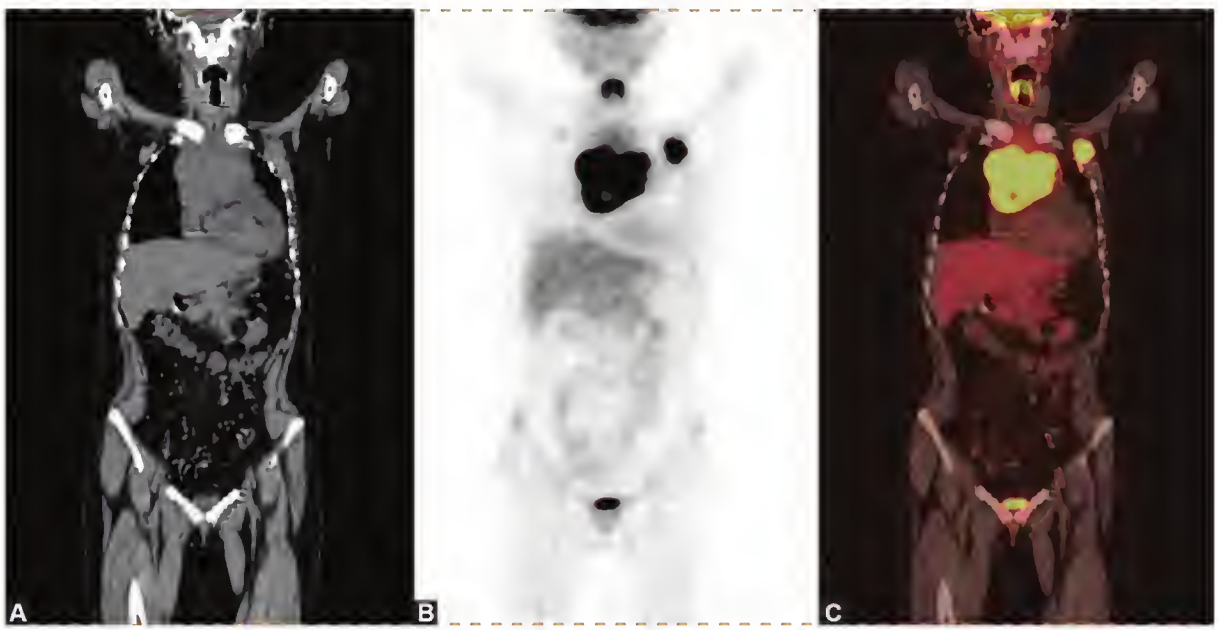
Bronchogenic carcinoma

Non small cell lung cancer (NSCLC), which is the most frequent type of lung cancer, needs invasive procedures such as thoracotomy, mediastinoscopy for nodal staging. Also, CT and MRI are not useful in this condition if the tumour has involved less than 1 cm of area. PET-CT has overcome all these limitations by being a non-invasive investigation, giving the metabolic picture of all sites involved in one setting. It is important for the management aspect of NSCLC as the therapy to be used depends entirely on the extent of the disease.

Colorectal cancer

In colorectal cancer (CRC) patients, metastasis is usually present in majority of them at initial presentation. CT is used as initial investigation for staging but PET-CT is superior in detecting unexpected liver metastases and extra-hepatic lesions. Mucinous adenocarcinoma is one type in CRC which is less FDG avid giving false negative results most of the time.

Lymphoma

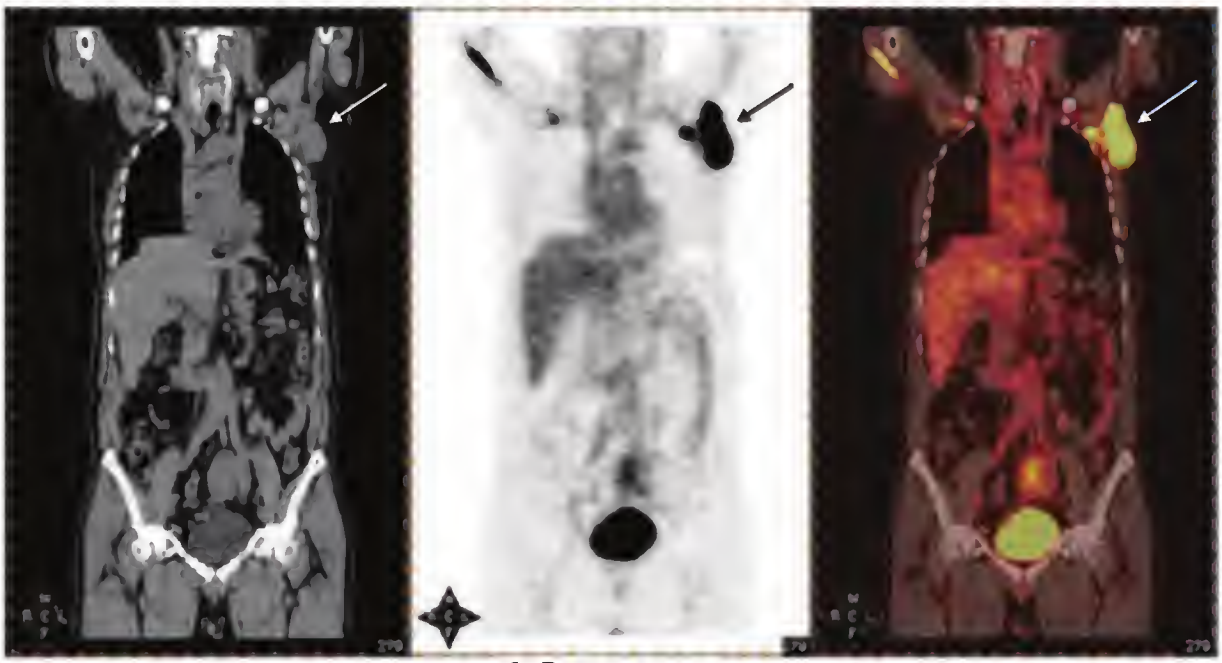


In patients with Hodgkin's disease (HD) and non-hodgkin's lymphoma (NHL), PET-CT detects more lesions which change the stage of the disease in almost 15% of patients when compared to conventional imaging like CT (**Figures 3A to C**). For histopathological examination of the lesion in HD and NHL, PET-CT can guide the biopsy from suitable and easily accessible site.

Cancer of unknown primaries and other cancers

Patients with head and neck cancers commonly present with cervical lymph node metastasis from an unknown primary. Here, PET-CT is a valuable tool in patients with an occult primary tumour in the head and neck region. PET-CT can identify primary tumour in approximately 30% patients and allow accurate tumour and lymph node staging, that is essential for treatment planning. PET-CT differentiates resectable and unresectable disease in oesophageal and gastric cancers and

Figures 2A to C: Axial sections of CT (A), PET (B) and PET-CT (C) showing focal areas of increased FDG uptake in outer quadrant of right breast in a 35-year-old female with dense breasts. Biopsy of lesion revealed intraductal breast cancer.



Figures 3A to C: In a known case of Hodgkin's lymphoma underwent PET-CT scan for initial staging. Coronal sections of CT (A), PET (B) and PET-CT (C) showing focal areas of increased FDG uptake in the mediastinum and left axillary lymph nodes suggestive of active disease in these regions.

helps in avoiding futile surgeries. However, the detection of regional nodal metastases is limited due to the small volume of the disease in some lymph nodes. The FDG uptake in osteosarcoma correlates well with histological grading or tumour aggressiveness. In patients with ovarian cancers having raised serum CA-125, accurate staging is very important for proper management. The PET-CT has high sensitivity and specificity as compared to conventional imaging modalities like transvaginal ultrasound (USG) and contrast enhanced computed tomography (CECT) in staging and detecting metastases. PET-CT may reveal unsuspected and occult metastases to the liver, bones, and lungs, those cannot be detected by conventional imaging, and this can change the management protocol in patients with pancreatic cancer.

Treatment Response Evaluation

PET-CT has emerged as a useful imaging modality that can evaluate the therapy response and differentiate responders from non-responders. As most of the chemotherapeutic drugs are cytostatic, conventional imaging like CT and MRI has limited value in evaluating the treatment response as they use the size criteria. However, PET-CT as functional imaging modality can show the treatment response earlier by determining the glucose uptake by tumour which decreases earlier than the size in solid tumours. PET-CT performed after 1-2 cycles of chemotherapy can differentiate progressive disease from remission better than conventional imaging modalities in lymphoma, NSCLC, etc. and can change the treatment plan accordingly (**Figures 4A and B**).

Figures 4A and B: A case of Hodgkin's lymphoma who underwent pre-chemotherapy (A) and post-chemotherapy PET/CT (B) imaging. In pre-chemotherapy scan, coronal sections of CT, PET and PET/CT are showing increased FDG uptake in multiple left axillary lymph nodes shown by arrows (upper row). In post-chemotherapy scan, coronal sections of CT, PET and PET/CT are showing resolution of FDG uptake in left axillary lymph nodes (arrows) suggestive of complete response (lower row).

In colorectal cancer patients, Delta SUVmax (absolute SUVmax change) and response index (RI), (per cent SUVmax change) are best predictive parameters in response evaluation of neoadjuvant chemotherapy.

In breast cancer patients, PET-CT detects metabolic changes much earlier than conventional imaging and clinical examination after initiation of chemotherapy. There is strong correlation between the quantitative changes in SUV and overall clinical assessment of response of skeletal metastases to therapy and changes in tumour markers in breast cancer patients. In patients with oesophageal carcinoma, PET-CT is more specific than CT and endoscopic USG for loco-regional lymph node metastasis and response evaluation to neoadjuvant chemotherapy.

Around two-third of patients with HD and 50% of patients with NHL show persistent mass lesion on conventional imaging modalities after treatment. However, PET-CT readily shows absent metabolic activity in these lesions and lower incidence of relapse in these patients proving its efficacy in treatment response monitoring in lymphoma.

CT is the imaging modality of choice in gastrointestinal stromal tumours (GIST), which can locate a mass lesion, contiguous organ invasion and distant metastases. Since the introduction of imatinib mesylate, PET-CT is being used widely in GIST. PET-CT may show significant decrease in FDG uptake early after imatinib therapy, while on conventional morphological imaging, tumour size may remain constant for a significant time. Therefore, PET-CT accurately separates responders from non-responders at an early stage, and is helpful during follow-up. However, in the assessment of the solid tumours, the role of PET-CT is yet to be determined.

Restaging/Recurrence and Prognosis

Most of the cancers relapse or recur even after the successful therapy. PET-CT is becoming standard of care in evaluating the recurrence of various cancers and in determining the prognosis. PET-CT has proven role in assessing the prognosis of NSCLC, pancreatic cancer, lymphoma, cervical cancer and other cancers as discussed below. In colorectal cancer, CT is frequently used to localise the site of possible recurrence, which has lower sensitivity and specificity. In a meta-analysis conducted on 577 patients, the sensitivity and specificity of FDG-PET for detecting recurrent colorectal cancer was found to be 97% and 76%, respectively. In head and neck cancers, PET-CT is sensitive and specific in detecting residual and recurrent lymph node metastasis and this can detect the complete metabolic response, and thus, predicting overall survival; it changed radiotherapy planning technique in 29% and altered TNM staging in 34% of the patients. PET-CT has been shown to be useful in malignant melanoma, ovarian cancer, recurrent cervical cancer, hepatocellular carcinoma (HCC), prostate and cancer of the bladder.

PET-CT IN INFECTIOUS AND INFLAMMATORY DISEASES

Infectious diseases are the major cause of morbidity and mortality in developing countries and the incidence of both community and hospital acquired infections is on the rise. Most of the times, focus of infection remains undetermined. For the successful management of patients with presumed or established inflammatory and septic diseases, the detection and localisation of infectious and non-infectious foci in soft tissues is of primary importance. Whenever, the lesions of infectious and inflammatory disease cause changes in local anatomy, capillary permeability, or tissue water content, the conventional imaging like USG, CT, and MRI are effective in detecting inflammation. Scintigraphic techniques are best used to localise inflammatory foci when normal anatomic landmarks are lost or obscured. FDG-PET-CT is also useful to detect infection and inflammatory foci. The enhanced uptake of FDG in activated inflammatory cells, such as lymphocytes or macrophages, is related to significantly increased levels of glycolysis as a result of increased numbers of cell surface glucose transporters, particularly after cellular stimulation by multiple cytokines. PET-CT is useful in the diagnosis, treatment response evaluation of infectious and inflammatory diseases, to find out recurrence/residual disease in case of chronic disorders and in pyrexia of unknown origin (PUO).

Diagnosis

PET-CT has shown its usefulness in diagnosing various difficult to diagnose infectious and inflammatory conditions. It has been successfully used in the diagnosis of tuberculosis (TB), sarcoidosis, osteomyelitis, vasculitis, human immunodeficiency virus (HIV) infection and infections in organ transplant.

Tuberculous lesions show variable FDG uptake according to the grade of inflammatory activity and they do not show any characteristic pattern. PET-CT helps in detecting unsuspected distant foci of infection (**Figure 5**). For the diagnosis of TB, biopsy and histopathological examination are essential many a times. Here, PET-CT is useful in guiding biopsy from metabolically active lesions. In another granulomatous disease sarcoidosis, although, PET-CT shows FDG uptake by sarcoid granulomas but it cannot distinguish sarcoidosis from HD or NHL and even from TB. However, PET-CT can assess the extent and degree of the disease once the diagnosis has been established.

In chronic osteomyelitis, PET-CT is highly sensitive in the detection of the disease, even in patients treated with antibiotics before FDG-PET imaging. When chronic osteomyelitis is suspected in complicated fractures, PET-CT appears to be the study of choice as FDG uptake normalises in less than 2 to 3 months whereas bones scintigraphy remains positive for longer periods following complicated fractures reducing the false positive results. Diagnosing osteomyelitis in diabetic foot using conventional imaging poses a challenge as findings of acute osteomyelitis may be similar to those of acutely evolving neuropathic osteo-arthropathy on CT, MRI which frequently coexist in diabetic patients. Here, the precise anatomic localisation of increased FDG uptake provided by PET-CT enables accurate differentiation between osteomyelitis and soft-tissue infection. In diagnosing the infected prosthesis, studies have shown variable results on the role of PET-CT. More studies are needed to confirm the role of PET-CT in the evaluation of periprosthetic infections or inflammation.

PET-CT is useful in early diagnosis and establishing the extent of the vasculitis in patients with several types of vasculitis such as giant cell arteritis, polymyalgia rheumatica, Takayasu's arteritis, periaortitis due to Wegener's granulomatosis, aortitis, unspecified large vessel vasculitis and infectious vasculitis. PET-CT is helpful in demonstrating giant cell arteritis in arteries exceeding 4 mm

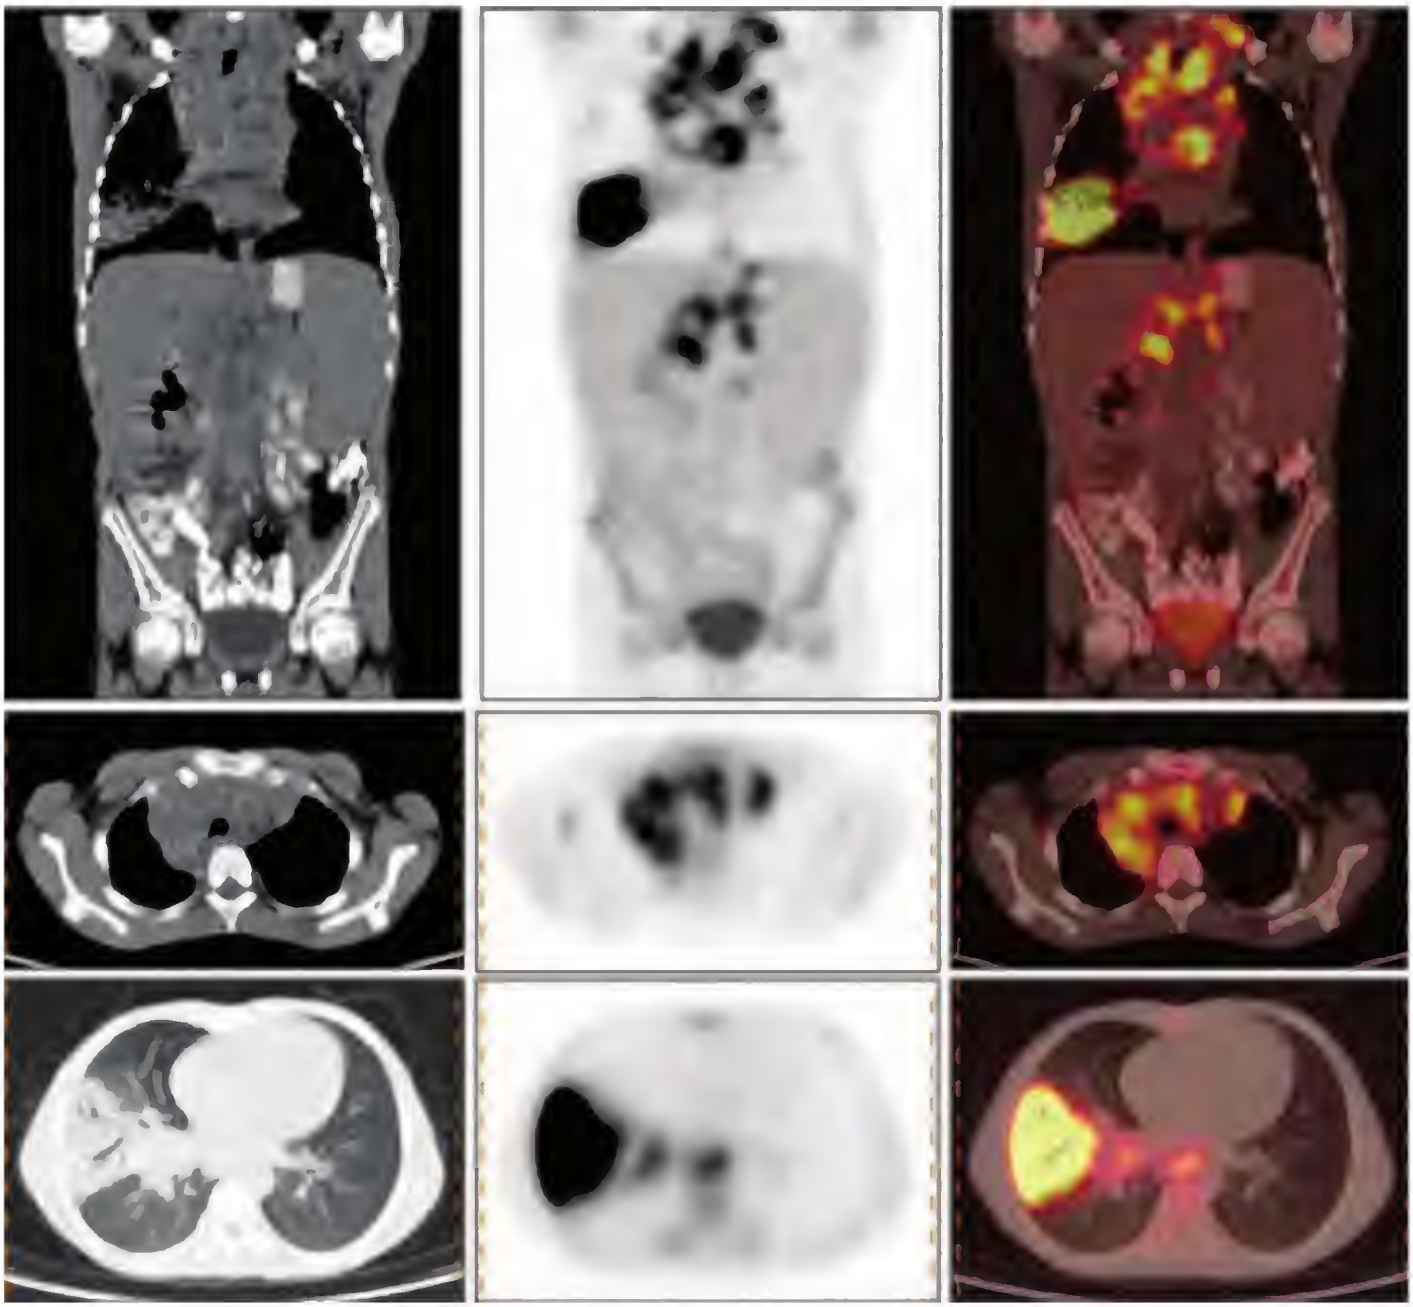


Figure 5: Patient is a case of extensive tuberculosis. Coronal (upper row) and axial sections (middle and lower row) of CT, PET and PET/CT are showing multiple focal areas of increased FDG uptake in left supraclavicular, mediastinal lymph nodes and right lung mass suggestive of active disease.

in diameter; however, in very small vessels it cannot replace the need of arterial biopsy for making the diagnosis.

In HIV-infected patients with central nervous system (CNS) lesions PET-CT has a major role in their management. PET-CT demonstrates activated lymphoid tissue in the head and neck region during acute stages, a generalised pattern of peripheral lymph node activation at the mid-stages, and abdominal lymph node involvement during the late disease. PET-CT imaging has been reported to be more accurate than CT or MRI in differentiating a malignant CNS lymphoma from non-malignant CNS aetiologies, such as toxoplasmosis, syphilis, and progressive multifocal leucoencephalopathy.

In organ transplantation cases, PET-CT can distinguish infection from rejection and hence, this non-invasive and repeatable test could reduce the number of biopsies required during the follow-up period of patients after organ transplantation. In inflammatory bowel disease (IBD), detection of disease and its extent can be assessed with PET-CT enteroclysis and good correlation has been demonstrated between the degree of inflammation and the uptake of FDG.

Pyrexia of Unknown Origin (PUO)

PUO diagnosis is still a challenge for the internists. The infections are the most common cause of PUO, followed by neoplasm and noninfectious inflammatory diseases. For improving the management in patients with PUO, the accurate localisation and characterisation of the underlying cause is of paramount importance. Because of high sensitivity of PET-CT in detecting malignant lesions, infections, and various inflammatory processes, PET-CT has the potential to play a role in the diagnostic protocol and management of patients with PUO but there are some disadvantages also in some cases. PET-CT cannot exclude cerebral disease or meningitis, because physiological uptake in the cerebral cortex in most cases

obscures any pathological uptake. Normal activity in the kidneys and the bladder severely hampers the delineation of the disease in these organs. With the development and the introduction of several new PET radiotracers, it is expected that PET-CT will secure a major role in future in the management of patients with inflammatory and other benign disorders.

Treatment Response Evaluation

In infectious and inflammatory diseases, PET-CT has the ability to monitor the response to therapy when baseline PET-CT study is available before the commencement of the therapy. It is mainly true for chronic granulomatous diseases. PET-CT can also detect residual/recurrent disease in some cases. PET-CT is useful in follow-up of patients with known TB, for monitoring response to treatment; however, more studies are needed to confirm its role, especially in spinal TB. With our own experience, we feel that PET-CT can be useful for detecting suspected recurrence and residual disease activity in patients treated previously. Similarly PET-CT will also be useful in assessing treatment response in patients with sarcoidosis. The PET-CT has been also used in IBD for the early diagnosis, assessing the extent of the disease and evaluating treatment response and disease activity in various stages of the disease.

PET-CT IN CARDIOLOGY

PET-CT has demonstrated its usefulness in patients with cardiac diseases. PET-CT quantifies the *in vivo* physiologic and pathologic processes including myocardial perfusion (coronary blood flow) and metabolism without disturbing their physiological properties. This very property of PET-CT is the basis for it being used as a clinical imaging tool for the quantitative assessment of myocardial perfusion and for the characterisation of tissue viability in patients with advanced coronary artery disease (CAD). Cardiac PET-CT helps in selecting the patients with CAD and left ventricular dysfunction that would benefit from coronary artery revascularisation. PET-CT also characterises the viability of myocardium which can prognosticate the outcome of the patients after revascularisation in patients with ischaemic cardiomyopathy and chronic left ventricular dysfunction. PET-CT also aids in assessing the presence and stability of plaques; however, it is not used routinely for the detection of any vascular disease. PET-CT is also used in the evaluation of cardiomyopathies, post-cardiac transplant evaluation and cardiac receptor evaluation for the regulation of cardiovascular functions.

PET-CT IN NEUROLOGY

The PET-CT is increasingly being used in neurology in the evaluation of epilepsy, brain tumours, dementias and movement disorders, although due to increased functional uptake of FDG by cerebral cortex the evaluation of meninges and cortical tissue is difficult. The PET-CT imaging of the brain allows non-invasive quantification of cerebral blood flow, metabolism, and receptor binding. In epilepsy, surgical removal of epileptogenic foci results in significant control of the seizures and the quality of life. Although, MRI identifies the focus of the seizure in most of the patients, but still a normal MRI has been reported in 20% to 30% of potential surgical candidates. PET-CT in ictal period shows an increase in glucose metabolism and cerebral blood flow in epileptogenic focus whereas, in post-ictal period the increased glucose uptake gradually returns to baseline. Interictally, there is hypoperfusion and decreased glucose metabolism in epileptic focus.

In brain tumours, higher FDG uptake as compared to the normal brain correlates with the higher histologic grade. PET-CT also prognosticates the shorter survival period in case of higher glucose metabolism. In disorders with dementia such as Alzheimer's disease (AD), PET-CT shows decrease in glucose metabolism in the temporoparietal lobes. In AD, a new PET tracer has been employed to target amyloid saline plaques and neurofibrillary tangles which shows prolonged retention in affected areas of the brain. Similarly newer tracers (2-carbomethoxy-3-(4-chlorophenyl)-8-(2-^{18}F-fluoroethyl) nortropane (^{18}F-FECNT) and F-DOPA) are being used in movement disorders, which allow assessment of the integrity of pre-synaptic dopaminergic neurones and are able to diagnose Parkinson's disease and other movement disorders, identify the speech and sensory-motor areas to minimise post-operative morbidity. It is also being used to measure the pharmacokinetic and pharmacodynamic effects of drugs of abuse on the human brain.

INTRODUCTION

Clinical pharmacology is the study of drugs in relation to clinical sciences and deals mainly with the effects of medicines in human beings. Apart from giving a scientific basis for drug use, clinical pharmacology also includes drug development, especially in man. For a physician, awareness of clinical pharmacology (and therefore the knowledge of drug behaviour in man) is necessary to guide rational therapeutics.

Although the genesis of pharmacology (Greek *pharmakos*, medicine or drug; and *logos*, study) is not very distinct, it is known that experimental demonstration of drug action began as far back in 1809, when François Magendie demonstrated, in dogs, that the spinal cord was the site of the convulsant action of *Nux vomica* (a strychnine-containing plant drug). Later in 1842, Claude Bernard discovered that curare acted at the neuromuscular junction to interrupt the stimulation of muscle by nerve impulses. However, pharmacology emerged as a separate science only in 1847, when Rudolf Buchheim was appointed as the professor of pharmacology at the University of Dorpat in Estonia. It was his student Oswald Schmiedeberg (1838–1921), who has established pharmacology as a special discipline and was also responsible for the pre-eminence of the German pharmaceutical industry up to World War II. His student, John Jacob Abel, became the first chairman of pharmacology in the USA.

The seeds of modern clinical pharmacology were sown as far back as 1937 when Harry Gold (who is considered the father of modern clinical pharmacology) described in the *JAMA*, the double-blind trial design. The formal subject 'Clinical Pharmacology and Therapeutics' was introduced in the USA only in 1960 by Gold. Then there was surge of knowledge in this field which established clinical therapeutics firmly.

SIX STEPS TO RATIONAL THERAPEUTICS

When drug treatment is rationally approached, six simple steps need to be taken. These have been summarised in **Table 1**. In this algorithm, the cornerstone for optimal therapeutics is an appreciation of the clinical pharmacology, i.e. the pharmacokinetics and pharmacodynamics of a drug.

PHARMACOKINETICS

Pharmacokinetics is the quantitative analysis of the time course of drug absorption, distribution, metabolism and excretion or to put in simple terms deals with 'what the body does to the drug'. This knowledge forms the scientific basis for deciding the dose and dosage regime of a medicine. Modifications can be made in the dosage form or in the chemical structure of a drug to influence individual pharmacokinetic parameters, thereby assisting in optimising dosing regimen (e.g. slow release formulations will delay the absorption, while modifications in lipid solubility of an injectable drug will change the distribution, metabolism and excretion, and thereby the duration of action). Knowledge of pharmacokinetic principles also assists in the development of new drugs, especially while selecting drug doses.

Information related to the absorption, distribution, metabolism and excretion of a drug allows for calculating the initial loading as well as maintenance doses to achieve and maintain target levels at the site of expected action (**Figure 1**). The route of administration (e.g. oral, ocular, inhaled, etc.) as well as several drug-related factors (including the formulation and this is where pharmaceutics plays a crucial role), and the site of drug absorption, including vascularity (e.g. muscles are very vascular and therefore allow good absorption) influence how much of a drug is absorbed into the systemic circulation. As the drug absorption is variable, an important parameter that is used to compare the availability of a drug at the site of action is bioavailability. This is defined as 'the rate and extent to which the active substance is absorbed from the pharmaceutical form and is available at the site of action'. A study of bioavailability is a useful tool to compare formulations (e.g. conventional to slow release) or generics. Comparative studies in animals or humans (clinical trials) are done only if entirely justified. When the bioavailability of two drugs, when administered in equimolar doses, is similar, these are considered to be bioequivalent and it can be assumed that their clinical effects would be comparable.

After absorption, a drug is rapidly distributed. For most drugs, distribution is characterised by a rapid mixing into one

Table 1: Six Steps to Rational Therapeutics

1. Making the correct diagnosis and defining each patient's problems.
2. Identifying the need and targets for drug therapy.
3. Understanding the clinical pharmacology of the medicines from which a rational choice can be made.
4. Selecting the appropriate medicine for that patient: Here the safety, tolerability, efficacy and price (STEP) of the drugs are good guidelines for making a choice when there is one [either between groups (e.g. alpha-blockers or ACE-inhibitors, or between drugs of the same group, e.g. enalapril or ramipril or lisinopril, or even between pharmaceutical brands of each medicine)].
5. Monitoring the treatment: Here the choice of the correct endpoint for both effect and safety is important as well as appropriate time points for modulating and individualising therapy. It is crucial to monitor for unexpected drug interactions and appropriately counselling the patient.
6. Developing a rapport with the patient to ensure complete and correct compliance.

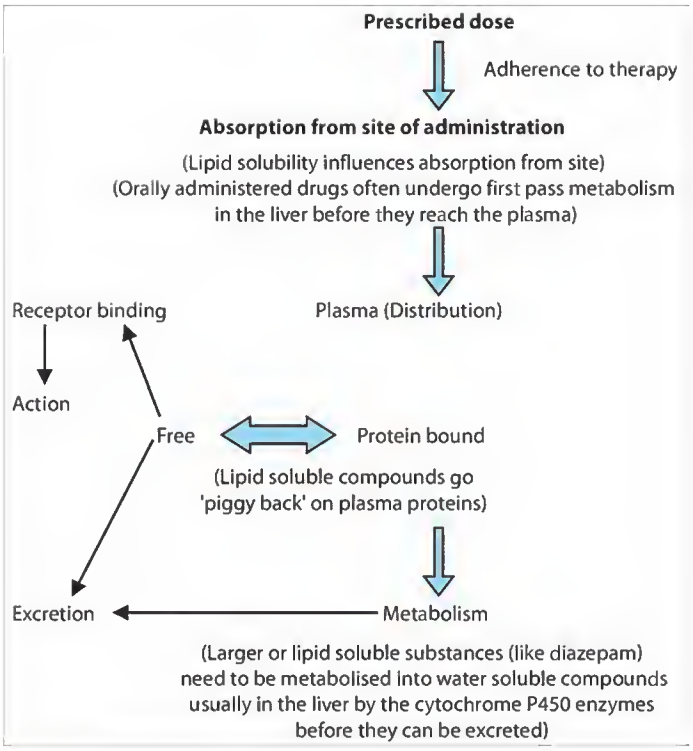

Figure 1: Fate of a drug in the body. All the parameters are influenced by various host- and drug-related factors (some of the key factors are indicated in brackets).

compartment consisting of blood volume and other tissues. This distribution depends on the molecular weight, lipid solubility, protein binding and active transport. Some other drugs (like diazepam) are initially distributed into a small central compartment [consisting of the well-perfused tissues like the brain (contributing to a rapid onset of action with minimal side-effects), blood and heart]. From this, these drugs are rapidly redistributed to a larger peripheral compartment (consisting of poorly perfused tissues like adipose) leading to a rapid reduction in the plasma concentration followed by a slower reduction which occurs due to renal clearance.

Clearance is the ability of the body to remove the drug from circulation and is clinically the most relevant in determining dosage (especially maintenance dose and intervals). The liver is responsible for biotransformation (although some drugs may be excreted via the bile) while the kidney excretes the drug or metabolites and may also be responsible for some metabolism. The hepatic microsomal enzyme system (CYP or cytochrome P450) which has been now studied in great detail is one of the major contributors to variability in drug clearance and the study of how an individual's genetic inheritance affects the body's response to drugs is called pharmacogenomics *(discussed in a subsequent chapter of sec. 6, chapter 9)*. Thirty CYP gene families have been identified in humans and the categories are based upon protein sequence homology. Most of the drug-metabolising enzymes are in the CYP 1, 2 and 3 families. The activity of CYP enzymes can be influenced by genetic and environmental factors [nutrition, alcohol, other drugs (cimetidine is an inhibitor while phenobarbitone induces these enzymes) and smoking] thus influencing drug metabolism.

Apart from this, several other factors influence clearance including many host and drug factors, influencing to a large extent, therapeutic decisions about the choice of drug and dosing regimes. *Prescribing in special conditions is discussed in chapter 4 in this section.*

A certain amount of the drug is cleared from the body in unit time. The time taken to clear 50% of a drug from the body is defined as the 'half-life' ($t_{1/2}$). Most drugs follow first order (exponential) kinetics and these drugs have a fairly constant $t_{1/2}$ (when rate of clearance depends on the concentration of the drug). However, some drugs follow zero order or saturation kinetics where the clearance processes get saturated at a point in time, thus leading to a fixed amount of the drug getting cleared rather than a fixed proportion. Thus, the $t_{1/2}$ now varies according to the concentration and can contribute to toxicity. Phenytoin is a good example, where as the dose increases, the clearance shifts from being exponential to a saturation type, making it important for close monitoring.

A useful clinical application of the knowledge of pharmacokinetics is applied in therapeutic drug monitoring (TDM) which is the measurement of drug levels in body fluids (mostly blood or plasma, and sometimes saliva, urine or cerebrospinal fluid) at intervals to minimise toxicity and maximise effect. Drugs that have a narrow therapeutic window, poor or no physiologic or therapeutic endpoints to guide dosage, and whose pharmacokinetics varies widely between individuals, are good candidates for TDM. Further, if there is a critical need to monitor adherence, TDM is a useful tool.

PHARMACODYNAMICS

Pharmacodynamics deals with 'what the drug does to the body' and is the study of the biochemical and physiological effects of drugs on the body and their mechanisms of action. Knowledge of pharmacodynamics helps in intelligent drug development and also forms the basis of rational drug therapy. Most drugs act by altering body's control systems by different mechanisms, e.g. by binding to receptors, interfering with transport processes, inhibiting enzymes, etc. Coupled with the body's homeostatic responses to the primary actions of the drug, a composite therapeutic effect occurs, which finally leads to well defined and desired clinical endpoints.

ADVERSE EFFECTS OF DRUGS

Unwanted effects are an integral part of drug use. It has been said by Mathew Prior (1664-1721) 'Cur'd yesterday of my disease, I died last of my physician!' Complete information regarding known adverse reactions as well as a knowledge of how to recognise and manage unexpected adverse reactions to medicines is an integral part of rational therapeutics. *Chapter 3 in this section deals with this important part of clinical pharmacology.*

Among the adverse reactions to drug, allergic reactions are clinically the most challenging for both diagnosis and management. Allergic reactions are generally of four types: type I (immediate, anaphylactic, e.g. penicillin), type II (antibody dependent cytotoxic reactions, penicillin induced haemolytic anaemia), type III (immune complex mediated) and type IV (lymphocyte medicated delayed reactions, contact dermatitis). Characteristically, allergic reactions do not show a correlation with the pharmacological properties of a drug, lack a linear relationship with the dose (i.e. a very small dose can precipitate a reaction), are rare and unpredictable, can recur on re-exposure,

usually disappear on withdrawal of drug and reappear on reintroduction of drug. Taking history of drug allergy is crucial before starting therapy as a rule, as allergic reactions, although common with some drugs, can occur with any medicine.

DRUG INTERACTIONS

Drug interactions are common in today's rampant practice of polypharmacy and if they go unrecognised, can lead to fatal outcomes. The true incidence of drug interactions is difficult to determine. Drug interactions can be pharmacodynamic (due to interactions at the receptor) or pharmacokinetic (related to absorption, distribution, metabolism or elimination of the drug).

Pharmacodynamic interactions occur due to additive, synergistic, or antagonistic effects from co-administration of two or more drugs (e.g. synergistic actions of antibiotics, additive effects of ethanol and benzodiazepines, or antagonistic effects, like anticholinergic effects of drugs such as amitriptyline with acetylcholinesterase inhibitors).

Pharmacokinetic interactions are also common. Interference with absorption of drugs by food is the most common example (e.g. Indinavir is rapidly absorbed in a fasted state and absorption is reduced by 80% with a high calorie/fat/protein meal while the absorption of saquinavir is increased significantly when given with a high fat meal. Chelation in the stomach (tetracycline or dairy products) is another cause for interaction. Alteration in gastrointestinal motility or pH also influences drug absorption (e.g. antacids, omeprazole, H2-blockers may decrease absorption of ketoconazole and itraconazole). Competition between drugs for protein or tissue-binding sites can increase free (unbound) concentrations leading to enhanced pharmacological effects (e.g. oral hypoglycaemic agents and nonsteroidal anti-inflammatory drugs). Drug metabolism interactions are very common and occur by co-administration with CYP inducers or inhibitors. Drugs can inhibit a specific CYP even though they are not metabolised by that isozyme, e.g. quinidine is a potent CYP2D6 inhibitor but is itself metabolised primarily by CYP3A4. Cimetidine, erythromycin, ketoconazole, ritonavir, fluoxetine, paroxetine (CYP2D6) and nefazodone (CYP3A4) are the common CYP inhibitors while drugs like rifampin, carbamazepine, phenobarbital or phenytoin induce CYP. Many medicinal plants have been shown to interact with drugs through interference of metabolism (the concentrations of indinavir are decreased in the presence of St John's Wort as it induces CYP3A4 while grapefruit, by inhibiting CYP3A4 can increase concentrations of saquinavir, benzodiazepines or calcium channel blockers).

For a clinician, recognising drug interactions is very crucial so as to manage the patient appropriately. A patient showing exaggerated toxicity or drug effects or treatment failure should trigger a high index of suspicion. When a drug interaction is suspected, the physician must study the time course of the interaction, investigate whether it is a drug class effect and assess if the interaction is clinically significant.

Understanding and applying these principles of clinical pharmacology form the basis rational therapeutics. However, an important principle of therapeutics that must be remembered is 'Drugs cannot work if patients do not take them!' When the physician reaches the decision that the patient requires medicine, a prescription results (**Table 1**). Perhaps the most crucial aspect of drug therapy is that of compliance which is defined as 'the extent to which a person's behaviour coincides with medical advice'. Noncompliance to medication can lead to serious problems for the patient as well as to the community. It is impractical to expect 'perfect' compliance, but useful to define what would be 'adequate' compliance in a given patient during therapy. Supervised therapy [as in directly observed treatment, short-course (DOTS)] assists in improving compliance. Improved communication to convince the patient of the need for compliance and simplifications of the regimes are some other methods reported to improve compliance. In fact, no drug can substitute for effective communication between a doctor and a patient.

An important aspect of drug therapy and response to medicines is the placebo effect and the physician needs to be aware of and exploit this phenomenon to the maximum. An essential part of a therapeutic decision is an assessment of the cost-benefit assessment *(see chapter on Pharmacoeconomics)*.

INTRODUCTION OF NEW DRUGS

New drugs are introduced into the market regularly by pharmaceutical companies and this is associated with aggressive marketing. After extensive preclinical and clinical research (*described in the section on drug development*), a drug is marketed for an approved condition for which it has been developed. When a drug is used for an indication or in an indication that is not approved this is called 'off-label' use and the responsibility for use rests on the physician alone. There has to be sufficient scientific justification for the off-label use. Research on the other hand for 'off-label' indications, new routes of administration or new formulations including fixed drug combinations require regulatory clearance. In India, drug choices are wide because of the variety of drugs approved. Additionally, each drug has several generics and to make a rational choice between these requires skill and a clear understanding of principles of clinical pharmacology.

An interesting feature of therapeutics in India is the widespread popularity of 'alternative' systems of medicine among patients. *Ayurveda, Siddha, Unani, Yoga,* Naturopathy and Homeopathy are officially recognised by the Government of India and most clinicians will come across patients, especially those with chronic diseases like asthma or arthritis using alternative systems of medicine. A physician must be aware and recognise that the medicines from alternative systems used by the patients may have an impact (favourable or unfavourable) on therapy including the occurrence of adverse reactions and drug interactions.

4.2 Rational Use of Drugs

Sangeeta Sharma

The availability of essential drugs is minimal and capacity of the facilities is grossly inadequate. The private sector is the most important source of health care in India, providing approximately 80% of the services. Patients have to shell out of their pocket payments for seeking private health services at the cost of other essential expenditure. The pharmaceutical industry has witnessed tremendous transformation since the 1950s but at the same time irrational, non-essential and hazardous drugs have flooded the market.

Access to essential medicines, high expenditure on medicines and irrational combinations are the three problems people face and public systems are challenged to respond to. Other concerns are the rising health care costs, increasing medicine costs, newer products and technology, over-dependence on investigations, diseases of old age, rising incidence of heart disease, cancer, increased expectations and reducing health budgets.

DRUGS: A CRITICAL INPUT

Drug expenditure is the most critical aspect of the financing of health services. Lack of drugs can block the operation of the health care system. Credibility, effectiveness and attendance at health services, depend on a large extent on patient being able to obtain relevant drugs at the right time. A good diagnosis is not much use if the patient cannot obtain the necessary treatment.

RATIONAL USE OF MEDICINES

Patients receive medications appropriate to their clinical needs, in doses that meet their own individual requirements, for an adequate period of time, and at the lowest cost to them and their community. Unfortunately, worldwide more than 50% of all medicines are prescribed, dispensed or sold inappropriately and 50% of patients fail to take their medicines correctly. Inadequate consulting time, very short dispensing time and incorrect use by patients is of great public health concern too.

Global Epidemic of Irrational Use of Medicines

Problems of irrational use of drugs and non-availability of drugs are often similar in many countries including India. Common types of irrational medicine use are:

- The use of too many medicines per patient (polypharmacy).
- Choice of more expensive drugs when less expensive drugs would be equally or more effective.
- Inappropriate use of antimicrobials, often in inadequate dosage, for non-bacterial infections—common cold, diarrhoea, etc.
- Overuse of injections when oral formulations would be more appropriate.
- Failure to prescribe in accordance with clinical guidelines.
- Failure to provide available, safe and effective drugs/vaccines.
- Under-use of life-extending drugs for illnesses, such as hypertension, heart disease, asthma, and other chronic illnesses.

Massive Detrimental Effects of Irrational Use of Medicines

1. Lack of access to medicines and inappropriate doses results in:
   - Serious morbidity and mortality, particularly for childhood infections and chronic diseases, such as hypertension, diabetes, epilepsy and mental disorders.
   - Overuse of medicines leading to wastage of meagre resources resulting in significant patient harm in terms of poor patient outcomes and adverse drug reactions.
2. Rising anti-microbial resistance:

   Overuse of antimicrobials is leading to increased anti-microbial resistance (AMR) and non-sterile injections to the transmission of hepatitis, HIV/AIDS and other blood-borne diseases. AMR is one of the world's most serious public health problems resulting in prolonged illness and hospitalisation, which are costly and the use of drugs other than first-line drugs may increase cost 100-fold, making them unaffordable.

   Development and spread of anti-microbial resistance is due to:
   - Overuse, misuse, and irrational use by doctors.
   - Non-compliance and self-medication by patients.
   - Non-human use of antibiotics in animal husbandry, aquaculture and agriculture.
3. Irrational overuse of medicines can stimulate inappropriate patient demand, and lead to reduced access and loss of patient confidence in the health system.

   The first step to correcting irrational use of medicines, i.e. promoting rational use of medicines, is to understand:
   - Types and amount of irrational use of medicines, so that strategies can be targeted towards changing specific problems.
   - Monitoring the reasons why medicines are used irrationally, so that appropriate, effective and feasible strategies can be chosen. People often have very rational reasons for using medicines irrationally. Causes of irrational use include lack of knowledge, skills or independent information, unrestricted availability of medicines, overwork of health personnel, inappropriate promotion of medicines and profit motives of selling medicines.

Table 1: Twelve Core Interventions to Promote More Rational Use of Medicines

1. A mandated multi-disciplinary national body—to co-ordinate medicine use policies.
2. Evidence-based clinical guidelines—to aid prescribers on how to treat patients.
3. Essential medicines list based on treatments of choice—to be followed in procurement and distribution of medicines.
4. Drugs and therapeutics committees—to monitor quality of care in the hospitals.
5. Problem-based pharmacotherapy training in undergraduate curriculum—to better equip future doctors in how to prescribe.
6. Continuing in-service medical education as a licensure requirement—in order to ensure that prescribers remain up-to-date with new treatments/guidelines.
7. Supervision of health care workers, audit of prescribing and feedback to prescribers—in order to help prescribers use medicines more appropriately.
8. Provision on independent information (drug bulletins) on medicines—in order to make sure that prescribers have sufficient unbiased information on medicines.
9. Public education about medicines to try and reduce inappropriate self-medication and demand for medicines and also to increase awareness about the importance of adherence.
10. Avoidance of perverse financial incentives such as prescribers earning money from the sales of medicines which encourage over-prescription of medicines.
11. Appropriate and enforced regulation, particularly concerning medicine promotional activities by the pharmaceutical industry, licensing of drug outlets (pharmacies, hospitals) and healthcare workers, and the availability of prescription-only medicines without prescription.
12. Sufficient government expenditure to ensure availability of medicines and staff.

Adapted from WHO, 2002.

Policies to Promote Rational Use of Medicines

Based on the available evidence, WHO has developed recommendations for twelve core national policies and structures that are needed to promote rational use of medicines (**Table 1**).

Essential medicines are those that satisfy the priority health care needs of the population. These can be selected with due regard to disease prevalence, evidence on efficacy, safety and comparative cost-effectiveness. Therefore, these should be available at all times in adequate amounts, in the appropriate dosage forms, with assured quality, and at a price the individual and the community can afford. No public sector or health insurance system can afford to supply or reimburse all medicines that are available in the market. Lists of essential medicines also guide the procurement and supply of medicines in the public sector, schemes that reimburse medicine costs, etc. Careful selection of a limited range of essential medicines results in a higher quality of care, better management of medicines, and more cost-effective use of health resources.

Clinical Guidelines or Standard Treatment

These guidelines is consist of systematically developed statements to help prescribers make decisions about appropriate treatments for specific clinical conditions. These are an effective tool for assisting health professionals to choose the most appropriate medicine for a given condition. Essential medicines list together with standard treatment guidelines are the most powerful tools for promotion of rational use of medicines.

4.3 Adverse Drug Reactions and Pharmacovigilance

MC Gupta

INTRODUCTION

Drugs have the potential to do good which may be trivial to lifesaving. Drugs, used appropriately, can improve both the quality and longevity of life, but drugs also have the potential to cause harm which may be trivial to death. No drug can be considered to be totally devoid of causing any harmful effects to the recipient. The principle of appropriate treatment entails making a balance between the benefit and the harm in such a way that the benefit always outweighs the harm.

ADVERSE DRUG REACTIONS

Magnitude of the Problem of Adverse Drug Reactions

In USA and Canada, adverse drug reactions (ADRs) are the fourth leading cause of death. Over one million Americans suffered from ADRs in 2009. Worldwide also, the ADRs are the sixth leading cause of death. Monetary costs involved in the management of these ADRs are astronomical, a staggering US dollar 75 to 180 billion which may almost be adequate to meet the cost of managing the cardiovascular diseases ($120 to 150 billion) or cancers ($130 to 195 billion). Responsibility of drug-induced injury raises important issues affecting medical practise, not only pertaining to development of drugs, but also of regulatory laws especially in view of the Consumer Protection Act (CPA) in India.

The overall objective of drug development is to ensure that medicinal products being produced are of acceptable quality, good efficacy and safety with a minimum possibility of causing serious adverse effects. All the hazards of drug use cannot be known before it is marketed; neither tests in animals nor clinical trials will reveal all the possible side-effects of the drug. These may only be known when the drug has been administered to a large number of patients over a considerable period of time.

Definition

Adverse drug reaction (ADR) is a response to the drug which is noxious and unintended, and which occurs at doses normally used in man for the prophylaxis, diagnosis, or therapy of disease, or the modification of physiological function.

ADRs have been classified into two broad categories: type A and type B. Type A (augmented) reactions are common, predictable, dose-dependent reactions that account for at least 80% of total reactions and are produced by known pharmacologic actions of the drug. Type B (bizarre) reactions, on the other hand, are uncommon and unpredictable, usually having an immunologic basis and occur only in susceptible individuals. More recently, further classes of ADRs have been defined. These include type C (continuous), which are dose related and time related, type D (delayed) which are time-related and type E (end of use) which are seen after withdrawal of a drug.

ADVERSE EVENT

1. Adverse event is any untoward medical occurrence that may present during treatment with a pharmaceutical product, which does not necessarily have a causal relationship with this treatment.
2. An adverse event may or may not be due to the drug, while an adverse drug reaction is always due to the drug.
3. Adverse event is more relevant to the new drugs where nothing is known of the adverse drug reactions of the molecule under trial.
4. An adverse event can eventually become the ADR of the drug, if it is proven with some certainty that it is because of the drug only.

PHARMACOVIGILANCE

World Health Organization (WHO) defines pharmacovigilance as 'the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other drug-related problems'.

Food and Drug Administration defines it as, 'all the post-approval scientific and data gathering activities relating to the detection, assessment and understanding of adverse events'.

Why Pharmacovigilance?

The information on the safety, collected during the premarketing phase of a medical drug, is inevitably incomplete with regard to the possibility of adverse reactions. Following are the important reasons as to why the pharmacovigilance activities should be routinely carried out.

1. Tests in animals are insufficiently predictive of human safety.
2. Limitations of the premarketing phases of clinical trials
   - Failure to detect rare and delayed adverse drug reactions.
   - Conducted in strictly controlled conditions and not in an actual clinical scenario.
   - Do not provide data
     - In children, elderly, seriously ill, pregnant and lactating patients
     - Patients with other diseases
     - Patients receiving other drugs
     - Patients from various populations
3. Aggressive marketing strategies of the pharmaceutical companies.
4. Fast changing physician and patient preferences.
5. Easy accessibility to drugs.

Pharmacovigilance is needed in every country, because there are differences between countries (and even regions within countries) in the occurrence of adverse drug reactions and other drug related problems. This may be because of differences in:

1. Disease and prescribing practices
2. Drug production distribution and use (e.g. indications, dose and availability).
3. Pharmaceutical quality and composition (excipients) of locally produced pharmaceutical products.
4. Genetics, diet and traditions of the people.
5. The use of non-orthodox drugs (e.g. herbal remedies) may pose special toxicological problems, when used alone or in combination with other drugs.

Data derived from within the country or region may have greater relevance and educational value and may encourage national regulatory decision-making. Information obtained in a certain country (e.g. the country of origin of the drug) may not be relevant to other parts of the world, where circumstances may be different.

The WHO International Drug Monitoring Programme may provide information on possible safety issues which may not yet have emerged within the country's data.

Aims of Pharmacovigilance

Pharmacovigilance is needed for the prevention of drug-induced human suffering and to avoid financial risks associated with unexpected adverse effects.

Major aims of pharmacovigilance are:

1. Early detection of hitherto unknown adverse reactions and interactions.
2. Detection of an increase in frequency of known adverse reactions.
3. Identification of risk factors and possible mechanisms underlying these adverse drug reactions.
4. Estimation of quantitative aspects of benefit/risk analysis and dissemination of information needed to improve drug prescribing and regulation.

The ultimate goals of pharmacovigilance are:

1. The rational and safe use of medical drugs.
2. The assessment and communication of the risks and benefits of drugs in the market to the clinicians.
3. Educating and informing the patients.
4. Making the appropriate regulatory decisions as and when required.

Methods of Pharmacovigilance

A number of methods have been employed for the pharmacovigilance activities, the spontaneous reporting being the most common, effective and cheap in terms of costs. Globally also, this method has the best acceptability. The various methods which can be used for the pharmacovigilance activities are:

1. Case reports and case series.
2. Spontaneous reporting, e.g. yellow card system in UK, blue card system in Australia, Med watch in USA and National Pharmacovigilance Programme (NPP) in India.
3. Prescription event monitoring.
4. Comparative observational studies, e.g. case control and cohort studies.
5. Pharmacy based postmarketing surveillance studies.
6. Intensive hospital monitoring.
7. Record linkage schemes by computer.
8. Population statistics.
9. Meta-analysis

Spontaneous Reporting of Adverse Drug Reactions

Spontaneous reporting is currently the major source of information in pharmacovigilance. This is a sensitive, powerful and a cost-effective system. It is expected now that all the prescribing clinicians should take the professional responsibility of reporting the adverse events causing a risk to the patient to the pharmacovigilance centre of their state/region, and thus, contributing to the NPP. The advantages of the spontaneous reporting are:

1. It can cater to large population.
2. It can cover all types of medicines including the herbals.
3. It is possible to do both in hospital and outpatients.
4. It may generate rapid alerts.
5. It is least likely to influence prescribing behaviour.
6. Low set-up and recurring costs.

The system has some disadvantages also like under-reporting by the clinicians, difficulty in detecting ADRs, number of the exposed unknown patients and there may be a bias in reporting the ADRs.

Who can report?

1. Professionals working in health care are the preferred source of information in pharmacovigilance, e.g. family practitioners, medical specialists and pharmacists.
2. Dentists, midwives and nurses.
3. Pharmaceutical manufacturers should ensure that suspected ADRs must be reported to the competent authority.
4. ADRs may be reported directly by the patients to the national or local ADR monitoring centres. It is important to communicate with their physicians for additional information and data verification.

What to report?

In the early stages of any pharmacovigilance system, reports on all suspected ADRs, known or unknown, serious or non-serious are encouraged, because it is necessary to create a 'notification or reporting culture'. All serious adverse events should be reported. A serious ADR entails, hospitalisation, disability, congenital abnormalitis or death.

1. *For new drugs (up to 5 years):* All suspected reactions, including minor ones, should be reported.
2. *For established drugs:* Serious or unusual suspected adverse reactions are to be reported. If an increase in frequency of a given reaction is suspected, then this is also reported.
3. Special fields of interest are drug abuse and drug use in pregnancy and lactation.
4. Lack of efficacy and suspected pharmaceutical defects is recommended.
5. Adverse reactions to cosmetics.
6. All suspected ADRs associated with drug-drug, drug-food or drug-food supplements interactions.
7. Suspected ADRs associated with the drug withdrawals.
8. ADRs occurring from overdose or medication error.

Pharmacovigilance is primarily concerned with the pharmaceutical medicines (including radiological contrast media, vaccines and diagnostics) but adverse reactions associated with drugs used in traditional medicine (e.g. herbal remedies) should also be considered.

The pharmacovigilance programme in general has not taken off very well in most countries really because of some misconceptions on the part of the clinicians, such as:

1. All serious ADRs are documented by the time, a drug is marketed.
2. It is difficult to determine if a drug is responsible.
3. ADRs should only be reported if absolutely certain.
4. One reported case is not going to make a difference.
5. One can have legal complications if he reports an ADR.

The general attitude of the prescribers which does not really help the cause of pharmacovigilance programme is amply shown by the 'seven deadly sins', *i.e. indifference, ignorance, financial incentives, legal hurdles, complacency, diffidence and lethargy*.

Stakeholders in pharmacovigilance

The stakeholders who can help in pharmacovigilance are the users (patients), prescriber (the clinician), supplier (pharma industry) and the Government. Media can also play an important role.

Communication tools

The main reason for poor success of the pharmacovigilance programmes all over the world has been a poor communication. It is required to use well-defined tools for an effective communication within the various participants of any such programme. Following are some of the proposed tools which are likely to help:

Vehicle	Issued by
"Dear Doctor" letters	Pharmaceutical manufacturers
Medicine alerts	National health authorities
Media statements	National health authorities/ pharmacovigilance centres
Patient information leaflets	National health authorities/ pharmacovigilance centres/ pharmaceutical manufacturers
Newsletters	National pharmacovigilance centres and WHO

Pharmacovigilance Scenario in India

The status of the pharmacovigilance activities in India has been dismal. A fresh effort is being made again to revive this programme by the Government through Drug Controller General of India (DCGI). The revised National Pharmacovigilance Programme has now chosen 24 centres for this all over the country with a nodal center at New Delhi. With such a large population using the drugs and a vast amount of expertise, the National Pharmacovigilance Programme in terms of implementation and an acceptable outcome should not be a problem, if all cooperate and report.

Good pharmacovigilance practices

The pharmacovigilance is an important tool in the lifecycle of a drug starting from the beginning of the clinical trials and going into the post-marketing phase with the sole motive of making the drug treatment safe for the patient. The various ingredients of these practices are as follows:

1. Education, training and access to reliable information for the clinicians and the patient.
2. Good pharmacovigilance regulations.
3. Development of a national pharmacovigilance database.
4. Good pharmacovigilance communication.
5. Good culture of spontaneous reporting by the clinicians and the patients.
6. Proactive industry initiatives.
7. Provision of convenient system of submission and feedback on reported ADRs.
8. Better patient care through better safety information.

CONCLUSIONS

The clinicians have to be aware of the harmful potential of the drugs and to be ready to detect the ADRs at the earliest and correlate them with the drug therapy and if so to manage them as best as possible to serve the best and safe interest of the patients which will go a long way for the success of the NPP. This will surely need the active and willing participation of all the stakeholders.

4.4 Prescribing in Special Situations

Uma Tekur

INTRODUCTION

Inter-individual and intra-individual variation in drug response is a well known phenomenon. It is, therefore, imperative that the health care providers are aware of the sources of such variations. This knowledge will help physicians prescribe drugs more effectively and safely.

The variations in the drug response may be:

1. *Pharmacokinetic variations* are chiefly due to alteration in the absorption, distribution, metabolism or excretion of drugs in an individual patient leading to an alteration in the concentration of drug available at the site of its action. These variations may be seen in malabsorption syndrome; heart failure, nephrotic syndrome (due to altered absorption); renal or hepatic impairment or in meningitis (variation in distribution, metabolism or excretion).
2. *Pharmacodynamic variations* due to difference in response to a drug. These may be seen in *Myasthenia gravis*, nephrogenic diabetes insipidus, familial hypercholesterolaemia, precocious puberty, etc.

The human body undergoes constant physiological changes throughout one's life. Definitive changes are observed in childhood, old age, and in women during pregnancy and lactation.

The present chapter will briefly discuss the drugs use: (i) at the times of physiological changes seen in pregnancy, childhood and old age, and (ii) in hepatic and renal impairment.

DRUGS IN PREGNANCY

There is a two-fold problem that should be taken care of while administering drugs during pregnancy, viz: (i) alteration in drug response due to variation in physiology, and (ii) the teratogenic effects of drugs.

A pregnant woman will require drug treatment primarily under two circumstances.

1. For the management of pregnancy related (obstetrical) conditions, and
2. For the management of medical conditions unrelated to pregnancy.

Obstetrical Conditions

The common obstetrical problems encountered during pregnancy are:

Nausea and vomiting

These symptoms are seen in early pregnancy and usually do not require any drug therapy. However, hyperemesis gravidarum may be treated with doxylamine (anti-histaminic) alone or in combination with pyridoxine. Metoclopramide should be avoided in pregnancy. Other antiemetics that may be safely used in pregnancy are, promethazine, cyclizine and prochlorperazine.

Anaemia

Due to increased demand of growing foetus anaemia occurs commonly. Folic acid and iron should be given routinely during pregnancy. Folic acid should be started as soon as pregnancy is diagnosed whereas iron may be started in second trimester. The risk of neural tube defects is significantly reduced with supplemental folic acid. This is in addition to a healthy diet that should be recommended throughout the pregnancy.

Pregnancy induced hypertension

It can present as pre-eclampsia or eclampsia. Apart from increase in blood pressure, eclmapsia manifests as seizures. Alpha methyldopa is the drug of choice for the management of hypertension whereas magnesium sulphate is used for the treatment of eclampsia.

Pre-term labour

Atosiban (oxytocin receptor antagonist), calcium channel blockers, terbutaline like drugs can be used for delaying the labour. In addition, dexamethasone can be administered to accelerate foetal lung maturation.

Placenta praevia

Drugs do not play much role in the management of this condition.

Rh isoimmunisation

To a mother with Rh negative blood group, if a baby is born with Rh positive blood group, anti-D (anti-Rh immunoglobulin) should be administered within 72 hours of delivery to prevent erythroblastosis foetalis that may occur during subsequent pregnancy.

Medical Conditions Complicating Pregnancy

General guidelines to be followed are:

1. As a general rule, drugs should be avoided during pregnancy.
2. The drugs having the best safety record over time should be used if necessary.
3. Newer drugs should be avoided unless safety is clearly established.
4. The drugs should be used at lowest effective dose and for shortest period.
5. Over-the-counter drugs cannot be assumed to be safe in pregnancy.

The following is a list of drugs that may be given during pregnancy if necessary.

1. ***Analgesics:*** Paracetamol and ibuprofen (at low doses) are safe during pregnancy. Other nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids should be avoided during pregnancy.
2. ***Anti-allergics:*** Older anti-histaminics like chlorpheniramine and promethazine are considered safe during pregnancy. Second generation agents like cetirizine should be avoided.
3. ***Anti-microbials:*** Penicillins, macrolides and cephalosporins are considered safe during pregnancy. Tetracyclines, aminoglycosides and fluoroquinolones should be avoided.
4. ***Anti-tuberculosis drugs:*** Rifampicin and isoniazid are safe during pregnancy. Streptomycin should not be used in pregnancy.
5. ***Anti-parasitic and anti-protozoal drugs:*** Diloxanide furoate (anti-amoebic) drug is safe during pregnancy whereas metronidazole should be avoided.

   Chloroquine and proguanil are safe antimalarials; and piperazine and niclosamide are preferred for worm infestations.
6. ***Anti-hypertensive drugs:*** Methyldopa, hydralazine, labetalol, clonidine and prazosin are safe during pregnancy. Angiotensin converting enzyme (ACE)-inhibitors and angiotensin receptor blockers are absolutely contra-indicated during pregnancy.
7. ***Anti-diabetic drugs:*** Insulin is safe to be used during pregnancy whereas oral anti-diabetic drugs should be avoided.
8. ***Hormones:*** Inhaled and topical corticosteroids can be safely used during pregnancy. Oral steroids like prednisolone in low doses may be given. However, high-dose and prolonged use of oral corticosteroids are not indicated. Thyroxine can be used safely for the treatment of hypothyroidism and propylthiouracil is used for hyperthyroidism.
9. ***Drugs for central nervous system (CNS) disorders:*** Haloperidol (anti-psychotic drug) is safe. Fluphenazine, clozapine should be avoided during pregnancy. Lithium is contraindicated. Amitryptyline, imipramine and fluoxetine are safe anti-depressants whereas other SSRIs should be avoided.
10. ***Anti-coagulants:*** Heparin and low molecular weight heparins are considered safe during pregnancy whereas oral anti-coagulants like warfarin should be avoided.
11. ***Asthma:*** Inhaled bronchodilators like salbutamol, and ipratropium, inhaled corticosteroids like beclomethasone and mast cell stabilisers like cromoglycate are safe drugs during pregnancy. Theophylline and oral corticosteroids should be avoided.
12. ***Laxatives:*** Dietary fibre, lactulose and Ispaghula are considered safe laxatives during pregnancy.
13. ***Anti-diarrhoeals:*** Oral rehydration salts should be used to prevent and treat the dehydration. Use of loperamide and diphenoxylate are unsafe.

Breastfeeding and Drugs

Many drugs are secreted in the breast milk. However, all the drugs do not necessarily cause harm to the baby. The clinician must determine the risk-benefit ratio of the continued breast-feeding while prescribing drugs to a lactating female. It is inappropriate to discontinue breastfeeding while on drug treatment or to continue breastfeeding while taking drugs that are contraindicated.

Two factors to be considered are:

1. Are these drugs indicated by themselves in children, e.g. penicillins?
2. Is there any risk to the infant in the concentration present in the milk?

Safety Assessment of Some Frequently Used Drugs

Analgesics

Analgesics such as paracetamol, ibuprofen, naproxen and codeine are considered to be 'safe', due to low transfer into breast milk. Aspirin is best avoided due to the theoretical risk of Reye's syndrome. Sumatriptan has a short half-life of approximately 2 hours and infant exposure can be almost completely avoided by expressing and discarding breast milk for approximately 8 hours after dosing. Tramadol has a low transfer into breast milk (insufficient data) therefore is to be avoided. Morphine is usually considered 'safe' because of low transfer into milk, and high first-pass metabolism.

Anti-helminthics

There does not appear to be any data on the transfer of mebendazole or pyrantel embonate into human breast milk although these agents are generally considered to be 'safe' due to poor absorption from the gastrointestinal tract.

Antibiotics

- Antibiotics such as penicillins, cephalosporins and macrolides are considered to be compatible with breastfeeding although there are theoretical risks of alterations to infant bowel flora and allergic sensitisation.
- The safety of metronidazole is controversial.
- The transfer of tetracyclines into breast milk is low but are avoided due to the possible risks of inhibiting bone growth or causing dental staining.
- Fluoroquinolones have been reported to cause arthropathies in immature animals and hence avoided.
- Sulphonamides such as sulphamethoxazole are avoided in infants with hyperbilirubinaemia or glucose-6-phosphate dehydrogenase deficiency.

Anti-coagulants

Heparins (unfractionated and low molecular weight) are considered 'safe' since do not cross into breast milk to a significant extent. Warfarin is also considered to be compatible with breastfeeding as transfer is low, and adverse effects and changes in prothrombin time have not been detected. However, it would be prudent to monitor the infant's prothrombin time during treatment.

Anti-convulsants

Carbamazepine, phenytoin and sodium valproate are generally considered to be compatible with breastfeeding although the infant should be observed for evidence of central nervous system depression. Lamotrigine and gabapentin are best avoided during breastfeeding.

Anti-depressants

Selective serotonin reuptake inhibitors (SSRIs) transfer into breast milk to varying extents. Paroxetine is the preferred SSRI in breastfeeding women. Fluoxetine along with its active metabolite, norfluoxetine transfers to a greater extent and, has a long half-life of one to two weeks and may accumulate in a breastfed infant. Tricyclic anti-depressants are considered to be compatible with breastfeeding. Moclobemide considered compatible with breastfeeding.

Anti-histamines

Promethazine, dexchlorpheniramine and diphenhydramine are considered to be safe although it would be prudent to monitor for evidence of sedation or irritability in the infant. Loratadine and fexofenadine are likely to be safe due to low transfer into milk.

Benzodiazepines

Sporadic use of midazolam and temazepam (short half-life) are safe. Diazepam (having long half-life) may accumulate and is associated with lethargy, poor suckling and reduced weight gain.

Recreational agents

These have particular problems because the dose and pattern of usage are uncontrolled. In addition most have relatively high infant doses. Alcohol consumption should be minimised during lactation (e.g. by withholding breastfeeding for about two hours after ingestion of a standard alcoholic drink). Caffeine exposure may lead to restlessness and irritability in infants. Smoking is best avoided by breastfeeding mothers.

DRUGS IN GERIATRICS

Ageing alters pharmacokinetics and pharmacodynamics, affecting the choice, dose, and dosing frequency of many drugs. The elderly have many chronic disorders and consequently use more drugs than any other age group. Safe, effective pharmacotherapy is one of the greatest challenges in clinical geriatrics. Appropriate use of drug requires an evaluation of potential benefits and risks.

EFFECT OF AGE ON PHARMACOKINETICS OF DRUGS

Absorption and Distribution

Absorption and distribution of drug tend to be trivial and clinically inconsequential. The relative decrease in total body water leads to higher blood (and often tissue) concentrations of some water-soluble drugs.

Hepatic Metabolism

Decreased hepatic blood flow significantly affects hepatic elimination of drugs. Hepatic cytochrome p450 enzymes is reduced. In the elderly, the initial doses of, labetalol, propranolol, verapamil should be reduced. Drugs with active metabolites lihe diazepam, chlordiazepoxide, amitriptyline, imipramine, chlorpromazine, thioridazine, risperidone, and morphine, meperidine, propoxyphene, may accumulate and have increased risk of toxicity. The maintenance doses of these drugs should be reduced.

Renal Elimination

Clinical implications depend on the contribution of renal elimination to total systemic elimination and on the drug's therapeutic index. The physiologic changes decrease renal elimination of the drugs. Creatinine clearance (measured by the Cockcroft-Gault formula) is used to guide of dose excreted by the kidneys.

$$Cl_{creat}\ (mL/min) = \frac{[140 - age\ (yr)]\ [body\ wt\ (kg)]}{(72)\ [serum\ creatinine\ (mg/dL)]}$$

For women, the calculated values are multiplied by 0.85.

EFFECT OF AGE ON PHARMACODYNAMICS OF DRUGS

Increased sensitivity due to ageing must be considered with drugs like morphine, pentazocine, warfarin, ACE-inhibitors and diazepam (especially when given parenterally) and tolbutamide, glyburide and beta-blockers should be used with caution because of serious dose-related toxicity.

For effective and safe sedation, the dose of midazolam should be decreased by 30% in elderly patients because of pharmacodynamic changes associated with age.

Principles of Drug Therapy in Elderly

Efficacy and safety are important considerations when prescribing drugs in the elderly. Therefore, use drugs with documented efficacy and lowest toxicity.

Dose must often be reduced in the elderly. In general, the starting doses of drugs are about one-third to one-half the usual adult doses.

Complexity of drug regimens (e.g. multiple drugs, frequent dosing, and variable doses) increases the risk of non-compliance. If a patient has more than one disorder, e.g. hypertension and angina then treat both conditions with a single drug like a beta-blocker or calcium channel blocker. Wherever possible choose long-acting or slow-release preparations for better compliance.

Cost of drugs can impose a major financial burden, hence least expensive drug with comparable efficacy should be considered.

Drug Therapy in Children

Children are not small adults. It cannot be assumed that a child's dose is proportional to an adult's dose (i.e. a 5 kg child requires 1/10 the dose of a 50 kg adult).

Pharmacodynamic Considerations

Children have increased risk with certain drugs because of differences in pharmacokinetics or because of drug effects on growth and development. Although the adverse effects are similar to those seen in adults, but children are at high-risk of accidental poisoning. Infants are at risk of toxicity from drugs used by adults.

Common drugs with unique or higher risk of adverse effects in children are presented in **Table 1**.

Drug dosing

In children, less than 12 years is always a function of age, body weight, or both. This approach is practical but not ideal; even within a population of similar age and weight, drug requirements may differ because of maturational differences in absorption, metabolism, and elimination. Thus, dose adjustments should be based on plasma drug concentration, wherever possible.

Table 1: Drugs Manifesting Unusual Toxicity in Children

Drug	Adverse effect
Local anaesthetics (e.g. benzocaine, mixture of lidocaine and prilocaine)	Cyanosis due to conversion of haemoglobin to methemoglobin
Sulphonamides	Kernicterus in neonates
Diphenoxylate	Respiratory depression and death as an overdose syndrome, usually in children < 2 years
Fluoroquinolones	Cartilage toxicity suspected based on animal studies, but adverse effects in humans are not proved
Chloramphenicol	Grey Baby syndrome in neonates
Prochlorperazine	Extrapyramidal effects, opisthotonus and bulging fontanelles. Febrile and dehydrated infants especially at risk
SSRIs	Increased incidence of suicidal ideation in children and adolescents
Tetracycline	Discolouration and pitting of tooth enamel. This adverse effect is restricted to children < 8 years

DRUGS AND LIVER DISEASE

Pharmacotherapy in liver disease can be discussed under two broad headings:

1. Drugs causing hepatotoxicity.
2. Hepatic disease affecting the drug pharmacokinetics and dynamics.

Drug-Induced Hepatotoxicity

The liver plays a central role in transforming and clearing chemicals and is susceptible to the toxicity from these agents. Major mechanisms of drug-induced hepatotoxicity include:

1. Interference with bilirubin transport and conjugation occurs, e.g. rifampicin.
2. Use of paracetamol and isoniazid cause cytotoxic damage.
3. Cholestasis occurs with orally active anabolic and androgenic agents and oral contraceptives, phenothiazines like chlorpromazine, trifluoperazine, promazine, pecazine, etc.
4. Mixed cytotoxic/cholestatic injury occurs with chlorpromazine. However, p-aminosalicylic acid may cause mixed hepatocellular liver injury.
5. Fatty liver (steatosis) occurs with the use of tetracycline.
6. Chronic active hepatitis, cirrhosis and subacute necrosis is seen with alpha-methyldopa, nitrofurantoin and isoniazid. Long-term administration of the antituberculosis drug (isoniazid) may lead to hepatic dysfunction.
7. *Liver tumours:* Anabolic steroids have been implicated as responsible for primary hepatocellular carcinomas and adenomas.
8. *Non-specific changes:* Certain hypotensives, vasodilators, anti-inflammatory agents and oral contraceptives cause a transient increase in transaminase levels.

List of Hepatotoxic Drugs

1. *Analgesics:* NSAIDs, acetaminophen.
2. *Anti-diabetic agents:* Acarbose, pioglitazone, sulphonylureas (e.g. Glyburide).
3. *Lipid-lowering medications:* HMG-CoA reductase inhibitors (statins) and nicotinic acid (niacin).
4. *Anti-hypertensives:* Labetalol, hydralazine, antiarrhythmics, amiodarone, procainamide.
5. *Antibiotics:* Erythromycin, estolate, isoniazid, nitrofurantoin, sulphonamides, tetracycline.
6. *Anti-fungal medications:* Fluconazole, itraconazole, ketoconazole.
7. *Anti-convulsant medications:* Valproic acid, carbamazepine.
8. *Psychotropic medications:* Bupropion.
9. *Tricyclic anti-depressants:* Chlorpromazine.
10. *Hormonal medications:* Tamoxifen, testosterone.
11. *Miscellaneous medications:* Halothane, methotrexate etretinate, protease inhibitors.

Hepatic Disease Affecting the Drug Pharmacokinetics and Dynamics

Liver is a metabolic factory of the body which controls and regulates the body physiology. A large proportion of drugs are metabolised and their pharmacological properties are regulated by the liver. In disease states of the liver, the metabolism of these drugs may significantly change and therefore these drugs may have enhanced action even bordering toxicity. Therefore, use of these drugs should either be reduced or stopped totally. Drugs excreted through the bile namely azithromycin, tetracycline, rifampicin and fusidic acid have a reduced excretion in cases of intrahepatic and extrahepatic obstruction.

Hypoalbuminaemia associated with marked liver dysfunction is associated with impaired metabolism of drugs which bind to albumin in the body. One of the examples is Phenytoin and the toxicity of such drugs is increased manifold. The effect of drugs like alcohol, opioids, sedatives or hypnotics may be prolonged and enhanced significantly in liver disorders.

Similarly, action of anti-coagulants may enhance mainfold in patients of advanced liver disease. The risk of bleeding also increases in patients with liver disease especially on NSAIDS and the bleeding may occur in areas like brain, kidney and subcutaneous tissue.

In liver disease, there are no clear cut guidelines available like that in CKD about the change in dosage schedule in cases of liver dysfunction. Therefore, the drugs may have to be reduced or stopped altogether.

DRUGS AND RENAL DISEASE

Pharmacotherapy in renal disease can be discussed under two broad headings:

1. Drugs causing nephrotoxicity.
2. Renal disease affecting the drug pharmacokinetics and dynamics.

Drugs Causing Nephrotoxicity

Many drugs can cause renal dysfunction.

Drugs causing prerenal damage

Nonsteroidal anti-inflammatory drugs (NSAIDs), even in short course, can cause acute renal failure; ACE-inhibitors can also cause a deterioration in renal function. Care should be taken when an ACE-inhibitor and NSAIDs are prescribed together as this combination may precipitate an acute deterioration in renal function.

Drugs causing intrarenal damage

Drugs that cause glomerulonephritis include penicillamine, gold, captopril, phenytoin penicillins, sulphonamides and rifampicin.

Drugs that may cause interstitial nephritis include penicillins, cephalosporins, sulphonamides, thiazide diuretics, frusemide, NSAIDs and rifampicin.

Aminoglycosides, amphotericin and cyclosporine can cause acute tubular necrosis.

Drugs causing postrenal damage (urinary tract obstruction)

High-dose sulphonamides, acetazolamide or methotrexate may cause crystalluria and could therefore cause obstruction. Tricyclic antidepressants, and alcohol may cause urinary tract obstruction due to retention of urine in the bladder.

Other nephrotoxic drugs

Cephalosporins: Cephaloridine, one of the first cephalosporins has been associated with direct renal toxicity but third generation cephalosporins, e.g. cefixime, have very rarely been reported to cause nephrotoxicity.

Analgesics: NSAIDs may cause acute renal failure. Analgesic nephropathy has been most commonly seen with combination analgesic that contain aspirin and/or paracetamol. Analgesic nephropathy is one of the few preventable causes of chronic renal failure. Discontinuation of the abused drugs often results in stabilisation or even improvement in renal function Lithium levels consistently above the therapeutic range have been associated with development of a nephrogenic diabetes insipidus.

Renal Disease Affecting Drug Pharmacokinetics and Dynamics

An accurate estimation of renal function, or glomerular filtration rate, requires sophisticated techniques. In practise, the serum creatinine concentration is used for day-to-day assessment of renal function. Creatinine clearance can be calculated using Cockcroft-Gault formula.

Dose Alteration in Renal Impairment

Generally dose adjustment is needed when the creatinine clearance is below 60 mL/min. Adjustments can be achieved by a reduction in dose, or an extension of the dosing interval, or both. List of some commonly prescribed drugs that require dose alteration in renal impairment are given in **Table 2**.

CONCLUSION

The dosage of drugs is based on the half life of the drug, age and weight of the individual. This dosage may need to be adjusted in special situations like, liver disease, kidney disease, pregnancy. This is important so that the function of that organ is not compromised further and due to poor excretion. The toxicity of drugs may ensure at therapeutic dosages due to retention in the body. In pregnancy the issue of medicine producing teratogenic effects and crossing the placental barrier may induce damage to the foetus.

Therefore this chapter has discussed some of important issues in drug usage in such situations. Adjustment of drug dosages has been highlighted. It is important for a clinician to know the pharmacology and metabolism of the drug along with the integrity of functional capacity of various organs where drug is metabolised or excreted and defects of various enzyme systems.

Table 2: Commonly Prescribed Drugs that Require Dose Adjustment in Renal Impairment

Class	Examples
Antibiotics/anti-fungals	Aminoglycosides (e.g. gentamicin), vancomycin, ceftazidime, cefepime, cephazolin, ciprofloxacin, fluconazole, piperacillin, carbapenems (e.g. meropenem), sulphamethoxazole
Anti-virals	Famciclovir, acyclovir, valacyclovir, valgancyclovir, gancyclovir
Anti-coagulants	Low molecular weight heparins (e.g. enoxaparin)
Cardiac drugs	Digoxin, sotalol, atenolol
Diuretics	If creatinine clearance is less than 30 mL/min: avoid potassium-sparing diuretics due to risk of hyperkalaemia-thiazide diuretics have limited efficacy
Opioids	Morphine, codeine, pethidine (due to risk of accumulation of active or toxic metabolites)
Psychotropics/anti-convulsants	Amisulpride, gabapentin, lithium, levetiracetam, topiramate, vigabatrin
Hypoglycaemic drugs	Metformin, glibenclamide, glimepiride, insulin
Drugs for gout	Allopurinol, colchicine
Others	Lamivudine, methotrexate, penicillamine

4.5 New Drug Development

Sadhna Joglekar

INTRODUCTION

Pharmaceutical medicine is a relatively new discipline, but is growing very rapidly. It deals with the discovery, development, evaluation and monitoring of drugs and devices, as well as with medical aspects of their commercial promotion.

THE PROCESS OF DRUG RESEARCH AND DEVELOPMENT

The research and development (R and D) process for a new drug can be subdivided into the following phases: discovery (basic chemical or structural research); preclinical R and D; clinical development and regulatory development.

In addition, two other processes contribute to the life-cycle of a drug, once it is marketed. These are pharmacovigilance and life-cycle management (which includes development of new or improved uses of the drug or new delivery systems).

DISCOVERY

In the early 50s and 60s, new drugs were discovered primarily through random screening and serendipity played a very crucial role. Structure-activity relationship (SAR) was a rudimentary science then. The 70s and 80s saw the process of pharmaceutical discovery evolve into a fine science of protein chemistry and enzyme elucidation. Combinatorial chemistry, genomics and high-throughput screening have characterised the 90s with a resultant drug discovery targeted at molecular and disease mechanism level.

Today, the starting point for the R and D activity is the identification of an unmet medical need. This is followed by the identification of specific molecular targets (e.g. cellular enzymes or receptors) with the help of protein biochemistry, immunology (antibody targeting), pharmacology and molecular biology. One of the latest entrants on the scene of target identification is the use of genomics and linkage analysis. A classic example of the success of this technique is the identification of apolipoprotein E (ApoE) as an important causative factor in Alzheimer's disease. Once a molecular target is identified, it is validated. If results of validation experiments appear promising, drug screens or assays are established to identify new chemical entities. An assay essentially integrates a biological system with chemical compounds that may become tomorrow's drugs. The sources of starting material for drug screens are chemical libraries, natural products, computationally designed drugs and drugs derived from medicinal chemistry which are modified using combinatorial chemistry.

Besides evaluation and validation of a new chemical entity, the drug discovery programme also includes cytotoxicity evaluation. Only compounds with good activity in '*in vitro*' assays with no cytotoxicity progress to animal testing.

PRE-CLINICAL/NON-CLINICAL TOXICOLOGY AND PHARMACOLOGY

Initiation of non-clinical toxicology studies marks the end of the discovery or research phase and the beginning of the development phase. Animal toxicology studies can be categorised into the following:

1. Acute toxicity: single dose and repeat dose
2. Subacute toxicity
3. Chronic toxicity
4. Special toxicological studies

Single dose studies are an important first step in establishing the safety profile of a new chemical entity, the aim being to test a range of doses, from those that produce no effect to those that produce some level of exaggerated effect. The results of these studies guide dose selection for the repeat dose studies, in which animals are provided continuous exposure to test drug to identify safe levels of the drug. Generally, animals are exposed to higher doses of the drug for longer duration than that planned in clinical studies. An important aspect of these studies is pharmacokinetic correlation called 'toxicokinetics'.

The duration of chronic studies depends to a large extent on the intended duration of therapy in clinical usage. It varies from 6 months to 9-12 months in rodent and non-rodent species.

Special studies include reproduction and teratogenicity studies, carcinogenicity studies and mutagenicity studies. It was the thalidomide disaster which highlighted the need to evaluate new drugs in reproductive toxicology studies. Carcinogenicity studies involve exposure of rodents to the new chemical entity for 18-24 months and are usually required for drugs intended to be used clinically for 6 months or more. Apart from these, special studies could also include neurotoxicity studies, metabolic studies, etc.

All preclinical studies intended to support further clinical work or marketing applications need to be conducted in compliance with good laboratory practices (GLP) and ICH (International Conference on Harmonisation) guidelines, wherever applicable. In addition, local national regulations stipulate different types of studies.

CLINICAL DEVELOPMENT

The successful culmination of *in vivo* animal data, receptor binding studies and *in vitro* functional assays, is a progression of the new chemical entity to clinical testing. The clinical development programme is divided into four phases. Although in earlier times, the testing of a drug used to progress from one phase to the next one in a step-wise manner, the temporal distinction between these phases has significantly blurred in recent times, due to evolving regulatory

environment, financial considerations and a need to expedite drug development. Definitions of phases of clinical trials are therefore purely functional and an investigational medicine is often evaluated in two or more phases simultaneously. It must be highlighted here that all clinical trials with drugs are regulated in India by the Schedule Y of the Drugs and Cosmetics Act, 1945 (http://cdsco.nic.in). Further, the Indian Council of Medical Research (ICMR) has issued guidelines for ethical conduct of biomedical research *(http://www.icmr.nic.in/human_ethics.htm)* and it is expected that all individuals conducting clinical research would follow these guidelines.

Phase I (First in Human) Studies

Phase I studies are the first opportunity for extrapolation from animal data to human exposure. These are initial safety studies, usually conducted in normal volunteers, the notable exception being oncology drugs which are evaluated in cancer patients even at Phase I level. The aim of these studies is to establish a dose range tolerated by volunteers for single and multiple doses. Additionally, pharmacokinetic studies are usually considered as Phase I studies, regardless of when these are conducted during a medicine's development.

Phase II (First in Patients) Studies

These are studies in a selected group of patients, with an aim to assess safety and identify the tolerable effective dose of the new drug. Phase IIa generally refers to pilot studies which may assess dose response, frequency of dosing, type of patient, etc. Phase IIb, also termed as 'pivotal studies', are well-controlled trials, usually representing the most rigorous demonstration of a drug's efficacy. Studies in this phase are usually exploratory in nature.

Phase III Studies

These are aimed at generating additional efficacy and safety data in relatively large number of patients in both controlled and uncontrolled trials. Special population groups such as the elderly or those with renal failure are also studied during this phase.

Phase III trials are often subdivided into IIIa (prior to regulatory submission of New Drug Application) and IIIb studies (after regulatory submission of New Drug Application but before its approval). Phase III studies are generally aimed at being confirmatory studies.

Phase IV Studies

New drug development does not stop when regulatory approval comes in. As a matter of fact, the true test of a new drug begins once it is available in the market and millions of patients are prescribed this drug in a real-world, uncontrolled environment. Specific studies are conducted after a medicine is marketed in order to provide additional information on efficacy or safety, or drug interactions or comparisons with other marketed drugs. Phase IV studies are distinct from post-marketing surveillance, which are observational or non-experimental in nature.

CLINICAL STUDY DESIGNS

While designing clinical studies, different methods are used to enhance the accuracy of the data and to reduce bias and effect of nondrug factors. Some of these techniques are given below.

Blinding

This technique is employed to reduce observer bias and patient bias by concealing the identity of the treatment being administered. If either the investigator or the patient is unaware of the treatment, the study is termed as 'single-blind' study. If both these parties are unaware, the study is termed as 'double-blind'.

Placebo-Controlled Study

In addition to the specific effects of the drug, the final patient response is often affected by non-specific factors such as patient's personality, attitude of the medical staff, appearance of the drug and the feeling of being looked after. To distinguish the pharmacological effect from non-specific effects, a pseudo drug, identical in appearance but pharmacologically inert (placebo), is administered.

Randomisation

In a comparative study, allocation of patients to different groups must be done by random assignment. Randomisation ensures random distribution of uncontrolled variability factors and ensures that patient assignment to treatment groups cannot be predicted.

Finally, one must be cognizant of the fact that the R and D process is fraught with inherent risks and is an expensive and time-consuming process. It is estimated that the end-to-end process can take upwards of 10 years and cost on an average in excess of US $800 million in the US before a chemical is marketed as a 'medicine'.

4.6 Pharmacoeconomics

Gurudas Khilnani

INTRODUCTION

The health expenditure is increasing day-by-day due to increasing cost of medicines and other health services. The expenditure is further escalated by increased life-expectancy, technological upgradation and increased demand due to increased awareness. Therefore, there is a need for optimal allocation of limited resources. Pharmacoeconomics is a subset of health economics that identifies, measures and compares the costs of medicines/treatments with outcomes. It helps us to make therapeutic choices among the alternatives. It should not be viewed merely as cost cutting academic exercise because it is an important aspect of rational therapeutics and enhancing patient care. Pharmacoeconomic analysis is also increasingly incorporated in clinical protocols for the evaluation of new drugs.

COMMON TERMS USED IN PHARMACOECONOMIC ANALYSIS

Efficacy

It is the utility of treatment in ideal (trial conditions) settings. Clinical effectiveness is the effect of treatment in clinical settings than in ideal settings.

Incremental Analysis

It finds out the superiority and benefit of new treatment over and above existing one. This is done by calculating additional cost of new treatment for treating one extra patient or how much extra cost is needed to discharge a patient one day earlier to the existing treatment. This is called as incremental or marginal cost, which is how much cost is changed with a small change in outcome. Incremental analysis is usually done for cost-effective analysis.

Cost Effectiveness

It compares natural units of beneficial outcome (e.g. reduction in HbA1c, life years gained, etc.) with the cost of treatment. Cost of a drug may be lower than the alternative available and therefore, total cost of treatment is considered. An example is use of low molecular weight heparin (LMWH) *versus* conventional heparin (CH). The cost price of CH is less than that of LMWH, but CH use requires frequent injections (nursing charges included) and monitoring by activated partial thromboplastin time (aPTT) test, which also has some cost. Thus, LMWH may become more cost-effective in certain situations. **Figure 1** gives four possible outcomes found in such a analysis.

It is obvious that a therapy, which is less costly and more effective, should be preferred. If a newer medicine or treatment is more costly but less effective, it should be discarded. When new treatment is more effective but more costly then cost-effectiveness analysis may provide quantitative data (how many life years are gained and is it worth to spend more?) for rational selection of new therapy. If new medicine/treatment is less effective and less costly, it is to be ascertained by cost-effectiveness analysis that existing medicine/therapy be retained or not.

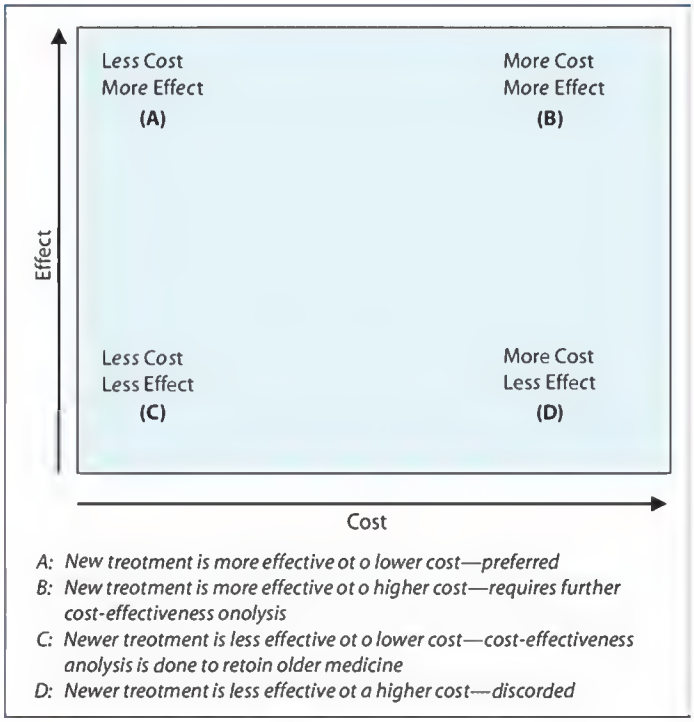

Figure 1: Cost-effectiveness analysis.

Perspective

Since overall cost reduction affects society at large, therefore societal perspective is considered in most of the pharmacoeconomic analyses.

METHODS OF PHARMACOECONOMIC EVALUATION

Utilising the basic fundamentals of economics, the cost is considered as one factor and is compared with benefit accrued from the use of medicine or treatment as another variable. Therefore, cost outcome analysis is an integral part of pharmacoeconomics. The data for analysis can be collected by prospective or retrospective studies. Another method is the use of 'modelling' such as decision analysis tree to make value based decisions.

Cost

This includes direct, indirect and intangible costs.

Direct cost

It is the cost of procurement of medicines and treatment. It includes price of medicines, nursing, hospitalisation, transportation and drug administration. These are measured easily.

Table 1: Types of Pharmacoeconomic Analysis

Type of analysis	Measurement	Example	Advantages	Disadvantages
Cost minimisation	Differences in costs with equal benefits Excess cost of branded drug	Generic versus branded drug use: Use of medicine by two different routes of administration	Simple, useful when outcomes are similar	Cannot be used when outcomes are different
Cost effectiveness	Health benefits in natural units (life years saved, heart attacks prevented, strokes prevented and costs in monetary units (rupees) Cost per (unit) patient saved	Use of heparin versus low molar heparin in acute myocardial infarction: effect on mortality	Magnitude of benefit of two treatments (defined outcome) is measured with monetary units	Cannot be used for direct comparisons of outcomes between the treatments of different conditions
Cost utility	Measures utility units, degree of well-being achieved. Measures qualitative and quantitative change Cost per QALY gained	Reduction in mortality and morbidity. Quality adjusted life years (QALYs)*	Can compare two treatments for different conditions	Utility units are not easily defined and fixed.Measured values vary with time and disease perspective
Cost benefit	Costs and benefits are measured in monetary terms (Rupees) Benefit: Cost ratio	Comparison of surgical treatment with drug treatment of chronic simple glaucoma	Dissimilar treatments (outcomes) can be compared	Difficulty in quantifying health benefit in monetary terms (Rupee value) Intangible benefits are usually ignored

** One QALY is living for one year in perfect health or living in half perfect health for two years and so on.*

Indirect cost

It is the cost of loss of work output and earnings due to patient's illness and family members' attendance during illness. These are difficult to measure.

Intangible cost

It is a cost due to pain, distress and suffering affecting quality of life. It is measured for cost-utility analysis. In addition, there is an opportunity cost which is the benefit foregone in opting for an alternative therapy or drug. For example, diversion of some of limited funds for procurement of a new anti-platelet drug may put constraint on the treatment of outdoor patients on antibiotics.

Benefit

It is the outcome which is measured in physical (natural) units such as number of strokes prevented, life years gained or it can be in utility units such as quality adjusted life years gained (QALYs) which involves quality and quantity both. The benefit may also be measured in monetary units as in cost-benefit analysis. In ascertaining benefit or outcome, one has to make assumptions and these assumptions may be varied in sensitivity analysis. There are four major types of PE analyses which are used in making decisions. **Table 1** shows the advantages and disadvantages of these types.

TYPES OF PHARMACOECONOMIC ANALYSES

The four common types of pharmacoeconomic analyses, their advantages and disadvantages are given in **Table 1**. Cost-minimisation and cost-effectiveness analyses are commonly used for evaluation of newer medicines and therapies. Cost-utility analysis requires a comprehensive analysis. Cost-benefit analysis is useful to compare the cost of different therapies in dissimilar disorders.

USES OF PHARMACOECONOMIC ANALYSIS

Pharmacoeconomic studies increase cost consciousness among the medical fraternity and health administrators. Pharmacoeconomic methods are utilised to assist hospitals, insurers, and health care professionals in making important decisions such as selecting medicines for hospital formularies, settling insurance claims of treatments from different hospitals, and formulating and implementing preventive health policy respectively. It assists clinicians to prepare standard treatment guidelines and to prescribe cost-effective medicines and therapies.

5.1 An Overview of the Immune System

Sita Naik

The immune system deals with a wide variety of organisms that are encountered in the environment, by preventing the establishment of infection and eliminating infections that gets established. The immune system has evolved to selectively destroy only foreign molecules and cells with little collateral damage to the host's own normal cells. The system is unique in its ability to retain a memory of each attack, allowing it to respond more efficiently to subsequent attacks by the same invader. Hence, individuals rarely suffer more than once from the same infectious disease such as chicken pox, mumps, or whooping cough.

The immune response consists of two broad overlapping sets of events, the early or first-line of defence that occurs within minutes to hours of encounter with foreign antigen, the innate or non-specific immunity and a delayed response, which occurs within days, called adaptive or specific immunity. The recognition of events constitute the afferent arm and the effector arm functions either through cells (cell-mediated immunity) or antibodies (humoral immunity).

CELLS AND ORGANS OF THE IMMUNE SYSTEM

Granulocytic Cells

The granulocytic cells are neutrophils, eosinophils and basophils. Neutrophils are the first cells to reach the site of infection. They engulf foreign particles in a membrane bound vacuole, the phagosome which fuses with neutrophil granules to form phagolysosomes. The enzymes within these granules digest the contents of the vacuole either by oxygen-dependent mechanism (respiratory burst) or oxygen independent mechanism. Eosinophils are phagocytic cells that participate in allergic responses. Allergens and parasites stimulate an immunoglobulin (IgE) antibody response and IgE coated antigen is recognised by the receptor for Fc portion of IgE on eosinophils. This results in release of its enzymatic contents which can destroy many parasites. Basophils are non-phagocytic cells which mediate immediate hypersensitivity responses. Mast cells are analogous to the circulating basophils and reside at various tissue sites. These cells are rich in granules containing histamine and other mediators of immediate hypersensitivity.

Mononuclear Phagocytes

These cells have a common lineage from haematopoietic precursors in bone marrow and enter the circulation as incompletely differentiated monocytes. They migrate into tissues to become mature macrophages such as microglial cells of central nervous system, Kupffer cells lining the vascular sinusoids in liver, alveolar macrophages in lung, etc. They ingest antibody coated antigens very efficiently through the large number of specialised Fc receptors they bear (**Figure 1**), a mechanism termed opsonisation. Neutrophils and other cells produce cytokines, which are low molecular weight proteins that regulate the intensity and duration of the immune response by acting on other cells and tissues. Macrophages are activated by locally produced cytokines and in turn secrete a variety of cytokines which are important for activation of the adaptive immunity. The ingested pathogen is broken down in phagolysosomes and antigenic fragments are transported to the cell surface in a form that can be recognised by antigen-specific T lymphocytes, and hence, the name 'antigen-presenting cell' (APC). These macrophages carry specialised plasma membrane glycoproteins called major histocompatibility complex (MHC) class II molecules. The density of MHC antigens on the cell surface is increased following activation, thus increasing their antigen presenting capability.

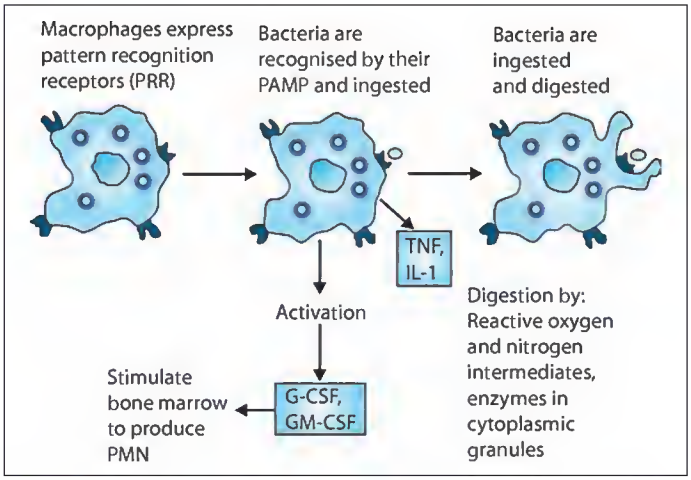

Figure 1: Macrophages bear several receptors (pattern recognition receptors or PRR) that recognise the PAMP on microbes and ingest them.

Dendritic Cells (DCs)

These are morphologically distinct cells with membranous or spine-like projections, which are located in the interstitium of most organs, except the brain, and are abundant in the T-cell-rich areas of lymph nodes and spleen. Immature DCs are efficient phagocytes and are abundant at locations where external antigens enter the body, namely skin, alveoli, gut mucosa, etc. They ingest newly entering antigens, undergo maturation, lose their phagocytic capability and become efficient APCs. Follicular dendritic cells (FDC) are located in the germinal centres of lymph nodes, spleen and mucosa-associated lymphoid tissues. These are not of bone marrow origin, are unrelated to the interdigitating DCs, do not bear cell surface MHC molecules and cannot act as APCs. They display 'trapped' antigens on their cell surface for recognition by B lymphocytes.

Lymphocytes

Lymphocytes mediate the adaptive immune responses and are of three types, T cells, B cells, and natural killer (NK) cells.

B lymphocytes (B cells)

B cells develop in the bone marrow and are characterised by the presence of membrane-bound immunoglobulin (Ig) molecules which are the receptors for antigens. Following

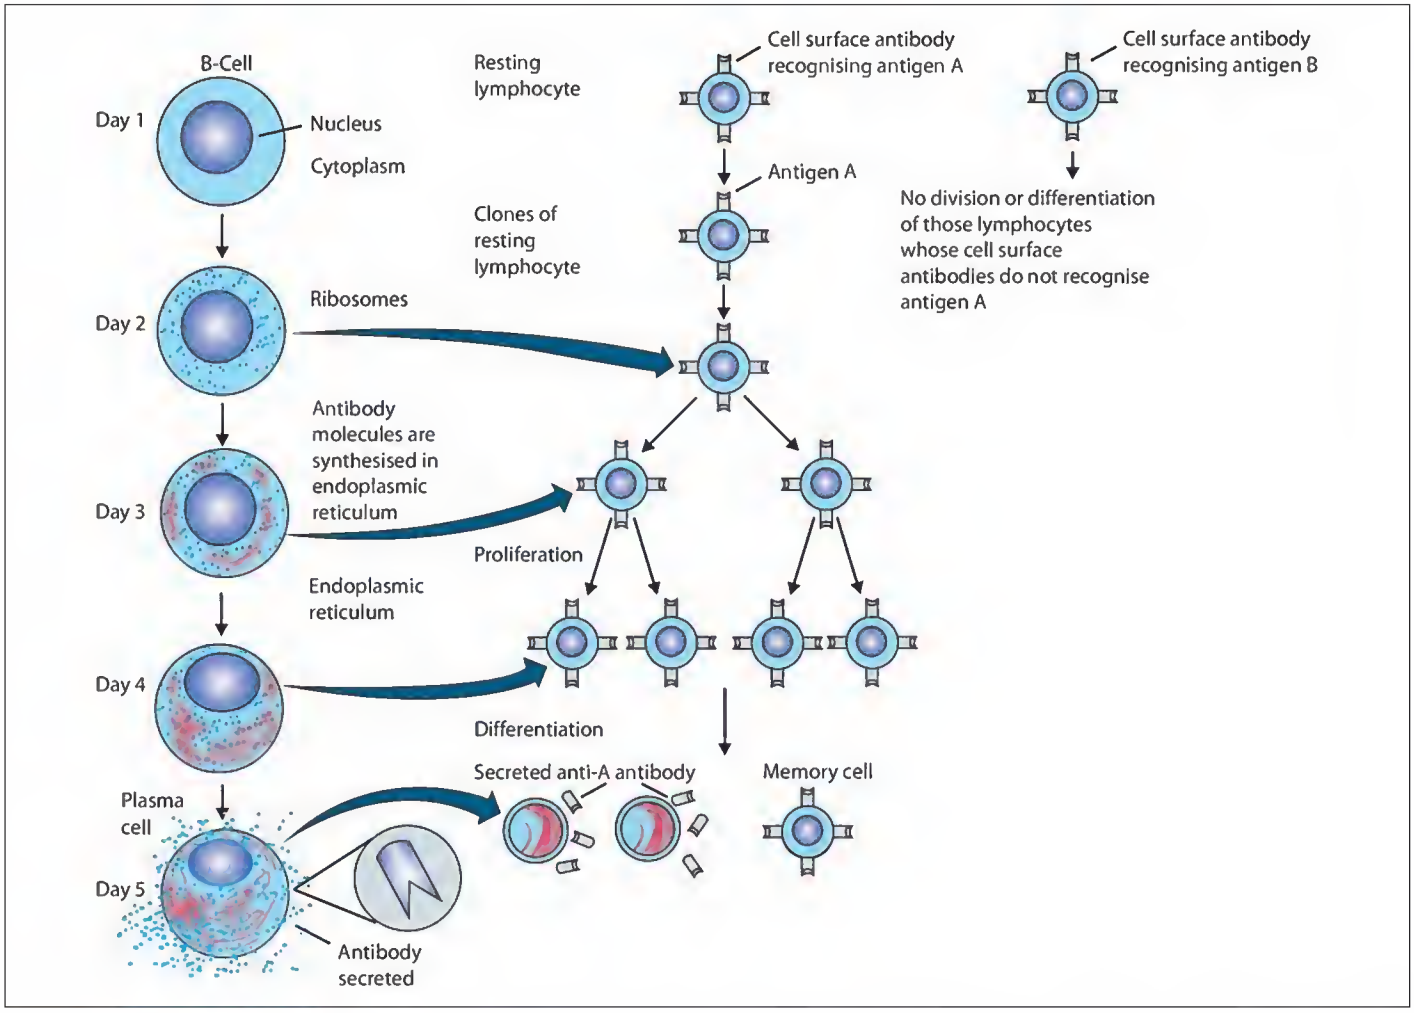

Figure 2: Maturation of B cells into plasma cell. Each B cells bears a unique surface immunoglobulin molecule, which is termed 'B cell receptor' (BCR). It arises from a population of undifferentiated stem cells and becomes committed to producing only one species of antibody molecule.

receptor binding to specific antigen, the cell divides and progeny differentiate into terminally differentiated, antibody producing plasma cells that cannot divide (**Figure 2**).

T lymphocytes (T cells)

T cells develop and mature in the thymus and acquire their specific cell surface receptor for antigen recognition, the T cell receptor (TCR). TCR recognises the modified antigenic fragments or peptides presented by the MHC antigens on APCs. MHC molecules are genetically diverse glycoproteins that are of two types, class I molecules expressed on almost all nucleated cells and class II molecules expressed on APCs. TCR engagement with MHC-peptide is followed by cell division and generation of effector T cells. These are of two types, CD4 expressing T helper cells (T_H cells) and CD8 expressing cytotoxic T lymphocytes (CTLs of T_C cells). T_H cells are activated by MHC class II bearing professional APCs leading to activation of other lymphocytes that are specific for the same antigen. CTLs recognise antigenic fragments along with class I MHC on cells infected with viruses, bacteria, yeast, protozoa, and parasites and kill them. They also are the principle mode of elimination of tumour cells. Cells are recognised by the CD nomenclature which refers to the monoclonal antibodies that react with a particular membrane molecule that are grouped together as a cluster of differentiation or CD.

Natural killer cells

These large granular lymphocytes are part of the innate immune response and do not have membrane markers of T cells (CD4 or CD8) or B cells (sIg) but bear CD16 and CD56. They can kill a wide range of tumour cells and some virus and lyse them; this is termed antibody dependent cellular cytotoxicity (ADCC). Hence, ADCC can occur only after the innate immunity is activated and antibodies are produced. NK cells have surface receptors with stimulatory and inhibitory functions (**Figure 3**). However, body's own cells are protected from NK-mediated killing because the ligands for the inhibitory receptors (killer Ig like receptor or KIRs) are MHC class I molecules which are present on all nucleated cells. Down regulation of MHC expression due to virus infections or malignant transformation makes these cells susceptible to NK cell-mediated killing through the stimulatory receptors. NK cells mediate cytotoxicity through enzymes present in their granules namely perforins that assemble within the membrane of the target cell to form transmembrane channels and granzymes that enter the perforin channels and activate caspases. Caspases are proteolytic enzymes that initiate the programmed death pathway.

The bone marrow, thymus, lymph nodes, spleen and various mucosa-associated lymphoid tissues are involved in the development of an immune response. Cells move freely

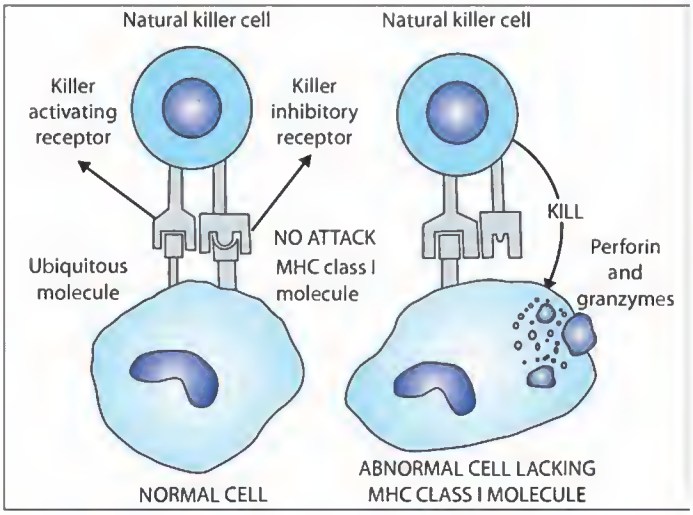

Figure 3: NK cells bearing activating and inhibitory receptors.

between organs and this permits immediate activation of the immune response at any site of entry of a foreign agent. All the cells originate in the bone marrow, except follicular dendritic cells. 'Clonal selection' of T lymphocytes, takes place in thymus resulting in the generation of mature T lymphocytes that recognise only non-self antigen.

INNATE IMMUNE RESPONSES

Unlike the adaptive immunity, innate responses lack antigen specificity and the same set of defence mechanisms acts against all pathogens. The earliest barriers to pathogen entry are physical and chemical ones such as ciliary action of bronchial mucosa, enzymes in saliva and sweat, acidity of the stomach, etc. Pathogens that breach these barriers are recognised by the innate immune system by specialised receptors that help to discriminate the invading organism as non-self. These molecular sensors that recognise broad structural, highly conserved motifs within microbial species that are not present in the host and are termed pathogen associated molecular patterns (PAMPs). These are various combinations of sugars, some proteins, particular lipid-bearing molecules and some nucleic acids, which are part of invading bacteria or viruses. The cellular receptors for PAMPs are the soluble and cell-bound pattern recognition receptors (PRRs). Soluble PRRs bind to and promote phagocytosis and complement-mediated lysis (**Table 1**).

The most important cellular PRR is the toll-like receptor (TLR) present predominantly on immature DCs and macrophages (**Table 2**). The members of this family are type 1 membrane proteins that bear a common structural element. In the extracellular domain consisting of repeating segments of 24 to 29 amino acids called leucine-rich repeats (LRR). A subset of the LRRs recognise the ligand and the cytoplasmic Toll/IL-1 (TIR) domain binds to adaptor proteins and activates signalling pathways. Each TLR detect a repertoire of conserved pathogen molecules and the complete set of TLRs can detect a wide variety of viruses, bacteria, fungi and some protozoa. Interestingly, TLRs that recognise extracellular ligands are present on the cell surface (TLR 1, TLR2, TLR4, TLR5, TLR6) while those that recognise intra-cellular ligands (TLR 3, TLR 7, TLR 8, TLR 9) are found within the cell.

Table 1: Pattern Recognition Receptors of the Innate Immune System

Receptor (location)	Target (source)	Effect
Complement (blood-stream,tissue fluids)	Microbial cell wall components	Complement activation, opsonisation, lysis
Mannose-binding lectin (blood-stream, tissue fluids)	Mannose containing microbial carbohydrates (cell wall)	Complement activation, opsonisation
C reactive protein (CRP) (blood-stream, tissue fluids)	Phosphatidylcholine, pneumococcal polysaccharide (microbial membranes)	Complement activation, opsonisation
Lipopolysaccharide (LPS) receptor, LPS-binding protein (LBP) (blood-stream, tissue fluids)	Bacterial lipopolysaccharide (Gram-negative bacterial cell walls)	Delivery to cell membranes
Toll like receptors (cell surface or internal components)	Microbial components not found in host	Induces innate responses
NOD family receptors* (intracellular)	Bacterial cell wall components	Induces innate responses
Scavenger receptors (SR) (cell membrane)	Many targets; Gram-positive and Gram-negative bacteria, apoptotic host cells	Induces phagocytosis or endocytosis

**Nucleotide-binding oligomerisation domain*

Table 2: Toll-like Receptors and their Ligands

TLRs	Ligands	Target microbes
TLR 1	Triacyl lipopeptides	Mycobacteria
TLR 2	Peptidoglycans GPI-linked proteins Lipoproteins Zymosan	Gram-positive bacteria Trypanosomes Mycobacteria Yeast and other fungi
TLR 3	Double-stranded RNA (dsRNA)	Viruses
TLR 4	LPS F-protein	Gram-negative bacteria Respiratory syncitial virus
TLR 5	Flagellin	Bacteria
TLR 6	Diacetyl lipopeptide Zymosan	Mycobacteria Yeast and fungi
TLR 7	Single-stranded RNA (ssRNA)	Viruses
TLR 8	Single-stranded RNA (ssRNA)	Viruses
TLR 9	CpG unmethylated dinucleotides Dinucleotides Herpes virus infection	Bacterial DNA Some herpes viruses
TLR 10, 11	Unknown	Unknown

Another cellular PRR, NOD (nucleotide-binding oligomerisation domain) 1 and NOD2 are present in the cytoplasm and recognises products of peptidoglycans of Gram-positive bacteria. The cell surface scavenger receptors (SR) internalise Gram-positive and Gram-negative bacteria and apoptotic cells.

TLRs are widely expressed on DCs, macrophages, neutrophils but not NK cells and are activated through a common pathway. This culminates in the production of a number of important pro-inflammatory cytokines and the important anti-viral cytokine, interferon-α. DCs are predominantly involved in acting as a link between adaptive and innate immunity while neutrophils and macrophages ingest the invading organism and destroy them.

COMPLEMENT SYSTEM

The complement system consists of about 20 serum proteins and is an important constituent of innate immunity. It is activated sequentially with amplification stages to ensure that single molecule can trigger generation of thousands of terminal effector molecules. The three pathways of complement activation are the classical pathway activated by antigen-antibody complexes, the alternate pathway activated by polysaccharides from yeasts and Gram-negative bacteria and the mannan-binding lectin pathway activated by the mannose containing proteins and carbohydrates on microbes (**Figure 4**). Activation of any of these pathways culminates in activation of C3 and generation of C3 convertase. This enzyme, via a final common pathway leads to assembly of C5-C9 complexes (membrane attack complex or MAC). The MAC forms transmembrane pore on the cell surface and death by osmotic lysis. MAC has a similar structure as perforin which is released by NK cells to mediate killing. Normal host cells also bear a number of complement regulatory proteins on their surface [complement receptor (CR) and decay accelerating factor (DAF)] which inhibit C3 convertase generation and prevent progression of complement activation. These molecules protect self cells from complement lysis while at the same time causing lysis of microbes which lack these molecules. Complement activation also leads to generation of C3a which acts as an opsonin and C5a which is an anaphylatoxin and vasodilator.

The functions of the complement system include: (i) lysis of invading bacteria, viruses and cells, (ii) opsonisation of organisms and promotion of their ingestion, (iii) clearance of immune complexes, and (iv) binding to specific complement receptors on immune cells and triggering their specific cell functions including the secretion of immunoregulatory molecules. Persons with absence of one of the alternative pathway proteins, late components (C3-C9) or one of the control proteins (H or I) are susceptible to severe infections with pyogenic organisms, particularly Gram-negative bacteria, particularly *N. meningitides*. Classical pathway deficiencies (C1, C4, and C2) are associated with increased risk of infection, though not as frequently as with the alternative pathway or late component deficiencies. Bacteria that cause recurrent infections in these patients include, but are not limited to *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Staphylococcus aureus*.

ACUTE INFLAMMATION

Acute inflammation is the early response of the body to invading organisms and is characterised by vasodilatation and increased local blood flow resulting in redness and warmth and extravasation of fluid into the extravascular space resulting in swelling and pain. In a few hours, leucocytes migrate into tissue spaces to phagocytose the invading organisms. These cells release pro-inflammatory cytokines, TNF-α, IL-1, IL-6, G-CSF and GM-CSF. TNF-α and IL-1 cause increased expression of E-selectin on endothelial cells and neutrophils which bear L-selectin bind to the endothelium, thus slowing their flow. The stable bond formed between LFA on the neutrophils and ICAM-1 on the

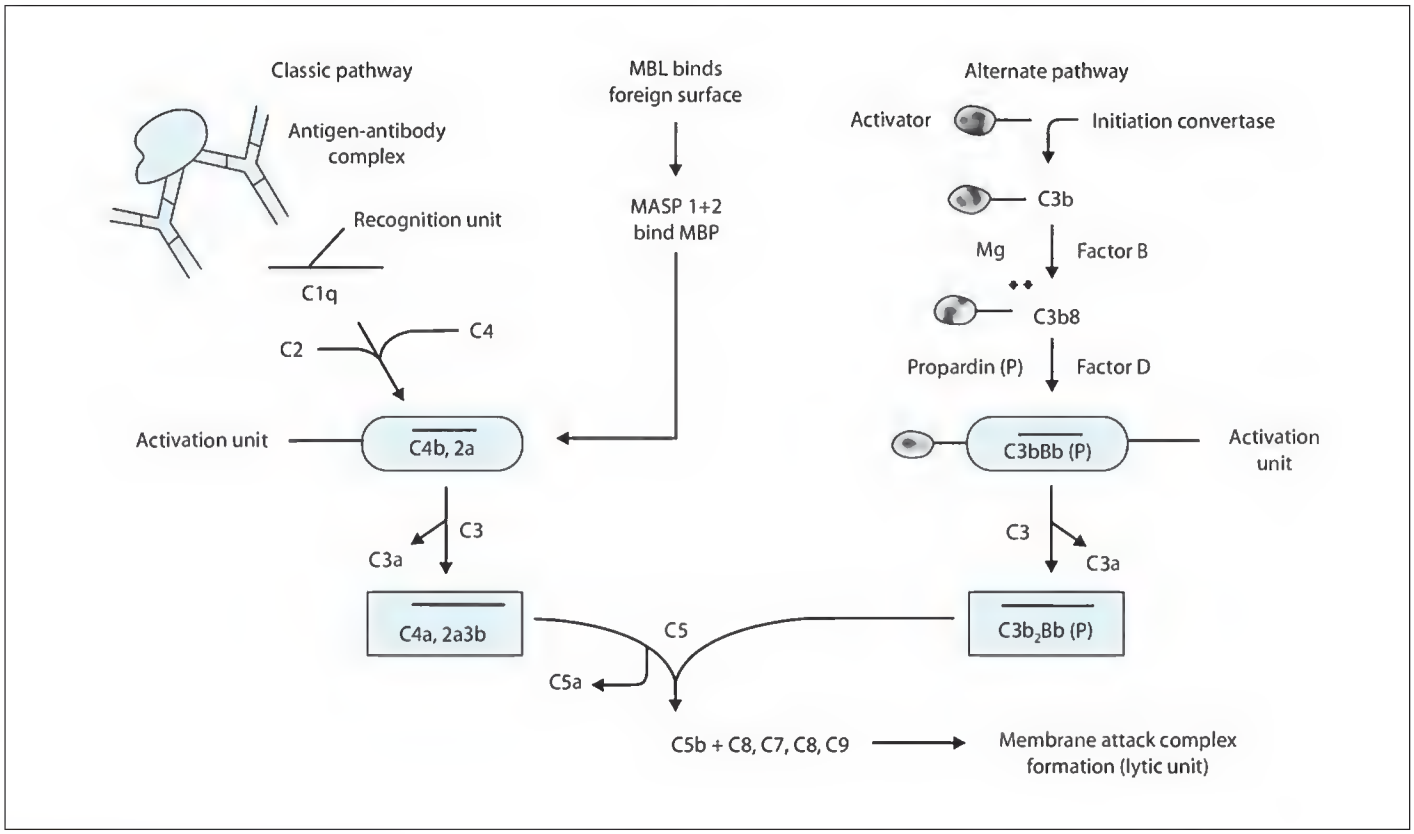

Figure 4: The complement activation pathways.

endothelium and the released chemoattractants of host (interleukin-8, leukotriene B4 and complement 5a) and bacterial origin (FMLP) helps the neutrophils to move out of the vascular compartment into spaces (**Figure 5**). These cells phagocytose and clear the pathogen. While G-CSF and GM-CSF stimulate the production of large numbers of leucocytes in the bone marrow, the vasodilators and anaphylatoxins, C3a and C5a, cause release of additional inflammatory mediators, including histamine from mast cells. The sluggish local blood flow and increased permeability of vessels allows a fresh supply of complement, coagulation and other proteins from the circulation to permeate into the inflamed tissues to maintain the inflammation. TNF-α, IL-1 and IL-6 also act at distant sites, particularly the liver, to induce synthesis of acute phase proteins such as C-reactive protein (CRP). This is widely used in clinical practice as a biomarker of the acute phase response. CRP can bind polysaccharides on the surface of pneumococci and phosphorylcholine on many other bacteria to act as an efficient opsonin.

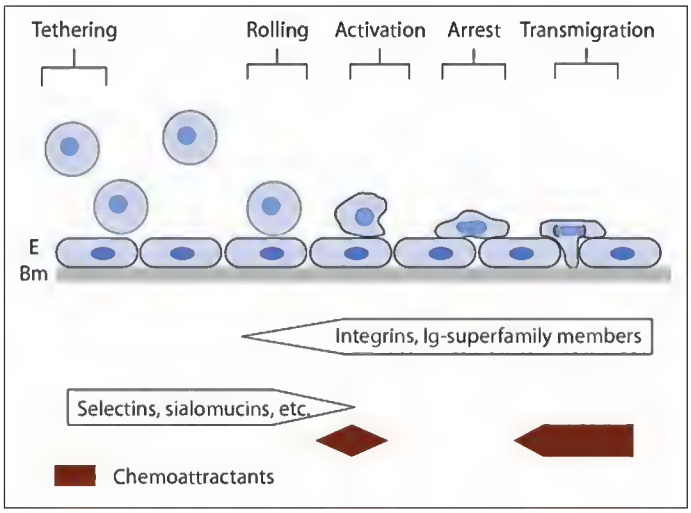

Figure 5: The multi-step cascade of leucocyte extravasation. The blood-borne cell makes transient contact with endothelial cells, which leads to the cell rolling along the vascular lining. If the cell gets activated, it subsequently adheres to the endothelium, seeks out inter-endothelial junctions and migrates through the basement membrane into the tissue.

ANTIGEN PROCESSING AND PRESENTATION

MHC class II bearing APCs process endocytosed antigens. The endocytic vesicles bearing antigen fuse with endosomes (**Figure 6**) and hydrolytic enzymes within the endosomes degrade foreign antigens into small peptide fragments of 10-20 amino acid length. These fragments bind to MHC class II molecules. MHC class II molecules are synthesised within the endoplasmic reticulum (ER) and move along the biosynthetic pathway into an endosome or lysosome. To meet the peptide and form the MHC-peptide complex. This gets transported to the cell membrane for recognition by the T cell receptor of CD4+ T cells.

Endogenous antigens that originate within the cells of the host organism also trigger immune responses. For example, cells that have become infected by a virus usually manufacture foreign proteins encoded by viral genes. Fragments derived from the viral proteins or from altered self-antigens as in the case of cancer cells (endogenous proteins) are degraded into short peptides of 8-10 residues by proteases that are part of a multimeric complex called *proteasome*. The peptides are transported into the ER where they bind to newly synthesised MHC class I molecules. The MHC–peptide complex moves through the biosynthetic pathway to reach the plasma membrane where the peptide is displayed for recognition by the TCR of CD8+ T cells (**Figure 6**).

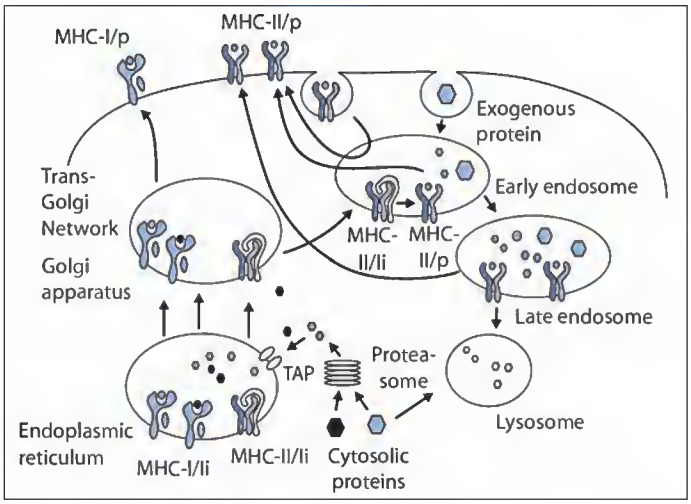

Figure 6: Processing of exogenous and endogenous antigens.

CD4 and CD8 molecules are expressed on mutually exclusive subsets of T cell and bind to a non-polymorphic site on the MHC II and MHC I molecules respectively. Thus, T helper functions of CD4+ cells is strictly dependent on recognition of the CD4 molecule by the class II molecule on APCs, a phenomenon termed 'restriction'. This stimulates antibody production, which is useful to neutralise or lyse extracellular organisms by a variety of mechanisms. The cytotoxic function of CD8+ T cells is class I 'restricted' and the endogenous pathway delivers peptides to MHC class I molecules which are recognised by cytotoxic CD8+ cells that kill the presenting cell. This is beneficial to the host since this is the only way intracellular antigens can be eliminated. Also, viruses can infect any cell in the body and it is advantageous that class I molecules are present on all nucleated cells. The distinct compartmentalisation of the exogenous and endogenous pathways for presentation of antigen to CD4 and CD8 cells respectively is a clever strategy to increase efficiency of dealing with infectious agents.

MATURATION OF T AND B LYMPHOCYTES

Autoreactive lymphocyte clones are deleted during development of T and B cells in the thymus and bone marrow respectively. Progenitor T cells from the early sites of haematopoiesis migrate to the thymus, undergo proliferation and begin to express their TCR; cells that fail to express their TCR die by the process of apoptosis. A process that is unique to T and B-lymphocytes, gene rearrangement, generates TCRs by a totally random phenomenon and has an estimated potential to produce over 10^{15} kinds of T cell receptors. Being a random process, rearrangement generates TCRs with equal frequency and affinity for foreign and self-antigen. To ensure that only T lymphocytes bearing TCRs for foreign antigens exit the thymus and all those that can react with self-antigen are eliminated (**Figure 7**), interaction of immature thymocytes with cortical epithelial cells rescues all T cells whose TCRs can recognise self-MHC molecules from apoptosis (positive selection). These cells interact with DCs and macrophages in the thymic medulla where all lymphocytes that bear TCR for self-MHC alone or self-antigen

plus self-MHC undergo apoptosis (negative selection). This is achieved by a unique arrangement in which, all self-antigens get expressed in the thymic medulla. This occurs under the control of the autoimmune regulator (AIRE) gene and genetic defects in this gene leads to the human autoimmune disease known as autoimmune polyendocrinopathy candidiasis-ectodermal dystrophy (APECED). A third subpopulation of cells, FoxP3 positive T regulatory cells, also develop in the thymus and play an important role in maintaining the balance within the immune system.

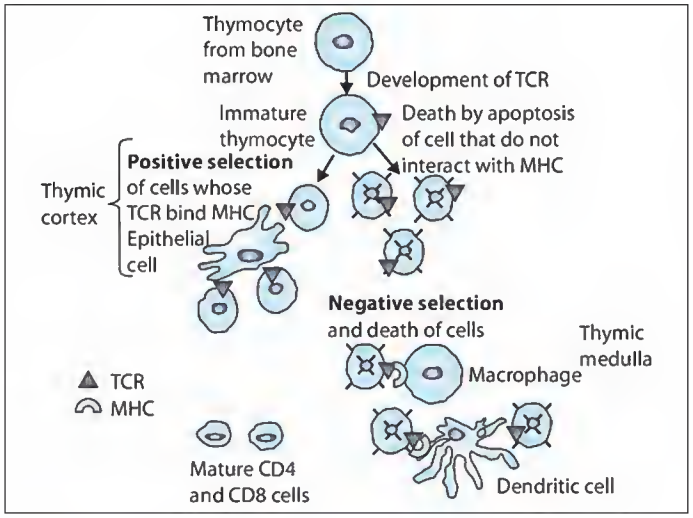

Figure 7: Thymic selection.

Thus, all T cells that leave the thymus recognise foreign antigen with self-MHC and do not recognise self-antigen. Less than 2% of the thymocytes that enter the thymus survive this rigorous selection exercise.

Unlike T lymphocytes, B lymphocytes recognise conformational epitopes on antigens through the B cell receptor (BCR); there is no antigen presentation or an MHC analogous molecule in BCR engagement. Hence, there is no requirement for a round of positive selection; however, negative selection of self-reactive B cells occurs in the bone marrow. As in the thymus, more than 90% of immature B cells are eliminated through negative selection.

Although the developmental process is aimed at providing an immune repertoire that can recognise and deal with all external antigens without any self-directed responses, many low-affinity anti-self T and B cells escape and survive. Self-reactive T cells and low titre autoantibodies can be demonstrated in most individuals if adequately sensitive methods are used and their frequency increases with age. Fortunately, autoimmune disease develop in only a small proportion of the population because peripheral tolerance mechanisms keep these autoreactive cells in an inactive state through T cell anergy. T cell activation only occurs following an initial pro-inflammatory response and upregulation of co-stimulatory molecules on APCs.

ADAPTIVE IMMUNITY

The unique features of the acquired immune response are specificity, diversity and memory. The response is specific to the structural components of complex protein, polysaccharide and other antigens termed epitopes or determinants. The unique receptors on T and B lymphocytes recognise even subtle differences between antigens. Due to the huge diversity of these receptors, the immune system can respond to an extremely wide range of antigen specificities. After each successful immune response, memory for the specific antigen is retained for long periods of time and it allows the body to respond more rapidly to subsequent encounter with the antigen.

ACTIVATION OF THE CELLULAR RESPONSE

Adaptive immunity, develops over 2-3 days, and following transport of antigens from the site of infection to the secondary lymphoid organs. Antigens are transported by DCs from the periphery to the lymph node, from blood to the spleen and from the mucosae to the mucosa-associated lymphoid tissues. As described earlier, at the site of inflammation, DCs are activated and become potent APCs bearing upregulated chemokine receptors. Lymphoid tissues constitutively express chemokines and DCs home to lymphoid tissues where they come in contact with the T lymphocytes. T lymphocytes are in continuous circulation throughout the body, taking 1-2 days to complete their sojourn. The large number of T cells that traffic through lymph nodes come in contact with the DCs bearing the processed antigen within the MHC class II. After a series of hit and trials, T cell bearing the correct TCR is found and TCR-MHC-peptide interaction, results in immediate activation of the T cell. Without interaction of the TCR with its cognate antigen, T cells remain quiescent and may recirculate through lymphoid tissues for many months or years. The TCR consists of an α and a β chain complexed with γ, δ, ε and ξ chains of the CD3 molecule (**Figure 8**). The α and β chains bind to the MHC/peptide complex and CD3ξ chain transduces intracellular signals that result in activation of a number of genes, including a variety of cytokine genes.

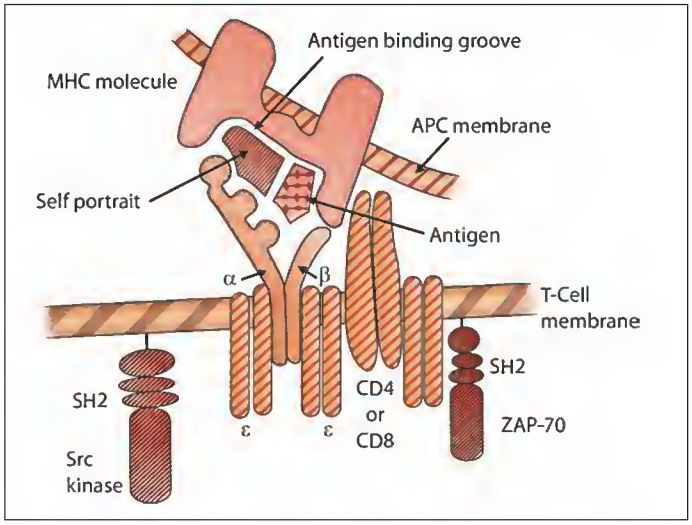

Figure 8: The T cell receptor–CD3 complex.

In addition to signalling through the TCR-CD3 complex, additional signalling through co-stimulatory molecules is required, failing which T cell activation is abortive for generating effector cells. Such T cells either get anergised or undergo programmed cell death. The most important co-stimulatory molecule is CD28, a homodimeric glycoprotein on T cells that interacts with two receptors, CD80 and CD86, expressed on APCs. While CD86 is expressed constitutively at low levels and CD80 is not expressed on professional APCs like DCs, but

get rapidly upregulated following activation by the pro-inflammatory cytokines. This is the critical role of innate immune responses, since failure to upregulate these molecules leads to anergised T cells. It also ensures that the effector arm is activated only when there is a genuine need to deal with overwhelming antigen load. CTLA4 or CD152 on T cells, is structurally related to CD28 and binds to CD80 and CD86 with higher affinity than to CD28. However, its engagement along with the TCR results in negative signalling.

Activated T cell expands clonally to produce large number of progeny which home back to the site of inflammation, guided there by tissue-specific adhesion molecules. However, all the activated cells do not leave the lymph node and some remain as central memory cells.

CELLULAR EFFECTOR RESPONSE

The effector T cells are of CD4+ helper (Th) and CD8 +cytotoxic (Tc) type and CD4 effector response diverges to either a Th1 or a Th2 type. The Th1 response is characterised by the cytokines TNFα, IL-2 and IFN-γ and Th1 expansion results in appearance of cell mediated immunity involving generation of specific CTLs and activated macrophages. Th2 cells make IL-4, IL-5 and IL-13 that are critical for induction of humoral immunity and eosinophilia. It is not clear what determines whether a particular response will be Th1 or Th2 in type. A new subset of T cells, the Th17 cells, secrete IL-17 and are involved predominantly in the maintenance of the inflammatory response. The mechanism of target cell lysis by CD8+ cells is same as NK cells, except that unlike NK cells, CTLs release these enzymes only on antigen stimulation.

THE HUMORAL RESPONSE

Immunoglobulins or antibodies neutralise toxins, prevent organisms adhering to mucosal surfaces, opsonise bacteria for phagocytosis and sensitise infected cells for lysis by antibody mediated cellular cytotoxic attack by NK cells while antigen-antibody complexes activate the classical complement cascade. B lymphocytes reside primarily in lymphoid tissues with little recirculation. They recognise native antigen, through the BCR, which is a membrane-bound immunoglobulin.

Immunoglobulins

There are five classes of immunoglobulins (Ig), namely IgG, IgM, IgA, IgE and IgD. They have a common structure consisting of two identical light (L) chains of approximately 22,000 Da and two identical heavy (H) chains of 55,000 Da or more (**Figure 9**). Each light chain is bound to a heavy chain by disulphide bonds and other non-covalent interactions and each set of H+L chains is bound to the other by similar bonds to form the four chain structure $(H\text{-}L)_2$. The numbers and position of the disulphide bonds vary among the different classes of Ig. Each H and L chain is made of variable (V) and constant (C) regions, with each light chain having one variable (VL) and one constant (CL) unit and heavy chains having one variable region (VH) and 3 to 4 constant regions (CH). The first 110 amino acids of the VH and VL chains show a great degree of variability (hypervariable regions) and form the region by which antigen is recognised. This, the antigen combining site, binds to the conformational epitopes on the antigen, which is formed by non-contiguous regions of the antigen and is dependent on its tertiary and quaternary structure. This is in contrast to the recognition of linear peptides by the TCR. The five types of H chains (γ, μ, α, ε and δ) can each combine with either of the two L chains (κ, λ) to form the molecules of IgG, IgM, IgA, IgE and IgD (**Table 3**).

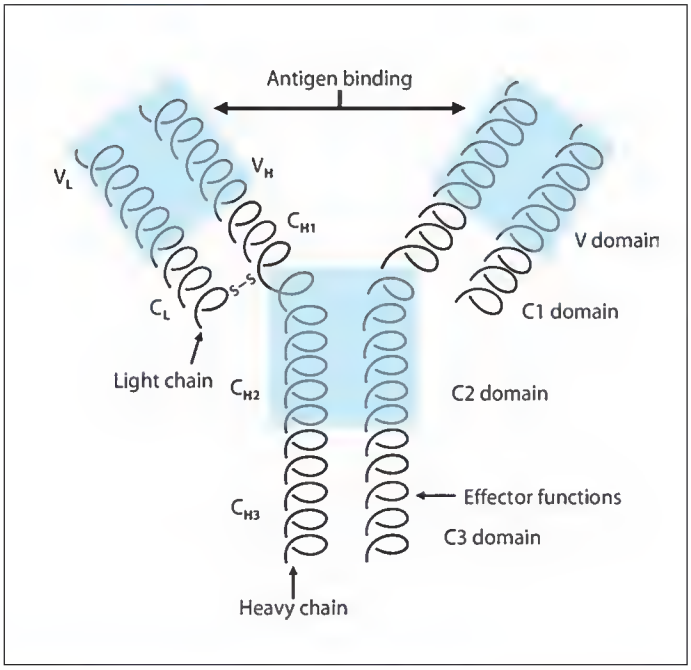

Figure 9: The arrangement of immunoglobulin.

Table 3: Immunoglobulin Classes and their Functions

	IgG	IgA	IgM	IgE	IgD
Molecular weight	150,000	150,000-600,000	900,000	190,000	150,000
Heavy chains	γ1, γ2, γ3, γ4	α1, α2	μ	ε	δ
Normal serum levels (mg/ml)	13.5	3.5	1.5	0.0003	0.03

Crosses placenta	+	–	–	–	–
Present on membrane of mature B cells	–	–	+	–	+
Binds to Fc receptor on phagocytes	++	–	?	–	–
Mucosal transport	–	++	+	–	–
Induces mast cell degranulation	–	–	–	+	–

Effector Functions of Antibodies

The first immunoglobulin produced during an immune response is IgM. Th2 derived IL-4, IL-5, IL-6 and IL-13 help in the antibody response. These cytokines also upregulate CD40 ligand (CD40L) on T cells which interacts with the constitutively expressed CD40 on B cells and APCs, an essential interaction to

switch the cell from IgM to IgG production. Most of the effector responses are most efficiently carried out by IgG and as the immune response matures IgG molecules undergo somatic hypermutation, a process by which the quality of the antibody to fit the antigen is improved. It is also evident that, the help provided by T cells is crucial for antibody production and most antigens are thus T-cell dependent. A few antigens especially polysaccharides, having a repeating structure can cross-link multiple BCRs and stimulate IgM response. However, this is not followed by affinity maturation or isotype switch and such responses wane rapidly. These are called T-cell-independent antigens.

REGULATION OF THE IMMUNE RESPONSE

An efficient immune response is characterised by augmentation of innate (antigen independent) response by the products of the adaptive (antigen specific) response. Pro-inflammatory cytokines, upregulate numerous cytokine receptors on T cells which bind with T-cell derived cytokines setting up paracrine and autocrine mechanisms for amplification of the immune and inflammatory processes. A Th1 response deals with intracellular pathogens while Th2 response favours antibody production (IL-4 favours class switching and IgE production, IL-5 eosinophilia); IL-4 provides stimuli for feedback amplification of the Th2 response and dampening of the Th1 response.

This cascade is exquisitely orchestrated and immune response is generated that is adequate to control this challenge. However, the expansion of the effector response is not uncontrolled; antigen elimination deprives the antigenic stimulus. The contraction occurs leaving behind long-lived memory cells for CD4, CD8 and B cell memory. These reside in secondary lymphoid organs, to be recalled for immediate and accelerated responses on subsequent exposure to the antigen.

The counter-regulatory mechanisms include negative signalling in T cells by CTLA-4, and T regulatory cells (Treg) which actively downregulate activated T cells. Tregs are CD4+ T cells that express cell surface CTLA4 and CD25 and have a characteristic transcription factor, FoxP3. Tregs are important for maintaining tolerance to self-antigens.

CONCLUSION

The immune system is an extremely fine-tuned orchestra that responds efficiently to external challenges only to the exact quantum that is required to deal with that challenge. Diseases are a consequence of failures of the development of the system (primary immunodeficiency), failures of the normal control mechanisms (autoimmunity and cancer) or excessive efforts to deal with the foreign challenge of chronic infections like tuberculosis.

5.2 General Concepts of Immunoinflammatory Disorders

Ramnath Misra

Understanding cellular and molecular basis of inflammation and immunology has helped to develop targeted therapy in several immunoinflammatory diseases, such as rheumatoid arthritis (RA), psoriasis, inflammatory bowel disease, ankylosing-spondylitis, juvenile idiopathic arthritis, systemic lupus erythematosus (SLE), inflammatory myositis, vasculitis, etc. Immunoinflammatory diseases result from an aberrant immune response and a heightened inflammation process consequent to generation of effector T- or B-cells. Though the precise trigger for the inflammation is not understood, the cells and molecules that cause the tissue damage have been elucidated in great detail in these conditions. Therefore, biological therapy directed at inhibiting key molecules or dysregulated cells have been successful in limiting tissue damage and increase the quality of life.

While hypersensitivity is an inappropriate immune response to antigens (allergens), autoimmunity is directed against self-antigens. Both situations result in inflammation that causes tissue damage by various mediators of inflammation.

THE NORMAL IMMUNE RESPONSE AND THE IMMUNOLOGICAL BASIS OF AUTOIMMUNITY

Immune response is mediated by the T-cells causing the cellular and B-cells producing antibodies. These cells work in collaboration helping each other in a coordinated way. There is a tight control over these T- and B-cells reacting against self-antigens in cells or tissues called the *'self-tolerance'*. During the embryonic maturation of these lymphocytes, most self reacting lymphocytes are removed by apoptosis (negative selection). A protein called autoimmune regulator (AIRE), is believed to stimulate expression of several peripheral antigens to the thymic epithelial cells. Mutations in the AIRE gene can cause polyendocrinopathy in experimental animals. Those lymphocytes that escape this central deletions are kept under control by peripheral mechanisms, such as lack of B7 by (APCs) to interact with CD28, repeated stimulation by self-antigen causing activation induced cell death and suppression by CD4+, CD25+ regulatory T-cells.

HOW DOES AUTOIMMUNITY DEVELOP

Several hypothesis have been proposed.

Sequestration of Self-Antigens

During thymic development, lymphocytes are not exposed to those self-antigens which are not expressed by the thymic epithelial cells. These include, but are not limited to, the lens protein, sperms or ova or myelin basic proteins (protected by the blood-brain barrier in the central nervous system). Later, an inadvertent exposure of the antigens, leads to development of autoimmunity.

Molecular Mimicry

Several host proteins and proteins of pathogens (bacteria, virus, etc.) share structural similarity and autoimmunity is a consequence of the immune response generated against the pathogen. For example, in acute rheumatic fever, cellular and humoral responses against the *Streptococcus* M protein cross-react against myocardial tissues causing carditis. However, cross-reactive microbial antigens have not been found even after extensive search in the classical autoimmune diseases, like juvenile diabetes, RA and SLE.

Altered Self-Antigen Presentation

In animal models of autoimmune diseases, it has been shown that autoimmune response to one antigenic epitope (part of the protein seen by the antibodies or T-cells) may spread to involve other epitopes which are normally not seen by lymphocytes. These later epitopes could be self-antigens.

Polyclonal B-Cell Activation

Many infectious agents, such as gram-negative bacteria, Epstein-Barr virus and cytomegalovirus cause polyclonal activation of B-cells. A wide spectrum of antibodies is produced in patients with AIDS and infectious mononucleosis as part of the diseases process. A persistent stimulation of T lymphocytes may also lead to polyclonal stimulation of B cells. Some of these antibodies may be directed against self-antigens.

Autoimmune diseases are polygenic in nature with a number of genes contributing to the causation of the disease. They result from a multi step process, probably triggered by an environmental factor, in a genetically susceptible individual. The risk of developing autoimmune diseases is higher among monozygotic twins than dizygotic twins and familial clustering is often seen. Unaffected healthy family members of patients have higher incidence of autoantibodies than normal healthy population. The susceptibility to autoimmune disease differs between two sexes with SLE, RA, and scleroderma affecting predominantly the females. This difference has been attributed to hormonal differences and the effect of circulating foetal cells in maternal blood during pregnancy.

BASIS OF HYPERSENSITIVITY AND AUTOIMMUNE DISEASES

Autoimmune diseases are classified as organ specific and systemic non-organ-specific (**Tables 1 and 2**). The immunological basis of hypersensitivity and autoimmune diseases have been described as Types I , II, III and IV reactions by Gell and Coombs.

Hypersensitivity is the inappropriate host response to an antigen which results in tissue damage of variable severity and even death. The hypersensitivity may be 'immediate' in which symptoms manifest within minutes to hours of exposure to the antigens or 'delayed', due to delay in the onset of symptoms up to days after the exposure to antigen.

Table 1: Organ Specific Autoimmune Diseases that are Caused by Antibodies Directed against Autoantigens

Diseases	Antibodies directed against cells/tissues	Effect
Type 1 Diabetes	Beta cells	Cell lysis
Grave's disease thyrocytes	TSH receptor	Stimulating
Myasthenia gravis	Acetylcholine receptor	Blocking Ach
Autoimmune haemolytic anaemia	Red cell surface antigens	Fc receptor mediated phagocytosis
Autoimmune thrombocytopaenic purpura	Platelet GpIIb-IIIa	Fc receptor mediated phagoctyosis by splenic macrophages
Goodpasture's syndrome	Alpha 3 chain of collagen	Complement mediated inflammation of the blood vessels in kidney and lung
Wegener's granulomatosis	Serine proteinase 3	Neutrophil damage

Table 2: Systemic or Non-Organ-Specific Diseases with their Respective Target Cells/Tissues

Disease	Self-antigen
Systemic lupus erythematosus	DNA, nucleosomes, Sm, histones, RNP, Ro, La lymphocytes, platelets
Rheumatoid arthritis	IgG, cyclic citrullinated peptide, synovium, cartilage
Sjögren's syndrome	Salivary glands, epithelial cells, kidneys
Polymyositis	Myocytes

Type I Hypersensitivity Reaction

This is also known as immediate or anaphylactic hypersensitivity. IgE antibodies are generated in the first exposure to antigen (allergens) and during the subsequent exposure binds to the Fc receptor for IgE which is expressed abundantly on mast cells and basophils. A subsequent exposure to the same allergen cross-links the cell-bound IgE and triggers the release of various biologically active primary (preformed) and secondary mediators (**Table 3**). The preformed mediators are responsible for immediate reaction, such as local oedema, increased secretion and bronchospasm. The secondary mediators are responsible for delayed phase reactions, and act by recruiting inflammatory cells which amplify the reactions. Of the recruited cells, eosinophils are particularly important and are preferentially expanded under the influence of (Th)2 derived cytokines, such as IL-3, IL-5 and GM-CSF. These mediators act on the surrounding tissues and cause vasodilatation and smooth muscle contraction. The clinical picture may vary from a mild local reaction to a severe systemic anaphlyaxis, which may be fatal. Systemic anaphylaxis may result from penicillin and administration of foreign proteins, such as antisera, intravenous immunoglobulins and monoclonal antibodies of murine origin. The clinical manifestations are skin urticaria, rhinorrhoea, rhinitis, conjunctivitis, angioneurotic oedema, respiratory stridor due to laryngeal spasm, asthma due to bronchoconstriction and abdominal cramps and diarrhoea. In severe cases death occurs due to shock and vascular collapse. The reaction usually takes 15 to 30 minutes from the time of exposure to the antigen, although sometimes it may have a delayed onset (10 to 12 hours).

The diagnosis is mainly clinical and in cases confirmation is needed, intradermal challenge with allergens may be done with caution.

Type II Hypersensitivity Reaction

Type II hypersensitivity is mediated by IgG or IgM antibodies directed against cell-bound antigens. Antibodies binding to cell surface antigens, activates the complement cascade and deposits of complement products C3b and C4b facilitates their ingestion and destruction by Fc receptor bearing macrophages. Preformed antibodies may cause transfusion reactions following incompatible blood transfusion, erythroblastosis foetalis due to placental transfer of maternal antibodies to the foetus with destruction of foetal red blood cells and autoimmune haemolytic anaemia.

The diagnosis of type II hypersensitivity diseases is made by demonstration of circulating or tissue-bound antibodies to target antigens. Some examples are Coombs test for haemolytic anaemias, antibodies to Ach receptor in myasthenia gravis, antibodies to glomerular basement membrane in Goodpasture's syndrome. However, antibodies are not of clinical importance, such as antibodies to platelet glycoprotein and glutamic acid decarboxylase (GAD) in type 1 DM. Here the diagnosis is dependent upon the manifestation of organ damage, such as purpura and hyperglycaemia, respectively.

Type III Hypersensitivity Reaction

In this type, immune complexes containing antigens and antibodies to auto or bacterial antigens are deposited in the capillaries and small blood vessels, causing complement activation, neutrophil activation and release of proteolytic enzymes leading to inflammation and tissue damage. SLE is a prototype example of type III hypersensitivity disease. Circulating antibodies to anti-nuclear antibodies (**Figure 1**) which are directed against a variety of nuclear constituents

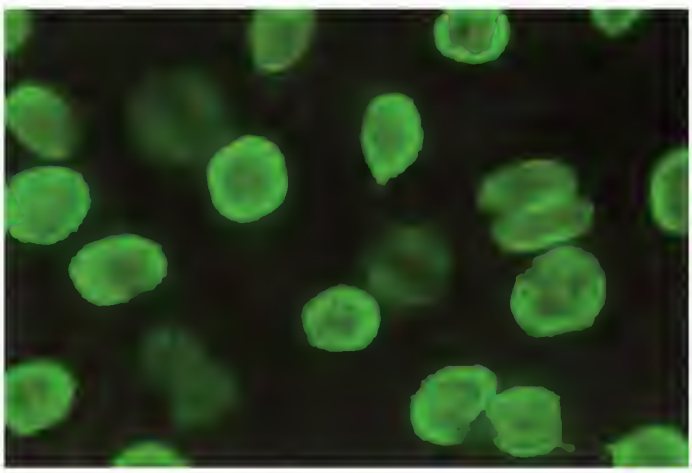

Figure 1: Anti-nuclear antibodies detected by indirect immunofluorescent assay. Circulating anti-nuclear antibodies with its antigens, such as dsDNA, nucleosomes gets deposited in the blood vessels to activate complement mediation inflammation and subsuequent damage.

Table 3: Primary and Secondary Mediators in Hypersensitivity Reaction

	Mediators	Effects
Primary (pre-formed)	Histamines	Smooth muscle constriction, vasodilatation, increased glandular secretions
	Enzymes (chymase, tryptase)	Generation of kinins and activated complement C3
Secondary mediators	Leukotrienes C4,D4	Vasoactive
Lipid mediators	Leukotrienes B4	Chemotactic for neutrophils and eosinophils
	Prostaglandin D2	Bronchospasm
	Platelet activating factor	Platelet aggregation, histamine release
Cytokines	TNF, IL-1, IL-3, IL-4, IL-5, IL-6	Mediate inflammation at the local site

(such as nucleosomes, DNA, Sm, U1RNP, Ro or SS-A, La or SS-B) get deposited at various sites giving rise to malar rash, photosensitivity, arthritis, glomerulonephritis, serositis and central nervous system involvement. Immunofluorescence microscopy of kidney biopsy reveals deposits of IgG, IgM and complement components C1q and C3. Other examples are serum sickness and primary Sjögren's syndrome.

Type IV Hypersensitivity Reaction

Also known as delayed type hypersensitivity (DTH), it is mediated by effector T-cells which have been earlier exposed to the same antigen. These cells accumulate at the site of entry of antigen, and get activated releasing cytokines that cause accumulation of monocyte/macrophage cells from the peripheral blood. A typical example is Mantoux test. This type of hypersensitivity is an important defence mechanism against parasites and intracellular organisms. When pathogen is not cleared within a week or so, a granuloma may form at the site which releases proteolytic enzymes and destroys the surrounding tissue. Such pathology of hypersensitivity is seen in sarcoidosis and other granulomatous conditions.

DTH can be measured by injecting the antigen intradermally and measuring the local reaction at 24 to 48 hours. Contact dermatitis and Bacillus-Calmette Guerin skin test are examples of DTH reaction. Histology reveals lymphocytes, monocytes, macrophages at the site of reaction. The granuloma seen in tubercular and in non-tubercular cases occurs after 21 to 28 days of antigen exposure and is also an example of DTH reaction.

CYTOKINES—KEY MEDIATORS OF INFLAMMATION

Although the triggering factor for an autoimmune disease is not known, much is understood about the sequence of events that follow. Studies in experimental models for autoimmune diseases have shown that cytokines are the key mediators of inflammation. They activate the cells from which they are produced and markedly influence the cell composition at the inflammation site and the reparative process that follow. For example, in RA, antibodies to cytokine targets have shown excellent results for controlling the signs and symptoms of the disease. The putative triggering agent in the synovial compartment activate the synovial macrophage which produce as key mediator of inflammation tumour necrosis factor TNF-alpha which has pleiotropic effect both locally as well as systemically. These include release of other proinflammatory cytokines (IL-1, IL-6, IL-18, IL-23 and GM-CSF), activation of endothelial cells and upregulation of adhesion molecules E-selectin and VCAM1, chemokine release (Rantes, MCP1, SDF1) causing leucocytes influx, induction of acute phase response in liver, chondrocytes and osteoclast activation causing cartilage and bone loss, and upregulating and maintenance of class II expression. These cytokines activate cells of the adaptive immune system, especially naive CD4+Th cells which are driven to Th1 and the recently described Th17 cells. IL17, in turn, activates synovial fibroblast to produce RANK L and in synergism with IL-1 and TNF activates osteoclast precursor cells to osteoclast causing bone resorption. IL17 has also been shown to be an important cytokine in psoriasis skin and joint lesions.

The elaboration of cytokine pathways has made it possible to develop monoclonal antibodies directed against TNF-α, IL-1, Th17, IL-6 to downregulate the proinflammatory process in RA, Crohn's disease, ankylosing spondylitis and psoriatic arthropathy with effective control of signs and symptoms of the disease.

5.3 Immunology of Infectious Diseases

Sita Naik

The earlier chapters have discussed how the immune response has evolved to protect the host from external infectious agents. The diversity seen in the T cell and B cell receptors have probably evolved over time to deal with the diversity of the infectious agents. The organisms, however, constantly evolve mechanisms to evade immune recognition and the effector immune response. Some of these will be discussed later in this section. Each new effort by the organism is reciprocated by the host response making the required adjustments. This constant evolutionary battle has given us the system as we know it today.

For an infection to establish itself in a susceptible host, it has to overcome the combined efforts of the innate and adaptive immune systems to eliminate it. The earliest barriers, which try to prevent the establishment of the infection, includes the physical one provided by the epithelial lining itself. The epithelial layer also provides specialised barriers, such as the ciliary processes of the lining epithelium of nasal passages and production of anti-bacterial peptides at many locations. The acidic pH of the stomach forms an effective barrier for any ingested agent as do the normal flora of the gastrointestinal, genito-urinary and respiratory tracts which competitively inhibit the binding of pathogen to host cells.

Although, there has been a significant decline in the morbidity and mortality caused by infectious diseases in much of the developed world, they continue to be a major killer in our country. The understanding of the immune response to infectious agents is also important in the context of new and emerging pathogens like severe acute respiratory syndrome (SARS) and the challenges posed by the old and well established ones like influenza virus. These have not spared any region of the world. In recent times, the major challenge has been posed by an infectious disease, caused by human immunodeficiency virus (HIV) pandemic and the resultant re-emergence of tuberculosis (TB), leishmaniasis, and other opportunistic infections.

VIRAL INFECTIONS

Viruses establish infection by entering cells often through specific cell surface receptors. They use the host cell machinery for their replication and in many instances this replication machinery is error prone, allowing many mutated forms to emerge. It is beneficial to the infecting virus not to kill the host cell. Viruses adopt various survival strategies, such as prolonged latency (HIV) or rapid transmission to a new host (influenza). The innate immune response plays a crucial role in viral elimination. Viral nucleic acids are recognised by the toll like receptors leading to the activation of interferon responsive elements and production of type 1 interferons (IFN-α and IFN-β). These cytokines bind to the type 1 IFN receptors and activate the JAK-STAT pathway which in turn activates several genes including 2'-5'-oligo-adenylate synthetase. This leads to activation of a ribonulease that degrades viral RNA. Other genes that contribute to the antiviral activity are also activated, including dsRNA-dependent protein kinase (PKR), a dsDNA dependent protein kinase that causes inactivation of protein synthesis, and thus, viral replication. Many other cell types such as macrophagges, monocytes and fibroblasts produce IFNs and interleukin (IL)-12 is an important cytokine produced during the innate response. This is a potent activator of NK cells which are efficient killers of virus infected cells.

Antibodies have a limited but important role in limiting acute infection. Both humoral and cellular responses are important for viral immunity. Antibodies that neutralise viral surface molecules involved in cell entry can prevent establishment as well as cell to cell spread of the virus. Secretory immunoglobulin (IgA) has an important role in this regard as in the case of attenuated oral polio vaccine. Further in the course of infection, antibodies can also agglutinate viral particles and function as an opsonising agent to facilitate Fc or C3b-receptor mediated phagocytosis of viral particles.

Most of the vaccines against viruses that are in use act by generating neutralising antibodies (HBV, polio). Antibodies also help in activating the complemet pathway leading to virus lysis. However, once infection is established, cellular mechanisms are required and the infected cell has to be lysed. Both CD4+ and CD8+ cells play important roles in antiviral immunity. The activated CD4+ cells secrete numerous cytokines, of which IFN-γ can induce an antiviral state in the cell, IL-2 helps in the maturation of precursor CTLs to a mature effector population and both IL-2 and IFN-γ activate NK cells which are important in killing infected cells in the initial days of the infection. In established infections, CTLs are probably the most important effector mechanism with CTL activity peaking 7 to 10 days following infection. Elimination of infected cells ensures that no virus infects new cells and perpetuates infection. Failure of CTL activity results in dormancy or chronicity of the infection.

Viruses have developed a variety of mechanisms to subvert the immune effector mechanisms directed against them, and thus, ensure their survival. For instance, hepatitis C virus can overcome the anti-viral effects of type I IFNs by interfering with the action of PKR. Herpes simplex virus (HSV)-1 and HSV-2 inhibit the antigen presentation by MHC class I, thus escaping CTL mediated target lysis. CMV, HIV and measles downregulate class I expression, thus interfering with efficient antigen presentation. Vaccinia virus secretes a protein that binds to C4b and inhibits classical pathway, while herpes simplex glycoprotein binds C3b and inhibits both classical and alternate pathways. Many viruses cause a generalised immunosuppression (mumps, measles, EBV, CMV, HIV) by various mechanisms.

Viruses constantly change their antigenicity as a strategy for evasion from immune mediated elimination. The classical example is of influenza virus where this strategy leads to emergence of new strains and the failure of previously generated immunity to protect against fresh infections. HIV also uses this strategy, with an estimated mutation rate 6.5 times faster than influenza. This has led to the difficulties in generating vaccines against these infections.

BACTERIAL INFECTIONS

Most bacterial infections are extracellular and specific antibodies bind and lyse these by activating the complement cascade on the bacterial cell wall leading to membrane pore formation. Gram negative bacteria also act as opsonins and thus facilitate phagocytosis and intracellular killing within the phagocyte. Many bacteria also release harmful toxins that are neutralised by the specific antibody as in the case of diphtheria. However, cell-mediated immunity is important in the case of intracellular bacteria.

Many bacteria too have evolved strategies to evade the host immune response. Many bacteria (*Neisseria gonorrhoeae, Haemophilus influenzae, Neisseria meningitidis*) secrete proteases that cleave secretory IgA at the hinge region, and thus, abrogate their ability to agglutinate these organisms. *N. gonorrhoeae* can change its surface antigens, thus evading the neutralisation by IgA. *Streptococcus pneumoniae* surface polysaccharide can prevent phagocytosis effectively while *S. pyogenes* do so by its surface M protein. The long side chains on the lipid A moiety of the cell wall core polysaccharide of Gram negative bacteria help resist complement mediated lysis. The elastase secreted by *Pseudomonas* inactivates C3a and C5a anaphylotoxins, and hence, decreases local inflammation. In some instances, the disease and symptoms are caused by the immune response against the pathogen and not the pathogen itself. In fact, pathogen induced cytokine production, usually TNF and IL-1, is responsible for septic shock and toxic shock syndromes. It also contributes to some of the pathology seen in tuberculosis.

Intracellular bacteria can survive within the protected environment of cells for long periods. The examples are *L monocytogenes* and more importantly, *Mycobacterium tuberculosis*. The sustained antigenic stimulation results in activation of CD4+ cells and the characteristic delayed type hypersensitivity response. The activated CD4+ cells secrete cytokines which attract large number of macrophages and these differentiate into epithelioid cells and sometimes coalesce to form multinucleated giant cells. The localised accumulation of lysosomal enzymes released by the activated macrophages leads to extensive tissue necrosis, seen as the caseous material at the centre of the this accumalation of lymphocytes, epithelioid cells and giant cells. Thus, the characteristic 'granuloma' which is considered to be pathagnomonic of tuberculosis is the outcome of the intense immune response against tubercular antigens. The immune effort is successful in restricting multiplication of the bacilli in the majority of cases. Failure to contain multiplication, leads to continuing tissue necrosis with eventual rupture of the granuloma and release of mycobacteria. This leads to the miliary lesions in the lung and establishment of infection at various extrapulmonary sites.

PARASITIC INFECTIONS

Diseases caused by protozoa and helminths account for considerable part of the disease burden in developing countries. Protozoa are mainly unicellular eukaryotes that live and multiply intracellularly. Of these, malaria and leishmania are of particular relevance to our country. The host does mount an immune response to malarial parasite, and anti-malarial antibodies can be demonstrated in those who have been infected. However, the parasite has a multi-stage life cycle in which it resides within erythrocytes as sporozoites and gametocytes, and within hepatocytes as merozoites. These are antigenically distinct stages and the immune response to these stages is not well understood. This has proved a challenge for the development of a malaria vaccine.

The immune response to leishmania has been better sudied. While leishmania major causes predominantly a cutaneous disease that is not seen in India, the visceral form of the disease that is endemic in parts of eastern India is caused by *L. donovani*. Those who resist infection have a robust TH1 response, while those who develop the disease have a TH2 biased response. Although these distinctions are more clearly seen in murine models of the disease, there appears to be a role for cellular immunity in protection against this parasite. However, leishmania also has two distinct antigenic forms, the infective promastigote, and the amastigote form which resides within the protected environment of the phagosome. The protective immunity is still far from clear and a vaccine is not on the horizon.

FUNGAL INFECTIONS

These are caused by entry of the fungal organism through inhalation or through sites of injury. They are often restricted at the site of entry by the barriers provided by the innate immune system. They are also restricted by phagocytosis by neutrophils and by the activation of the complement system. The important role of the immune system is evident from the fact that non-pathogenic commensal fungi can cause disease in the immunocompromised host. The best example of this is the *Candida albicans* which can cause a serious systemic illness in acquired immunodeficiency syndrome patients.

5.4 Primary Immunodeficiency Disorders—A Clinical Approach

Surjit Singh

The large majority of children who appear to have had 'frequent' or 'very frequent' infections in infancy are completely normal when examined clinically. A small minority, however, who need further investigations can be identified clinically. In these children, possibility of an underlying primary immunodeficiency disorder (PID) should be seriously considered. Of course, the more common secondary causes of immunodeficiency [e.g. human immunodeficiency virus (HIV) infection] and conditions which may mimic an immunodeficiency (e.g. cystic fibrosis, α-1-antitrypsin deficiency, Kartagener's syndrome and gastro-oesophageal reflux disease) should be excluded.

PIDs are a heterogenous group of conditions with the majority of cases presenting in infancy and early childhood and some conditions, e.g. common variable immunodeficiency (CVID) manifesting in late childhood or even in adult life. PIDs are not as rare as is often believed and if immunoglobulin (Ig) subclass deficiency and IgA deficiency are included, the prevalence rate may be as high as 1/250 - 1/1000 population. However, there is a spectrum of illness and majority of children with 'minor' immunodeficiencies may not develop clinically symptomatic diseases. A PID should be suspected when a child has two or more of the following signs:

1. Four or more new ear infections within a year
2. Two or more serious sinus infections within a year
3. Two or more months on antibiotics with little effect
4. Two or more cases of pneumonia per year
5. Failure of an infant to gain weight or grow normally
6. Recurrent deep skin or organ abscesses
7. Persistent thrush in the mouth or elsewhere on the skin in children more than 1 year old
8. Need of intravenous antibiotics to clear infections
9. Two or more deep-seated infections, like meningitis or cellulitis
10. A family history of immunodeficiency

CLASSIFICATION OF PIDs

PIDs are classified based on the affected component of the immune system. The International Union of Immunological Societies has suggested one such classification system which is enumerated below:

1. Severe combined immune deficiencies in which both T- and B-cells are defective, e.g. severe combined immunodeficiency (SCID)
2. Predominantly antibody deficiencies, e.g. X-linked hypogammaglobulinaemia (XLH)
3. Other well-defined immunodeficiency syndromes in which there are non-immunological features, e.g. ataxia-telangiectasia (AT)
4. Diseases of immune dysregulation, e.g. X-linked lymphoproliferative syndrome (XLPS)
5. Congenital defects of phagocytic cells, e.g. congenital neutropaenia. Affected children may present with life-threatening bacterial or fungal infections
6. Defects of innate immunity relating to monocyte and dendritic cell function
7. Autoinflammatory disorders, e.g. periodic fevers
8. Complement deficiencies. Affected children may have a clinical presentation like, that of XLH. Further, children with C2 and C4 deficiency may present with an autoimmune disease mimicking lupus

Based on the clinical experience from various centres which may not necessarily reflect the true epidemiological situation, 60% to 70% of PID cases are due to humoral immunodeficiencies, 15% to 20% due to cellular immunodeficiencies, 10% to 15% due to phagocytic cell defects and 10% to 20% due to miscellaneous causes.

APPROACH TO A CHILD WITH SUSPECTED PID

Clinical History

The age of presentation is important and earlier the age of onset in children, the more severe is the immunodeficiency. Appearance of recurrent/serious infections before the age of 6 months is suggestive of a severe combined immunodeficiency or a neutrophilic disorder. Children with XLH usually present after the first 6 months of life while the usual age of presentation of CVID is the second decade of life.

Type of Infection

The type of infection may suggest a specific immunodeficiency syndrome (**Table 1**).

Family History

The inheritance pattern provides some leads to diagnosis. For instance, ataxia telangiectasia and certain forms of chronic granulomatous disease (CGD) and SCID have an autosomal recessive inheritance while XLH, XLPS, Wiskott-Aldrich syndrome, hyper-IgM syndrome, SCID and CGD have an X-linked recessive inheritance.

Physical Examination

Generally, children with a serious immunodeficiency usually fail to thrive and conversely an underlying serious PID is unlikely in a well-looking school going child even if there is a history of – 'frequent' infections. Some PIDs have an associated syndrome which can be picked up on physical examination (**Table 2**).

Investigations

A broad diagnosis of the PID group can be made based on history and findings. Investigations should be done with a specific PID in mind since these only serve to confirm the clinical suspicion. HIV infection should be excluded before embarking on investigations for a PID.

Table 1: Type of Infection and Associated Possible Immunodeficiency Syndrome

Type of infection	Likely immunodeficiency
Viral, fungal, mycobacterial/bacterial infections starting within a few weeks of birth	SCID
Recurrent pyogenic bacterial infections (e.g. *Streptococcus pneumoniae, Haemophilus influenzae*) starting from early infancy	Humoral immunodeficiency syndrome (e.g. XLH) complement deficiency
Recurrent pyogenic bacterial infections (e.g. *Streptococcus pneumoniae, Haemophilus influenzae*) starting late in childhood	CVID
Recurrent Staphylococcal 'cold abscesses' and respiratory infections (especially with pneumatocoeles)	Hyper-IgE syndrome
Recurrent *Giardia lamblia* infection	IgA deficiency; other humoral immunodeficiencies
Cryptosporidiosis in early childhood	SCID
Recurrent (Staphylococcal) skin infections, persistent fungal pneumonia, recurrent Staphylococcal pneumonia, multiple liver abscesses	CGD
Disseminated Bacillus-Calmette Guerin (BCG) infection	SCID
Recurrent mycobacterial infections	Defect in interferon γ, interleukin-12 receptor pathway
Recurrent Neisseriae infections	Late complement deficiencies

Table 2: Symptoms and Clinical Features with Associated Immunodeficiency Syndromes

Clinical features	Likely immunodeficiency
Failure to thrive since early infancy, diarrhoea, rash, atrophic tonsils and lymph nodes	SCID
Failure to thrive, recurrent respiratory infections in a boy with onset after 6 months	XLH
Recurrent respiratory infections starting later in childhood, diarrhoea, hepatosplenomegaly	CVID
Infantile eczema (often atypical), recurrent infections since early infancy and bleeds(due to thrombocytopaenia) in a boy	Wiskott-Aldrich syndrome
Typically coarse facial features with history of recurrent Staphylococcal infections	Hyper-IgE syndrome
Slowly progressive ataxia, recurrent bacterial infections (especially pneumonia), bulbar/facial telangiectasia	Ataxia-telangiectasia

Screening Tests

Screening tests should include a complete blood count and peripheral smear examination, quantitative serum immunoglobulin assay, chest radiograph and markers for T (CD3) and B (CD19) cells (**Table 3**). Hypogammaglobulianaemia is diagnosed if the serum immunoglobulin levels are below -2 SD of the age related norms. The physiological hypogammaglobulinaemia in the first 3 to 6 months of life, may get abnormally prolonged to

Table 3: Screening Tests

Investigation	Clinical correlate
Haemogram	
Haemolytic anaemia	CVID
Lymphopaenia	Cell mediated immunodeficiency
Neutropaenia	Agranulocytosis
Marked polymorhonuclear leucocytosis	CGD, leucocyte adhesion molecule deficiency
Thrombocytopaenia	Wiskott-Aldrich syndrome, CVID
Peripheral blood smear	
Giant granules in neutrophils	Chediak-Higashi syndrome or variants
Quantitative serum IgG, IgA, IgM	Several humoral and cellular PIDs; levels to be interpreted in the context of the clinical diagnosis
Chest radiograph	
Persistent pneumonia	Chronic granulomatous disease
Pneumatocoeles	Hyper-IgE syndrome
Absent thymic shadow	SCID
T- and B-cell markers (CD3; CD19)	Absent or low T- and B-cells in SCID; B cells absent with normal T-cells in XLH

persist even at 18 to 24 months (and sometimes longer), a condition known as transient hypogammaglobulinaemia of infancy (THI).

Confirmatory Tests

If the clinical findings and screening tests suggest a PID, more detailed investigations are necessary (**Table 4**). If antibody deficiency is suspected on clinical grounds and serum immunoglobulin level is normal, an IgG subclass deficiency or a functional antibody defect should be suspected.

Table 4: Confirmatory Tests

Detailed analysis of lymphocyte subsets by	
Flow cytometry	CD3: T- cell marker CD19, CD20: B-cell marker CD16, CD56, CD57: natural killer (NK) cell marker CD4: Marker for helper-inducer subset of CD3 lymphocytes CD8: marker for suppressor cytotoxic subset of CD3 lymphocytes
Lymphocyte proliferation using mitogen, phytohaemagglutinin	Functional assessment of T- cells
Complement component assays	For complement deficiency
Nitroblue tetrazolium dye reduction test	Useful and simple test for diagnosing CGD
IgG subclasses by nephelometry or ELISA (G1, G2, G3, G4)	A child with deficiency of one subclass may have a normal level of total IgG because of compensatory over-production of other subclasses
IgE	Levels are frequently above 2000 IU/mL in the hyper-IgE syndrome

Prenatal Diagnosis

As the genetic defect is now known for several of the PIDs, many of these disorders can be diagnosed prenatally using chorionic villus sampling, cultured amniotic cells or foetal blood sampling. Prenatal diagnosis has been successfully carried out for XLH, some forms of SCID and the Wiskott-Aldrich syndrome. Further, under special circumstances sex determination by ultrasonography can be used to exclude X-linked PIDs.

TREATMENT

Prevention of infection is an integral part of the management of children with PIDs. This is achieved using prophylactic antimicrobials, judicious use of vaccines and early treatment with appropriate anti-microbials after exposure. If a blood product has to be transfused, the donor should be screened for cytomegalovirus infection. For cell-mediated immunodeficiencies, the blood should be doubly irradiated to prevent development of graft-versus-host disease.

Intravenous immunoglobulin (IVIG) given in doses of 400-600 mg/kg every 3 to 4 weeks has improved the outlook for children with humoral PID. Replacement immunoglobulin can now also be given subcutaneously (100 mg/kg weekly), but such preparations are yet to be marketed in our country. Haematopoietic cell transplantation (with peripheral blood stem cells or bone marrow) is the treatment of choice for cellular immunodeficiencies and since children with severe forms of SCID cannot reject the donor stem cells, pre-transplantation chemotherapy is not required in many cases. Gene therapy using viral vectors has been successfully used in patients with adenosine deaminase activity (ADA)-deficient SCID, X-linked SCID and in the Wiskott-Aldrich syndrome.

PROGNOSIS

With timely diagnosis and appropriate treatment, children with several of the PIDs can lead a normal life. Most patients with a humoral immunodeficiency disorder can survive to adulthood with replacement immunoglobulin. Disorders, like hyper-IgE syndrome, chronic granulomatous disease and IgG subclass deficiency can be successfully managed with prophylactic anti-microbials. In the case of ataxia-telangiectasia, the immunodeficiency is usually not severe but these patients succumb to other complications (e.g. malignancies). Haematopoietic stem cell transplantation carried out expeditiously, is the only treatment option for severe forms of cellular immunodeficiencies (e.g. SCID, Wiskott-Aldrich syndrome). Long-term survival rates of matched haematopoietic stem cell transplantation for PID are now upwards of 90%.

SPECIFIC IMMUNODEFICIENCIES

Severe Combined Immunodeficiency

This group of PIDs is characterised by the absence of T- and B-cell (and sometimes natural killer cell) function. The inheritance pattern is either autosomal recessive (e.g. ADA deficiency SCID) or X-linked recessive (e.g. X-linked SCID), the latter being the more common. Other types of autosomal recessive SCID include Janus kinase 3 deficiency (T-B+NK-) and IL-7Rá deficiency (T-B+NK+). Affected children develop severe infections with opportunistic organisms soon after the neonatal period and in the first 6 months of life. Typical presenting features include failure to thrive, rash, diarrhoea, pneumonia and oral thrush. Physical examination may show absence of tonsils and impalpable lymph nodes. Live vaccines must be avoided.

X-Linked Hypogammaglobulinaemia (XLH)

Affected boys usually remain well during the first 3 to 6 months of life due to the presence of maternally acquired IgG. After this, they present with serious and recurrent bacterial infections. Laboratory investigations reveal a panhypogammaglobulinaemia with normal numbers of T-cells but absent or very low numbers of B-cells in the peripheral circulation. The genetic defect is at the level of the tyrosine kinase gene located on the X chromosome.

Common Variable Immunodeficiency

CVID is a group of disorders characterised by hypogammaglobulinaemia and a normal B-cell number. Many patients also have a T-cell defect but this is more difficult to document and characterise. Low levels of lymphocyte proliferation following mitogen stimulation may be demonstrable. A number of mutations in different genes have been identified, all causing the same phenotype. Patients usually become symptomatic after the first decade of life and associated autoimmune features (e.g. leucopenia, haemolytic anaemia, arthritis) are commonly seen. Hepatosplenomegaly and lymphadenopathy are prominent clinical features. Patients with CVID need to be closely monitored for the development of lymphoreticular malignancies.

Immunoglobulin A Deficiency

IgA deficiency is the most common form of PID with prevalence of 1:350-1:650. IgA deficiency is diagnosed if the serum IgA level is less than 5-10 mg/dL or if the level is below -2SD of the age related normal value. While majority of the patients may remain asymptomatic throughout life, some do have an increased incidence of respiratory and gastrointestinal infections and allergic disorders. A small proportion of these patients may have an associated deficiency of one of the IgG subclasses (e.g. IgG2, IgG4). Autoimmune diseases associated with IgA deficiency include lupus, rheumatoid arthritis and chronic active hepatitis. Some patients with IgA deficiency may develop anti-IgA antibodies and this may lead to unfavourable transfusion reactions if the patient is given blood products.

IgG Subclass Deficiency

IgG subclass deficiency, a condition with undetermined clinical significance, is the most common form of PID seen in clinical practise. One may suspect the condition if a patient presents with the clinical phenotype of a humoral immunodeficiency has normal (or, at times, even elevated) levels of serum immunoglobulins. The disorder can present in early childhood or later.

Wiskott-Aldrich Syndrome (WAS)

WAS, an X-linked recessive immunodeficiency disorder, is caused by a mutation in the gene encoding a cytoplasmic protein, Wiskott-Aldrich syndrome protein. WAS is expressed in haematopoietic cell lineages and controls the assembly of actin filaments. Children present with eczema, recurrent serious

bacterial infections and thrombocytopaenia, characterised by small sized platelets. Children with WAS present in early infancy and have impaired immunological responses to the polysaccharide antigens. They are especially susceptible to infection with *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Neisseria meningitidis*. Serum IgM levels are low, while IgE may be elevated. The clinical phenotype is variable ranging from a very fulminant course with repeated infections to milder forms in which children survive childhood. Long-term complications include development of lymphoreticular malignancy.

Ataxia-Telangiectasia

Ataxia-telangiectasia is an inherited disorder of DNA repair mechanism with characteristic susceptibility to radiation-induced chromosomal damage. Serum IgA levels are low with IgG subclass deficiency. Patients present with progressive cerebellar ataxia that becomes evident around 2 to 3 years of age. Affected children may have recurrent respiratory infections that are less severe than seen in WAS. The telangiectasia become apparent around 4 to 6 years of age and may be first noted over the lateral aspect of bulbar conjunctiva. Most children need to be supported with prophylactic antimicrobials. There is a risk of development of lymphoproliferative malignancies later in life. Bone marrow transplantation is not a treatment option in this condition.

DiGeorge Syndrome

DiGeorge syndrome is a T-cell deficiency disorder of varying severity which is associated with abnormal embryogenesis of the 3rd and 4th pharyngeal pouches. The phenotype includes severe neonatal hypocalcaemia causing tetany, hypoparathyroidism and congenital cardiac defects (e.g. truncus arteriosus, transposition of great vessels). Patients have a typical facies characterised by low-set ears, micrognathia, shortened and upturned philtrum of the upper lip and hypertelorism. Patients with milder degrees of immunodeficiency may be given only supportive management while those with more severe forms of the disease are candidates for haematopoietic stem cell transplantation.

Chronic Granulomatous Disease (CGD)

CGD is a group of disorders characterised by defects in superoxide radical generation due to reduced activity of the NADPH oxidase. Both denovo mutations, and X-linked recessive (mutations in the X-chromosome gene encoding $gp91^{phox}$) or autosomal recessive (mutations in the gene encoding $p47^{phox}$ on chromosome 7) inheritance occur, X-linked being the most frequent. Patients present with recurrent life-threatening infections often starting very early in life. Infections are caused by catalase-positive bacteria (e.g. *Staphylococcus aureus*, *Serratia spp.*) or fungi, especially *Aspergillus*. Typical clinical findings include a persistent non-resolving pneumonia, prominent lymphadenitis and multiple liver abscesses. Osteomyelitis of the small bones of hands and feet is also characteristic. Long-term prophylaxis with a combination of trimethoprim-sulphamethoxazole and itraconazole has resulted in significant reductions of morbidity and mortality in this condition.

5.5 Laboratory Investigations in Immune-Mediated Diseases

Amita Aggarwal

Immune-mediated diseases occur either because of lack of an appropriate immune response as in immunodeficiency states or an abnormal response like in allergic diseases and autoimmune disease. Laboratory investigations play an important role in diagnosis of patients with such immune disorders. The available tests need to be used judiciously in order to provide a cost-effective and efficient approach to diagnosis.

AUTOANTIBODIES IN SYSTEMIC AUTOIMMUNE DISEASES

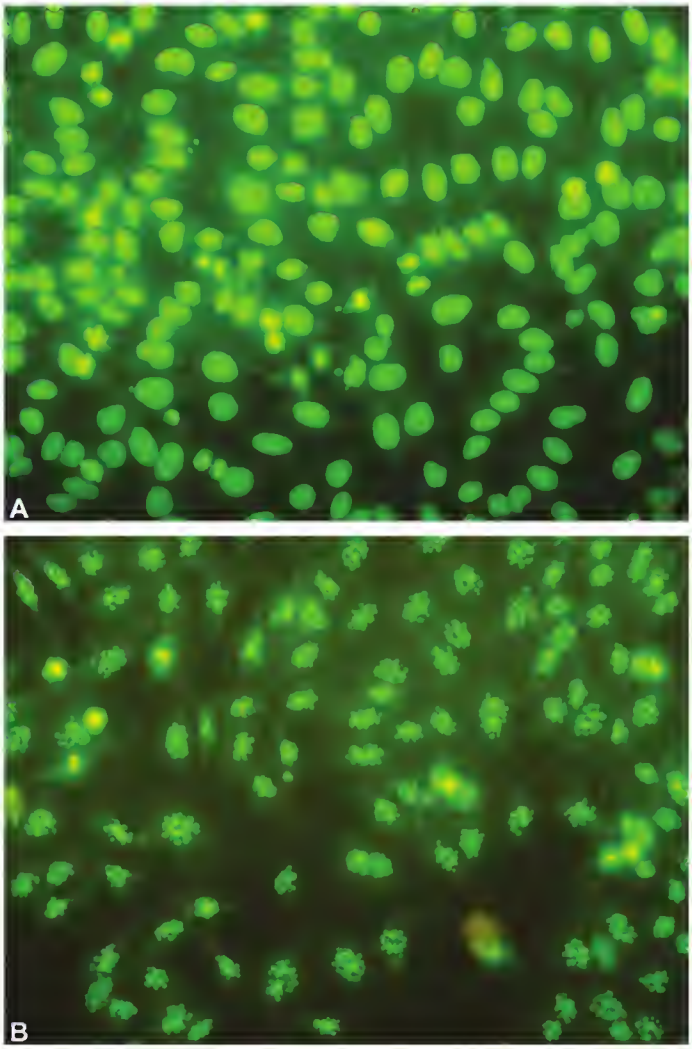
Autoantibodies directed against self-antigens are present in many autoimmune diseases. These may be directed to any constituent of cell, be it cell membrane, cytoplasm, deoxyribonucleic acid and other proteins in the nucleus. Although their pathogenetic role is not clear, they are good diagnostic markers due to their frequent association with specific diseases. However, the mere presence of an autoantibody is not equivalent to disease and absence of an autoantibody does not exclude a disease. The common antibodies used in clinical practise are given in **Table 1**.

Table 1: Autoantibodies that are Commonly Used and their Disease Association

Antibody	Associated disease
Rheumatoid factor	Rheumatoid arthritis, Sjögren's syndrome
Anti-nuclear antibody	Systemic lupus erythematosus (SLE), systemic sclerosis, inflammatory myositis, Sjögren's syndrome (**Figures 1A and B**)
Anti-dsDNA	SLE
Anti-proteinase 3	Wegener's granulomatosis
Anti-myeloperoxidase	Microscopic polyarteritis nodosa, Churg-Strauss syndrome
Anti-cardiolipin	Anti-phospholipid syndrome, SLE

Rheumatoid Factor

Rheumatoid factor (RF) is an antibody directed against the Fc portion of immunoglobulin (IgG) and is usually of IgM type. RF is detected by latex agglutination, nephelometry or enzyme linked immunoassay and the results should always be expressed in International Unit (IU) for ease of comparison between different laboratories or methods. Presence of RF in a patient with joint disease increases the probability of diagnosis of rheumatoid arthritis (RA). It is present in 75% to 85% of patients with RA and in 10% of children with juvenile arthritis. In a patient with established RA, its presence suggests a more aggressive disease. It is also present with lesser frequency in infections like malaria, leprosy and tuberculosis, malignancies and other autoimmune diseases like Sjögren's syndrome, SLE, etc. The prevalence of RF increases with age and geriatric population have a prevalence of approximately 20%. Thus, in elderly patients with vague joint pains, presence of RF should not lead to a diagnosis of RA. RF titres correlate poorly with activity of disease in RA, and therefore, there is no utility in repeating the test.



Anti Citrullinated Peptides Antibody (ACPA)

ACPA are a set of antibodies directed against citrullinated self peptides and are highly specific for a diagnosis of RA. Anti-cyclic citrullinated peptide (anti-CCP) is the most often used test and has a specificity of 95% and a sensitivity of 65-70%. In contrast to RF, it is rarely seen with other connective tissue diseases and infections. In early arthritis, presence of anti-CCP antibodies increases the likelihood of RA.

Antinuclear Antibody (ANA)

ANA is a heterogenous group of autoantibodies directed against components of nucleus including deoxyribonucleic acid, ribonucleic acid (RNA) associated proteins (nRNP, Sm, La, Ro), nucleolar proteins, centromere, etc.

The 'gold standard' for ANA detection is indirect immunofluorescence (IIF) assay using Hep2 cells (**Figures 1A and B**).

Figures 1A and B: Antinuclear antibody positivity on Hep2 cells by immunofluorescence microscopy. (A) Homogeneous pattern suggestive of antibodies to dsDNA and (B) Centromere pattern suggestive of limited systemic sclerosis.

The recently developed ELISA tests are inferior to IIF both in sensitivity and specificity. The IIF test also has the advantage that the fluorescence pattern can give an indication regarding the target antigen against which the antibody is directed. For instance, rim pattern suggests antibodies to dsDNA and is suggestive of SLE, while a centromere pattern is typical of patients with limited systemic sclerosis (**Figure 1B**). ANA is used as a screening test and its detection increases the likelihood of the diagnosis of a connective tissue disease in a patient with multisystem involvement. Further investigations, like anti-dsDNA antibodies, anti-Sm antibodies are needed to establish the specificity of the ANA present in the sera. ANA is also positive in other conditions, such as infection, malignancy, RA and juvenile idiopathic arthritis.

Antibodies to dsDNA

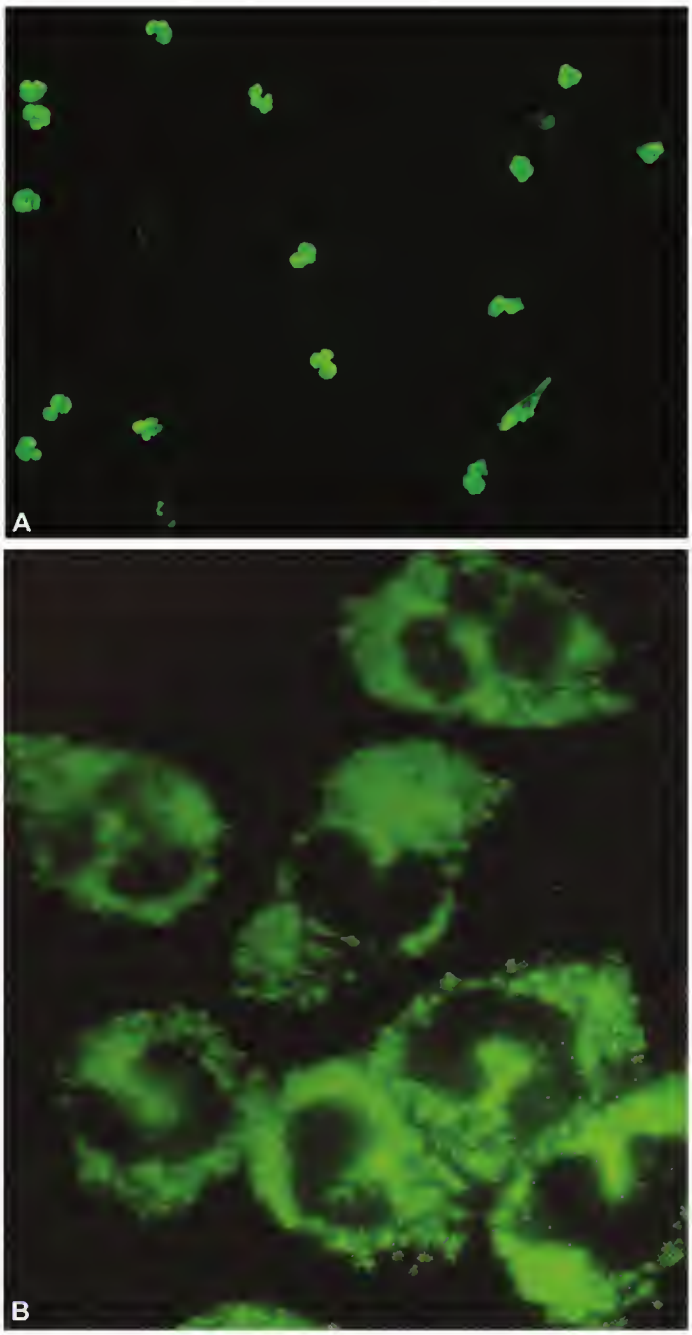
Antibodies to dsDNA are a hallmark of SLE. They are detected by IIF using *Crithidia luciliae*, Farr assay (liquid phase radio-immunoassay) or ELISA. *Crithidia luciliae* is a protozoan parasite of *Leishmania* family which has a prominent kinetoplast made of dsDNA. Anti-dsDNA titre is raised in about 60% of patients with SLE and has a good correlation with presence of lupus nephritis. Serial measurement can help in monitoring of the disease activity. However, a rise in the antibody titre alone does not warrant a change in the treatment which should be made in the context of clinical parameters.

Antibodies to Extractable Nuclear Antigens

Antibodies to extractable nuclear antigens (ENAs) comprise of antibodies to various RNA associated proteins. Each antibody has a specific disease phenotype associated with it and variable prevalence (**Table 2**). ENAs are detected using ELISA or immunoblotting. Since antibody titres do not correlate with disease activity, qualitative assays like immunoblot or line assays are as useful as quantitative assays like ELISA.

Table 2: Antibodies to Nuclear Target Antigens

Antibody	Disease	Prevalence
Anti-Sm	SLE	30%
Anti-nRNP	SLE	40%
	Mixed connective tissue disease	100%
	Rheumatoid arthritis	15% to 20%
Anti-Ro	Primary Sjögren's syndrome	60%
	SLE	30%
Anti-La	Primary Sjögren's syndrome	30%
	SLE	15%
Anti-centromere	Limited systemic sclerosis	50%
Anti-Scl 70	Diffuse systemic sclerosis	45%



Antiphospholipid Antibodies

Presence of antibodies to phospholipids is mandatory for the diagnosis of antiphospholipid (APL) syndrome. Cardiolipin is the most commonly used substrate. IgG and IgM antibodies are measured by ELISA and the results are expressed as mild, moderate and marked elevation. IgA antibodies to cardiolipin can also be detected, but have less diagnostic value.

Anti-beta 2-glycoprotein 1 antibodies which are directed against a co-factor required for binding of cardiolipin are more specific for diagnosis and are detected by ELISA. Detection of anti-prothrombin antibodies may be used as a substitute for lupus anticoagulant assay but it has low sensitivity. Antibodies against other phospholipids, like phosphotidylserine, annexin-V, are not useful clinically.

Antibodies to Neutrophil Cytoplasmic Antigens

Anti-neutrophilic cytoplasmic antibodies (ANCAs) are serological markers of severe necrotising vasculitis affecting the small vessels and are seen in patients with Wegener's granulomatosis, Churg-Strauss syndrome and microscopic polyarteritis nodosa. ANCA is detected using IIF assay with human neutrophils as substrate. Two patterns of staining are recognised namely cytoplasmic (cANCA) and perinuclear (pANCA) (**Figures 2A and B**). The antigenic target of cANCA is proteinase 3 (PR3) which has specificity of 85-90% for diagnosis of Wegener's granulomatosis. pANCA is mainly

Figures 2A and B: ANCA positivity on neutrophil smear showing: (A) pANCA pattern; (B) cANCA pattern.

directed against myeloperoxidase (MPO) and is present in 60% of patients with microscopic PAN. pANCA or an atypical staining pattern is also positive in other diseases, like ulcerative colitis, RA, SLE, etc. However, the antigenic targets are variable (cathepsin G, lactoferritin, BPI, elastase, etc). Antibodies to MPO and PR3 are usually detected by ELISA and quantitative measurement of antibodies to PR3 is helpful in monitoring disease activity in patients with Wegener's granulomatosis. ANCA is not useful in a patient with classical polyarteritis, Takayasu's arteritis, etc.

ORGAN-SPECIFIC AUTOANTIBODIES

The characteristic autoantibodies found in the organ-specific autoimmune diseases along with their prevalence is given in **Table 3**. Most of these can be detected by IIF assays using appropriate tissue substrates or by ELISA. Quantitative titres are not useful in the management of these conditions and the IIF tests have adequate sensitivity to assist in diagnosis. In many of these diseases, detection of antibody only suggests an autoimmune aetiology and is not required for diagnosis. For instance, the diagnosis of Graves' disease is based only on clinical findings and hormone levels. Antibodies to insulin, GAD65 and IA-2 though present years before onset of type 1 diabetes mellitus are not useful in diagnosis.

Table 3: Organ-Specific Autoantibodies

Disease	Antibodies	Prevalence
Hashimoto's thyroiditis	Thyroid microsomal antibodies, antibodies to TPO	85% to 90%
Graves' disease	Antibodies to TSH receptor	90% to 95%
Type 1 diabetes mellitus	Antibodies to Islet cells, insulin, GAD65, IA2	75%
Pernicious anaemia	Antibodies to parietal cells	85% to 90%
Chronic active hepatitis	Antibodies to smooth muscle (actin) Antibodies to liver-kidney microsomes	Type I CAH Type II CAH
Primary biliary cirrhosis	Antibodies to mitochondria (pyruvate dehydrogenase)	90%
Coeliac disease	Anti-endomysial antibodies, antibodies to tissue transglutaminase	95%
Immune thrombocytopaenia	Antibodies to platelets (GpIIb/IIIa)	80% to 90%
Autoimmune haemolytic anaemia	Antibodies to RBCs (Rh antigen)	95%
Myasthenia gravis	Antibodies to acetylcholine receptor	70% to 75%
Goodpasture's syndrome	Antibodies to basement membrane	60% to 70%

INVESTIGATION FOR IMMUNODEFICIENCY DISEASES

Immunodeficiency diseases are broadly classified into T-cell defect, B-cell defect, complement deficiency or phagocytic defect. Laboratory investigation of a patient with immunodeficiency is a step-wise process:

- Exclusion of secondary causes
- Screening tests to detect common diseases
- Second level tests to confirm an immunodeficiency disease
- Advanced test for diagnosis of rare immunodeficiency diseases.

Screening Tests

These are simple, easily available tests that help in excluding a major immunodeficiency state. These include: immunoglobulin levels and B-cell count for B-lymphocyte defects; lymphocyte count and CD4/CD8 numbers by flow cytometry, delayed type hypersensitivity test with multiple antigens (PPD, tetanus toxoid, *Candida*, *Trichophyton*) and chest radiograph for thymic shadow for T-lymphocyte defects; phagocyte morphology, IgE levels and NBT reduction test for neutrophil function defects; and CH50 and serum C3, C4 levels for complement defects.

Second Level Tests

If an underlying immunodeficiency is suggested or there is high index of suspicion, additional tests are performed. The tests include iso-haemagglutinin titres, antibody response to tetanus toxoid for B-lymphocyte defects; lymphoproliferative assay to mitogen and recall antigens for T-lymphocyte defects; chemotaxis, superoxide production and bactericidal assay for neutrophil function defects; and AH_{50} for defects of complement function.

Advanced Tests

These are performed to establish the exact cause of the immunodeficiency disease. The exact genetic defect has been identified in many conditions, such as mutations in btk, CD40 and CD40L gene in B-cell defects, interleukin (IL)-2 receptor gamma chain, and TCR signalling molecules in T-cell defects. in NADPH oxidase system in neutrophil defects and serum complement C5-9 complex in complement deficiencies and gene mutation analysis can provide an exact diagnosis.

All these tests need to be performed using appropriate age-matched controls, especially for cellular assays as the immune system has different maturity at different ages. The normal reference values of immunoglobulins for all age groups should be established for each population group. **Table 4** provides a guideline for evaluating immunoglobulin results, since antibody deficiency is present in more than half the children with immunodeficiency.

Tests for Allergic Diseases

Although allergic reaction is mediated by IgE and, total IgE levels are elevated in patients with allergic diathesis, this is not of diagnostic value. Antigen-specific IgE measured by radio-allergosorbent assay helps to identify the specific offending allergens. The skin or prick test is commonly used for identification of the offending agent in allergy prone individuals. A large number of probable allergens are injected intradermally along with saline as a negative control and

histamine as a positive control. The immediate wheal and flare response is observed and allergens giving positive reaction are used for de-sensitisation programme.

Table 4: Immunoglobulin (Ig) Levels as Clue to Diagnosis of Immunodeficiency Diseases

Ig Levels	Diagnosis
Levels of all immunoglobulins reduced	X-linked agammaglobulinaemia, severe combined immunodeficiency, intestinal lymphangiectasis, common variable immunodeficiency
Only IgA reduced	Selective IgA deficiency
IgM: normal or increased IgA, IgG: reduced	X-linked hyper IgM syndrome
IgG, IgA, IgM: normal IgG subclass reduced	Selective deficiency of IgG subclass
Transient reduction in IgG, IgA	Transient hypogammaglobulinaemia of infancy

The patch test in which allergen is applied to the skin is useful for identifying cases of contact dermatitis. All provocative tests should be done under close supervision as sometimes they can aggravate the symptoms.

PRESENCE OF ABNORMAL IMMUNOGLOBULIN OR PARAPROTEIN

A malignant clone can produce hypergammaglobulinaemia in some B-cell malignancies. Serum electrophoresis, in which proteins are separated, based on their size, is helpful in their diagnosis. Normal serum shows five distinct bands, of albumin, α_1 globulin, α_2 globulins, β globulins and γ globulin of which albumin has the fastest mobility. The normal γ globulin band is replaced by a single sharp band called the M peak in multiple myeloma. Other diseases, like primary amyloidosis, Waldenstrom's macroglobulinaemia and monoclonal gammopathy of uncertain significance can also give an M band.

In 10% to 15% of cases of multiple myeloma no M peak is seen as only light chains are produced and immunofixation has to be performed. Immunofixation can also help in typing of paraprotein.

In conclusion, a wide array of tests are available for evaluation of immunological diseases. However, they should be used judiciously in the appropriate clinical setting to get best help from the tests.

5.6 Pharmacological Manipulation of the Immune System

Mitali Chatterjee

Diseases with an immunological basis occur as a result of aberrations of the immune response. Therefore, an effective drug for these diseases should have the ability to modulate the immune response by inducing immunosuppression, tolerance or immunostimulation. Such manipulations are used to prevent allograft rejection, boost the immunosurveillance against cancers and treat allergic conditions.

INDUCTION OF IMMUNOSUPPRESSION TO LIMIT GRAFT REJECTION

Drugs that induce immunosuppression and result in an effective organ transplant can act at one or multiple steps involved in T cell activation and proliferation pathways.

Corticosteroids

The advent of corticosteroids in the 1960s revolutionised the arena of organ transplantation. Steroids are classical immunosuppressants that form the mainstay of treatment. They act to dampen antigen presentation by APCs. Steroids bind to steroid receptors, are transported to the nucleus and bind to the glucocorticoid response elements to regulate the transcription of many genes. Their effects on the immune system include blocking of T cell activation cascade, downregulation of interleukin (IL)-1 and IL-6 genes, and through indirect mechanisms IL-2 production. Glucocorticoid receptor complexes also increases Iκβ expression, curtailing NF-κβ which causes enhanced apoptosis of activated T cells. Since long-term steroids administration has serious adverse effects, which may even be life-threatening, introduction of newer agents and steroid-sparing protocols have been developed.

Azathioprine, Mizoribine and Mycophenolic Acid

Antiproliferative agents such as azathioprine inhibit *de novo* purine biosynthesis, prevent mitosis and consequently proliferation of rapidly dividing cells, including T and B lymphocytes. The purine salvage pathway in lymphocytes is less active than in other rapidly dividing cells. Hence, these cells are more dependent on the *de novo* synthesis of DNA and RNA building blocks. Inhibition of *de novo* nucleoside synthesis achieves a milder immunosuppression than with cyclosporine A (CsA) or rapamycin and it also inhibits many other cell types. Newer anti-proliferative agents are mycophenolate mofetil and rapamycin. Mycophenolate mofetil selectively prevents proliferation of activated T lymphocytes by inhibiting purine synthesis and non-competitive inhibition of the type II isomer of inosine monophosphate dehydrogenase (IMPDH). Rapamycin inhibits graft rejection by blocking IL-2 activation and phosphorylation of 70 S6 kinase inhibiting progression of cells from G to S phase.

Cyclosporine and Tacrolimus (FK 506)

The introduction of CsA, a calcineurin inhibitor which inhibits normal T cell signal transduction was a great leap forward for transplantation. However, due to the narrow therapeutic range coupled with high intra- and inter-patient variability of CsA, it was replaced by a newer calcineurin inhibitor, tacrolimus, which also inhibits IL-2 but is 10 to 100 times more potent than CsA. The antiproliferative effect of calcineurin inhibitors is mediated by its binding to an immunophilin (cyclophilin for cyclosporine and FKBP12 for tacrolimus); they block phosphatase activity, prevent induction of cytokine genes, importantly IL-2 and halt cell cycle progression of T cells. These compounds are hydrophobic in nature and easily penetrate plasma membranes. The introduction of these agents caused dramatic alterations in the outcome of renal transplantation and has brought down the frequency of acute rejection episodes from 85% to 50%. The occurrence of post-transplant diabetes mellitus, especially when combined with steroids and associated nephrotoxicity, are important complications associated with both tacrolimus and cyclosporine.

Sirolimus (Rapamycin)

This is another fungal metabolite, which is structurally related to FK-506 and binds to same proteins. However, its mechanism differs from that of FK-506, since it prevents phosphorylation of a p70 kinase in the CD-28 co-stimulatory and IL-2R signal transduction pathway. Rapamycin blocks T cell proliferation during late G1 and pre-S phase of the cell cycles. Thus, rapamycin inhibits late signals in T cell activation while cyclosporine and FK-506 inhibit an early signal in T cell receptor signal transduction pathway and these compounds have synergistic effect when given together.

Anti-Lymphocyte Globulin

More general immunosuppression is achieved by use of anti-lymphocyte globulin, which has an overall lymphocyte depleting property. This has been licensed for a long time and was widely used prior to the availability of the more specific agents like OKT3 and anti-IL 2R antibodies. A disadvantage of using polyclonal ATG is the general recommendation to administer the medication via central venous access.

BLOCKING THE T CELL RECEPTOR AND CO-RECEPTOR

The OKT3 was the first mouse antibody licensed for use in humans; it is directed against the CD3 antigen that is closely associated with the T cell receptor. The principal mechanism of action of OKT3 is inhibition of cell-mediated immunity by binding to CD3 and promoting phagocytosis or complement mediated lysis of CD3+ T cells. Anti IL-2 receptor antibody prevents T cell activation by blocking the binding of IL-2 to activated T cells. This approach would prevent T cell activation and a monoclonal murine IgG2 directed against the ε chain of the pentapeptide CD3 complex (OKT3) has been approved for human use. However, it needs to be administered in large doses to achieve effective T cell silencing and at this dose the toxicity is considerable. Hence, this drug is only used to treat acute rejection.

Another approach is the use of humanised monoclonal antibodies against the IL-2 receptor (anti-CD25), such as daclizumab and basiliximab. These target only activated T cells, while sparing resting T cells. Targeting costimulatory receptor/ligand pairs is a viable alternative for triggering immunosuppression. Antibodies to the CD40/CD40 ligand have been shown to induce long-term graft survival by inhibiting release of Th1 cytokines interferon (IFN)-gamma, IL-2 and IL-12 and concomitant up-regulation of Th2 cytokines. Inducing blockade of the B7/CD28 costimulation pathway using CTLA-4 Ig which binds to CD28 also prevents activation of T cells. A long-term goal in transplantation research is to develop therapies that would induce graft-specific tolerance for which alloreactive T cells would be targeted, leaving other T cells competent to function effectively.

ROLE OF IMMUNOTHERAPY IN CANCER

In contrast to the graft situation, immunotherapy in cancer involves stimulation of the immune system for the elimination of residual tumour. It has been proposed that cancers evolve from a chronic inflammatory environment which suppresses the cell-mediated immunity and encourages tumour angiogenesis. The immune response directed at the tumour can be enhanced by a variety of approaches including vaccines, infusion of T cells, or cytokines. These approaches either increase the number of effector cells and/or increase production of soluble mediators, such as lymphokines.

VACCINES

Specific tumour antigens can be administered as vaccines. However, the inability of these antigens to stimulate a strong T cell response limits the utility of such vaccines. The immunogenicity of these antigens can be augmented by a variety of immunological approaches that are not being discussed here. In fact dendritic cell vaccines using monocyte-derived DCs pulsed with tumour antigens have been evaluated in early clinical trials using HER-2/neu peptide in case of metastatic breast carcinomas and gp100, MART-1 and MAGE-3 antigens in stage IV melanomas. In melanomas, heat shock protein gp96, gp100, tyrosinase, and MAGE have been used as vaccines with adjuvants such as BCG. Responses have been modest with some instances of complete or partial remissions or prolongation of survival. The immunogenicity of tumours is also enhanced by infecting irradiated tumour cells with viruses transduced with genes expressing cytokines (e.g. IL-2) and granulocyte-macrophage colony-stimulating factor (GM-CSF), or genes for HLA molecules or co-stimulatory molecules. These injected tumour cells undergo apoptosis or are destroyed by inflammatory responses and the shed antigens are processed by dendritic cells and presented to T cells. The disadvantage of tumour cell-based vaccines are that antigen is prepared from tumour cells extracted from surgical resection or biopsy specimens and, hence, has to be individualised for each patient.

Viral vectors and naked DNA in the form of plasmids encoding tumour antigens are administered to muscle cells. A prime boost approach has been applied where the patient is first immunised with vaccinia virus, encoding the gene for carcinoembryonic antigen (CEA), followed by CEA protein. Clinical responses have been limited, but various modifications of these strategies continue to be explored.

MONOCLONAL ANTIBODIES

Monoclonal antibodies can cause death of tumour cells both directly by apoptosis and blocking of growth factor receptors or indirectly by antibody-dependent cell-mediated cytotoxicity. An example of antibody-dependent cell-mediated cytotoxicity is that of rituximab, a chimeric antibody targeting CD20 that is expressed in B cell malignancies. The antibody binds to CD20 on B cells and to Fc receptors present on monocytes, macrophages, and natural killer cells leading to tumour cell destruction. Monoclonal antibodies may also bind complement and trigger the complement cascade, causing complement-dependent cytotoxicity. The end result is a membrane attack complex that literally perforates the cell membrane, causing cell lysis and death.

Successful therapy with monoclonal antibodies is handicapped by the qualitative and quantitative heterogeneity in distribution of antigens on malignant cells. The poor blood flow to tumours may not permit adequate concentrations of the systemically delivered antibodies to reach tumour cells. The presence of high interstitial pressure within the tumour also prevents binding of monoclonal antibodies. Since most monoclonal antibodies are of rodent origin, there exists the possibility that the host will mount an immune response to these antibodies. This response not only decreases the efficacy of monoclonal antibody therapy, but also eliminates the possibility of re-treatment. Despite these obstacles, there has been tremendous success in the clinical application of monoclonal antibodies in haematological malignancies and solid tumours (**Table 1**).

CYTOKINES

Cytokines regulate the innate immune system and function in cascades. Thus, clinical trials of individual cytokines have rarely been found effective. Some of the individual cytokines that have been tested and found to be beneficial are mainly for the treatment of haematological malignancies or immunogenic tumours and include IL-1 β, Interferon-α, IL-12 and GM-CSF.

Interferon

IFN-α is a family of molecules that up-regulate genes for MHC class I, tumour antigens, adhesion molecules and is additionally an anti-angiogenic agent. It promotes B and T cell activity, stimulates macrophages, dendritic cells and upregulates Fc receptors. The benefit of IFN-α therapy in renal cell carcinoma is small but consistent and it is now considered as second-line therapy. It is also effective in metastatic melanoma where it enhances disease-free and overall survival. However, toxicity remains a major problem and patients have to be adequately hydrated and given treatment for the associated depression and decreased energy levels.

Interleukin-2

IL-2 is a T cell growth factor that binds to a specific tripartite receptor on T cells. Patients treated with high doses of IL-2 have shown clinical responses in renal cell carcinoma and melanoma. IL-2 has also shown activity in non-Hodgkin's lymphoma, leukaemias and lymphomas, post-stem cell transplant. However, high-dose therapy with IL-2 results in severe toxicity akin to a state of septic shock. Hypotension, low systemic vascular resistance, high cardiac output, grade 3/4 haematological, hepatic and renal toxicity, and pulmonary oedema have all been

Table 1: Monoclonal Antibodies Approved for Cancer Therapy

Name	Target site	Indications
Alemtuzumab	CD52	CLL
Bevacizumab	VEGF (receptor for vascular endothelial growth factor)	Metastatic colorectal cancer; non-small cell lung cancer, pancreatic cancer, breast and ovarian cancer
Cetuximab	HER1, receptor for epidermal growth factor (EGFR)	Colorectal, head and neck cancers
Edrecolomab	Glycoprotein 17-1 A	Colorectal cancer
Epratuzumab	CD22	Indolent, aggressive non-Hodgkin's lymphoma
Gemtuzumab ozogamicin	CD33	Relapsed AML
Ibritumomab tiuxetan	CD20 (conjugated with Indium-111 or Yttrium-90)	Non-Hodgkin's lymphoma
Panitumumab	receptor for epidermal growth factor	Colorectal cancer
Pertuzumab	Inhibits dimerisation of HER-2 with EGFR	Lung cancer, metastatic breast carcinoma
Rituximab	CD20	Lymphomas
Tositumomab	CD20 (conjugated with I^{131})	Non-Hodgkin's lymphoma
Trastuzumab	HER2, receptor for epidermal growth factor	Metastatic breast carcinoma
Vitaxin	Vascular integrin α(v)beta(3)	Solid tumours

documented but are nearly always reversible. A similar scenario was recently reported in a phase I trial of the anti-CD28 MAb RGN 1412; CD28, a superagonist and activator of T cells triggered by a cytokine storm resulting in a 'systemic inflammatory response syndrome' or SIRS.

Granulocyte Macrophage Colony Stimulating Factor (GM-CSF)

GM-CSF has been approved for use in stem cell and bone marrow transplantation to aid reconstitution of the myeloid series. In patients with stage III and IV melanoma, chronic, intermittent GM-CSF following surgical resection improved long-term survival and treatment was well tolerated.

Interleukin-12 (IL-12)

IL-12, a heterodimeric protein that promotes NK and T cell activity, is a growth factor for B cells. IL-12 given alone has minimal therapeutic benefit but has shown utility as a vaccine adjuvant as it can induces a strong T helper 1 response. IL-12 boosts the response to peptide vaccines in patients with resected stage III and IV melanoma.

FLt3L Ligand (FLt3L)

FLt3L stimulates progenitor cells in the bone marrow resulting in an increase in DCs. Patients with HER-2/Neu overexpressing breast or ovarian cancers were administered FLt3L which showed evidence for enhanced HER-2/Neu T cell response, indicating its immunomodulatory potential.

Immunotherapy may be the next great hope for cancer treatment. While monoclonal antibodies, cytokines, and vaccines have individually shown promise, it is likely that the best strategy to combat cancers would be a multipronged approach since cancers have multiple mechanisms of preventing the activation of and evading an immune response. Through these concerted efforts, our ultimate achievable goal may be a durable anti-tumour immune response that can be maintained over the course of a patient's life-span.

TREATMENT OF ALLERGIC DISEASES

Allergic diseases including asthma are emerging public health problems. They are characterised by an abnormal immune response to ubiquitous and generally innocuous environmental antigens which cause disease in atopic individuals. Immediate phase responses are usually followed by the development of late phase reactants and eosinophilic inflammatory processes driven by the production of Th2 lymphocytes of IL-4, IL-5, IL-9 and IL-13.

Conventional treatment of allergic conditions includes antihistaminics and anticholinergics to relieve symptoms along with corticosteroids to suppress the allergic inflammatory processes. However, while this approach effectively controls symptoms, discontinuation of these medications results in reappearance of symptoms on re-exposure to the offending allergens. Therefore, these therapies have a limited capacity to alter the natural course of allergic diseases and the underlying immunological processes remain uncorrected.

Current therapies for allergic conditions are aimed at neutralising the allergic response. Allergen-based immunotherapy aims at inducing a shift in helper T cells from Th2 cytokines (IL-4 and IL-5) towards production of Th1 cytokines, IFN-γ and IL-12, which control IgE production. It is accompanied by induction of T-regulatory cells via an enhanced release of IL-10 which induces long-term hyporesponsiveness to the allergen. The IgG blocking antibodies that develop, compete with IgE for binding to allergens and prevent aggregation of IgE complexes with the α chain of the high affinity IgE receptor on mast cells. Collectively, this prevents release of mediators of inflammation from mast cells and basophils, prevents infiltration by inflammatory cells, and decreases the number of mast cells.

Another approach is to induce allergic specific tolerance so that exposure to a particular allergen fails to produce symptoms. Immunotherapy involves administering increasing concentrations of extracts of allergens; this induces hypo-sensitisation or desensitisation and attenuates symptoms for several years even after being discontinued. The potential risk involved of fatal anaphylaxis, particularly during the up-dosing phase, necessitates that allergen immunisation should always be conducted in a hospital setting. To overcome this problem, 'hypoallergic naturally occurring' allergens prepared from plants and trees have been tested and found to be effective in

minimising the risk of anaphylaxis. An alternative approach is administration of 'recombinant' allergens, wherein the cysteine residues have been removed by site directed mutagenesis. Allergen immunisation is carried out by various approaches. By subcutaneous immunotherapy (SCIT), wherein patients are sensitised to one or more environmental allergens, for 3 to 5 years of SCIT, can give long-term remission for 3 to 5 years following discontinuation of SCIT. The alternative approach, sublingual immunotherapy (SLIT), has the advantage of route of administration but unlike SCIT, long lasting immunomodulating effects are yet to be established. SLIT simply helps to reduce incidence of rhinitis and medication usage. A third approach is DNA vaccines which induce a strong Th1 response. This can be further enhanced by administration of immunostimulatory sequence of CpG motifs, such as GACGTC, which is the ligand for Toll like receptor-9 on dendritic cells. This leads to activation of signalling pathway of MAPK, NF-kappaB, cytokines (IFN-α, IFN-β, IL-10, IL-12) along with co-stimulatory molecules (e.g. CD409, B7); collectively this helps to shift away from a Th2 pro-allergic response towards a Th1 response. Fusion proteins, e.g. IL-12 fused with the prototype allergen OVA also potentiate Th1-based immune response and reverse established allergic responses. Other alternatives include blocking IgE or its synthesis and interruption of the Th2 dependent allergic cascade. This has been achieved using omalizumab, a recombinant humanised monoclonal antibody against IgE, which not only neutralised IgE, but also inhibited IgE production in B cells and decreased expression of FceR1 on basophils. Importantly, it did not permit activation of mast cells, basophils or monocytes rendering it non-anaphylactogenic. Inhibition of IL-4 and IL-5, and treatment with soluble recombinant IL-4 receptor has been reported to improve severe atopic asthma.

IMMUNOTHERAPY FOR AUTOIMMUNE DISEASES

Conventionally, treatment for autoimmune diseases was based on therapies that reduced inflammation and induced non-specific immunosuppression. However, as autoimmune diseases are chronic, prolonged use of anti-inflammatory drugs such as non-steroidal anti-inflammatory drugs, or corticosteroids, translates into a shorter life expectancy and a poor quality of life. The improved understanding of the immunopathogenesis of autoimmune diseases has led to a shift towards targeting specific signalling molecules associated with the adaptive immune response. The growing number of targeted therapeutics now includes monoclonal antibodies, soluble receptors and molecular mimetics. Possibly the greatest success story has been neutralising TNF-α by infliximab, the humanised monoclonal antibody against TNF-α in the treatment of rheumatoid arthritis. This principle of TNF-α blockade has also been extended for Crohn's disease, ankylosing spondylitis, psoriatic arthritis and psoriasis and has also led to the development of other TNF-α blockers (**Table 2**). Although the long-term safety is satisfactory, it must be kept in mind that anti-TNF-α treatment has been associated with an increased incidence of tuberculosis, production of anti-nuclear and anti-double stranded DNA antibodies.

Targeting B cells decreases production of autoantibodies and also depletes B cells, thereby decreasing the proportion of antigen presenting cells. Rituximab is a human-mouse chimeric antibody specific for CD20, a B cell antigen that rapidly depletes B lymphocytes. It was initially approved for the treatment of B cell lymphomas but has been effectively applied in patients with idiopathic thrombocytopaenic purpura, autoimmune

Table 2: Monoclonal Antibodies that are Approved or Being Evaluated for Use in Autoimmune Diseases

Disease	Biological effect	Antibody	Binding epitope
Rheumatoid arthritis	Auto-antibodies, immune complexes	Denosumab Infliximab Lenercept Etanercept Alemtuzumab Abatercept Anakinra Rituximab Anti-IFNg	Nuclear factor kappa B TNF Soluble TNF p55 receptor Soluble TNF p75 receptor CD52 CTLA-4Ig IL-1RA CD20 IFN-γ
Type 1 diabetes mellitus	Decreased insulin production	Anti-CD3 (OKT3)	CD3
Systemic lupus erythematosus	Auto-antibodies cause complement mediated lysis, Type-III hypersensitivity reactions	Rituximab Anakinra BG9588, IDEC 131	CD20 IL-1RA CD154 CD154
Multiple sclerosis	Myelin destruction	Alemtuzumab Natalizumab	CD52 Alpha-4 integrin
Psoriasis	Activation of T cells in dermis	Infliximab Alefacept Efalizumab	TNF LFA3-Ig CD11a

haemolytic anaemia, vasculitis, dermatomyositis, rheumatoid arthritis, Sjogren's syndrome and systemic lupus erythematosus. However, there are reports of progressive multifocal leukoencephalopathy following its use. Other biologicals targeting CD20 include MAbs ocrelizumab, ofatumumab, hA20 and TRU-015 that also act by depleting B cells. An alternative approach to B cell depletion is modulation of B cell function by targeting CD22, thus, preventing B cell activation. Antibodies to CD3 are also being tried to induce immune tolerance to both allo- and autoantigens, the goal being to achieve self-tolerance. The CD3 antibodies are showing promising results in type 1 diabetes (**Table 2**).

The limitation of the targeted therapies is that despite their high selectivity for immune cell subsets or receptors, they need to be applied at multiple intervals to retain their effectiveness. The risk of excessive immunosuppression remains a concern. Therefore, it is currently recommended that for long-term improvement, targeted therapy should be coupled with conventional anti-inflammatory agents.

Taken together, our enhanced understanding of the immune system in the last two decades has led to the availability of a large number of novel treatments and strategies to tackle immune based diseases. However, our inability to date, to achieve complete success by immunotherapy indicates the complexities of the immune response that cannot be tackled by a single agent but instead by adopting a multipronged approach.

5.7 Immunology of Organ and Haematopoietic Stem Cell Transplantation

Narinder K Mehra, Jamshaid A Siddiqui

Transplantation is the treatment of choice for functional failure of many organs. The success of transplantation depends on the degree of histocompatibility between donor and recipient, among other factors. The genetic difference between recipient and the donor is determined by a set of immune response genes clustered together as human leucocyte antigen (HLA) system. These antigens play an important role in immune discrimination between self and non-self (foreign) molecules.

MAJOR HISTOCOMPATIBILITY COMPLEX

The blood group system (A, B, O), the major histocompatibility complex (MHC) and the minor histocompatibilty antigens (mHA) that include the male specific H-Y antigen system constitute the histocompatibility system in humans. The MHC of man, the HLA system, is located on the short arm of chromosome 6 extending over approximately 4 megabases of DNA. The MHC molecules bind peptide fragments derived from protein antigens (viruses, bacterial peptides, mismatched transplant antigens, etc.) and display them on the surface of antigen presenting cells (APCs) evoking effector responses upon recognition by the T-cell receptor (TCR).

The four inherent features of the MHC are the extraordinary high polymorphism of its genes at the population level, tight linkage among its various loci, non-random association of HLA alleles and its multi-peptide binding ability making it an important immune response control system. The major clinical role of HLA testing remains in the area of donor selection in organ and stem cell transplantation.

GENETICS OF HLA

The human MHC gene cluster contains three distinct groups of loci, a centromeric *'class II region'* which has HLA-DP, DQ and DR loci, a telomeric *'class I region'* that contains the classical HLA-A,B,C and a central 'non-HLA' or *'class III region'* which contains genes whose products are involved in the complement cascade (C2, C4 and properdin factor Bf) and various non-immunological functions (**Figure 1**). Both class I and II gene products show important differences in structure, function and tissue distribution. Matching donors and recipients for HLA-A, B and C for haematopoietic stem cell transplantation (HSCT) loci of class I and of HLA-DR/DQ loci in the class II region during organ and bone marrow transplantation is critical to the survival of a graft.

HLA Class I Genes

HLA class I molecules are expressed on all nucleated cells. Of the 35 loci that have been described so far, HLA -A, -B and -C are the most important. Using tools of molecular biology and DNA typing methods, 238 alleles have been identified in locus

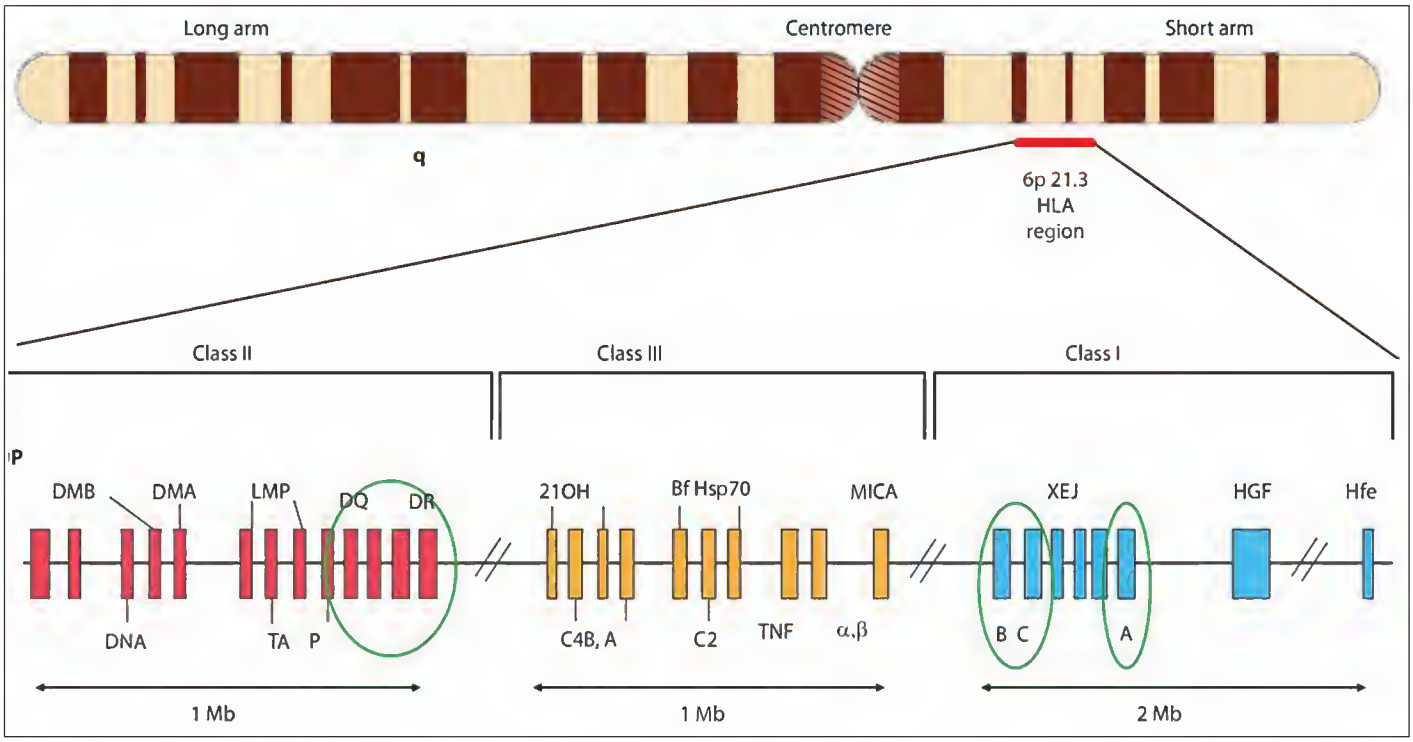

Figure 1: Human major histocompatibility complex (MHC) with chromosomal location and gene map showing multiple genes on the short arm of chromosome 6 (6p21.3). The two way array shows the genetic distance covered by the respective regions on the chromosome. The circled loci are highly polymorphic and are important for donor-recipient matching in the transplantation context. Note that MICA (MHC class I related chain A) is situated in close proximity to the HLA-B locus.

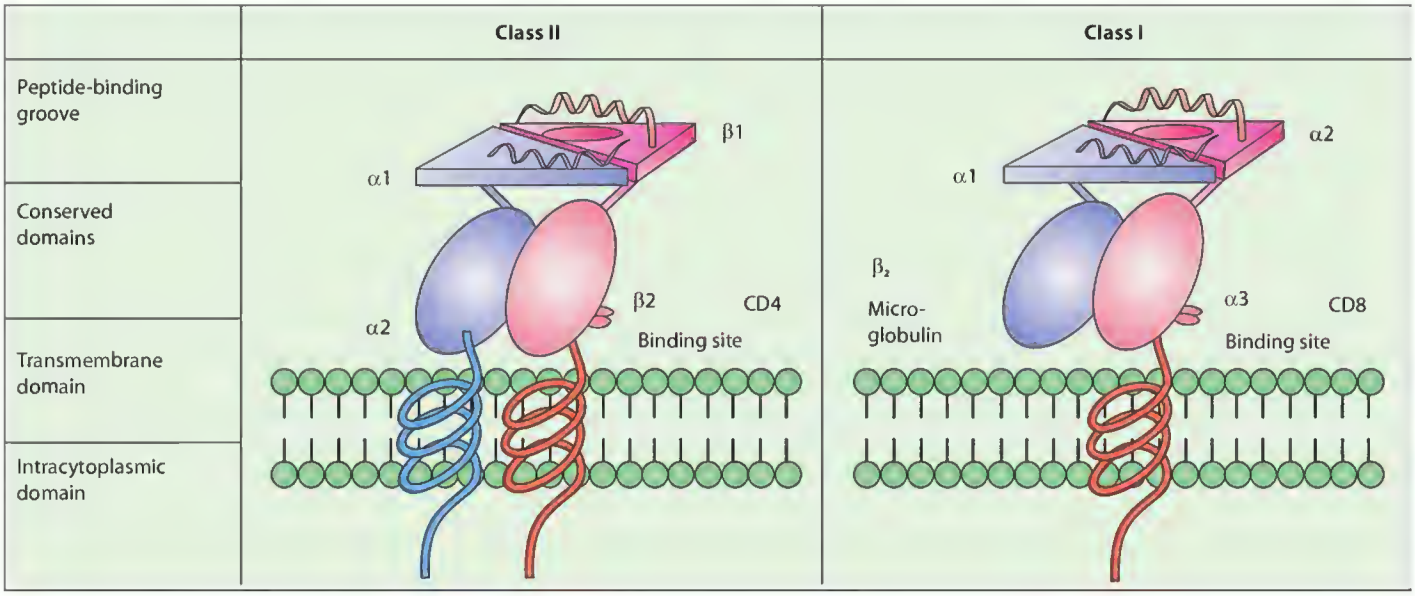

Figure 2: Schematic view of HLA class II and class I molecular structures showing the peptide binding cleft formed between α1 and β1 domains in case of class II and α1 and α2 domains in case of class I molecules. The membrane proximal domains (α2, β2 of class II and β2m and α3 of class I) are conserved and non-polymorphic.

A, 451 in locus B, and 238 in locus Cw. These molecules are heterodimeric glycoproteins consisting of an MHC encoded alpha or heavy chain and non-MHC encoded light chain (beta-2 microglobulin) (**Figure 2**). The extracellular portion of the heavy chain is folded into three globular domains, α1, α2 and α3 and associates noncovalently with the β2 microglobulin (β2m). X-ray crystallography of class I molecule has revealed that the region distal from the membrane is formed by α1 and α2 domains which take part in antigen binding. Functionally, MHC class I molecules bind to CD8 co-receptor molecules on the T-cells and therefore, present non-self-antigens to CD8+ T-cells. MHC class II molecules bind to CD4 co-receptors molecules on T-cells and hence, they present antigen to CD4+ helper T-cells.

HLA Class II Genes

The HLA-class II region of the human MHC has at least six subregions termed DR, DQ, DO, DN, DM and DP. They are expressed as heterodimers on the cell surface and are composed of an α (alpha) gene and a β (beta) chain that traverse the plasma membrane (**Figure 2**). Their tissue distribution is restricted to specific cells of the immune system involved in antigen presentation (APCs), namely B lymphocytes, macrophages, monocytes, epithelial cells, dendritic cells, Langerhan's cells and Kupffer cells. Currently, 438 DRB1, 71 DQB1 and 59 DPB1 alleles can be recognised using DNA typing methods of polymerase chain reaction and oligonucleotide probes.

Class III Genes (Central Genes)

At least 39 genes have now been located in a 1000 kb stretch of DNA within the class III region interposed between class I and class II regions. This includes the complement genes C2, C4 and Bf (factor β), the TNF-α and TNF-β genes and the Hsp 70 (heat shock protein) genes.

NOMENCLATURE OF HLA

In HLA nomenclature system colons (:) are introduced into the allele names to act as demiliters of separate fields. Thus, the allele HLA-A*02010101 is designated as HLA-A*02:01:01:01, where the first 2 digits following the star sign represent the HLA allele family, which often corresponds to broad serological HLA antigen (in this case HLA-A2). The 3rd and 4th digits correspond to the order in which the sequences were determined, 5th and 6th digits the synonymous substitutions in coding region and 7th and 8th digits the variations in introns or untranslated regions.

POLYMORPHISM AND INHERITANCE

An individual inherits two alleles of each of the above loci, one each from either parent. A complete set of alleles on the same chromosome is usually inherited (a *haplotype*) and the two HLA haplotypes in an individual derived after family testing constitute the *genotype*; the total HLA antigen profile is the *phenotype*. Siblings in a family have a 25% chance of being HLA-identical, 50% chance of being HLA-haploidentical (sharing one parental haplotype only) and 25% chance of being HLA-unidentical (**Figure 3**).

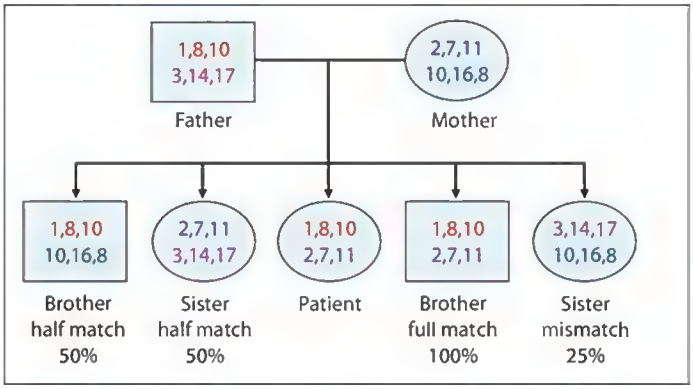

Figure 3: Segregation of HLA haplotypes in a family. The sibs inherit one haplotype from each parent and accordingly four different haplotypic combinations are possible. In this case, the patient is HLA-identical with her younger brother, HLA-unidentical with her younger sister and shares only one haplotype (haplo-identical) with her elder brother and sister.

SELECTION OF OPTIMAL DONORS

The MHC is the major barrier in selection of HLA matched donors for patients requiring solid organ or HSCT. The probability of finding a 100% matched donor is higher among the family members, because of the haplotypic inheritance pattern of the MHC. Four main donor categories are considered for HSCT: (1) HLA-identical sibling; (2) family donors other than siblings-defined by extended family testing, and who share HLA-A,B,C,DR and DQ alleles; (3) HLA-identical cord blood following antenatal testing; and (4) the unrelated HLA matched donors obtained through marrow registries.

The best HSCT results are seen in patients with a genotypically HLA-identical sibling. The probability of finding such a donor is approximtely 30% to 35%; about 30% of remaining patients are successful in finding a matched, unrelated voluntary donor through unrelated donor marrow registries. Large global, American and European registries have been established; however, Asians-Indians are poorly represented in them. An Asian-Indian Donor Marrow Registry (AIDMR) has been established at the All India Institute of Medical Sciences, New Delhi since 1994 and has close to 5000 registered voluntary Asian-Indian donors.

Matching strategies for renal transplantation consider only HLA-A, HLA-B and HLA-DR loci. In renal and other solid organ transplantation, a direct relationship exists between graft survival and the level of matching. Four types of donors are generally available for renal transplantation. Family donors include parents, siblings and offspring and their match status is determined by the parental haplotype inheritance and whether they share one, both or no HLA haplotypes (**Table 1**). In HSCT, the level of HLA matching is much more critical than solid organ transplants and is limited to *HLA-identical* sibling donors. This is because of the risk of graft versus host diseases (GVHD) where T-cells in the stem cell graft react against allogeneic host HLA molecules expressed on all tissues.

Table 1: Donor Categories for Renal Transplantation and Probability of HLA Match

Donor category	Match probability	Match designation
Family donors		
Parents	50% match or one haplotype match	Haploidentical
Siblings	25% chance of full match	HLA identical
	50% chance of one haplotype match	Haploidentical
	25% chance of no haplotype match	HLA unidentical
Offsprings	50% match or one haplotype match	Haploidentical
Cadaver donor	Generally poor	Expressed as mismatch (mm) for the number of HLA antigens shared in HLA– A, B, and DR loci: for example, full house match (0/6 mm) or grades of 1 to 6 antigen mm
Spousal donor	Generally poor	
Unrelated donor	Generally poor	

HLA = Human leucocyte antigen

Most grafts from unrelated donors are mis-matched at several HLA loci. The 10 year graft survival of 70% seen in the HLA-identical sibling grafts is significantly reduced to 50% for the HLA haploidentical parental donor grafts and < 40% for those involving poorly matched cadaver donors as is seen in the long-term renal graft survival compiled by the UCLA registry (**Figure 4**). The 'half-life' (the period at which at least half the grafts are still functioning) is 25 years for well-matched HLA-Id sibling grafts, 11.5 years for parental donors and only 7.8 years for cadaver donor grafts which are generally mis-matched. There has been no significant improvement in the half-life of grafts even following introduction of highly effective immunosuppressive agents including tacrolimus and sirolimus.

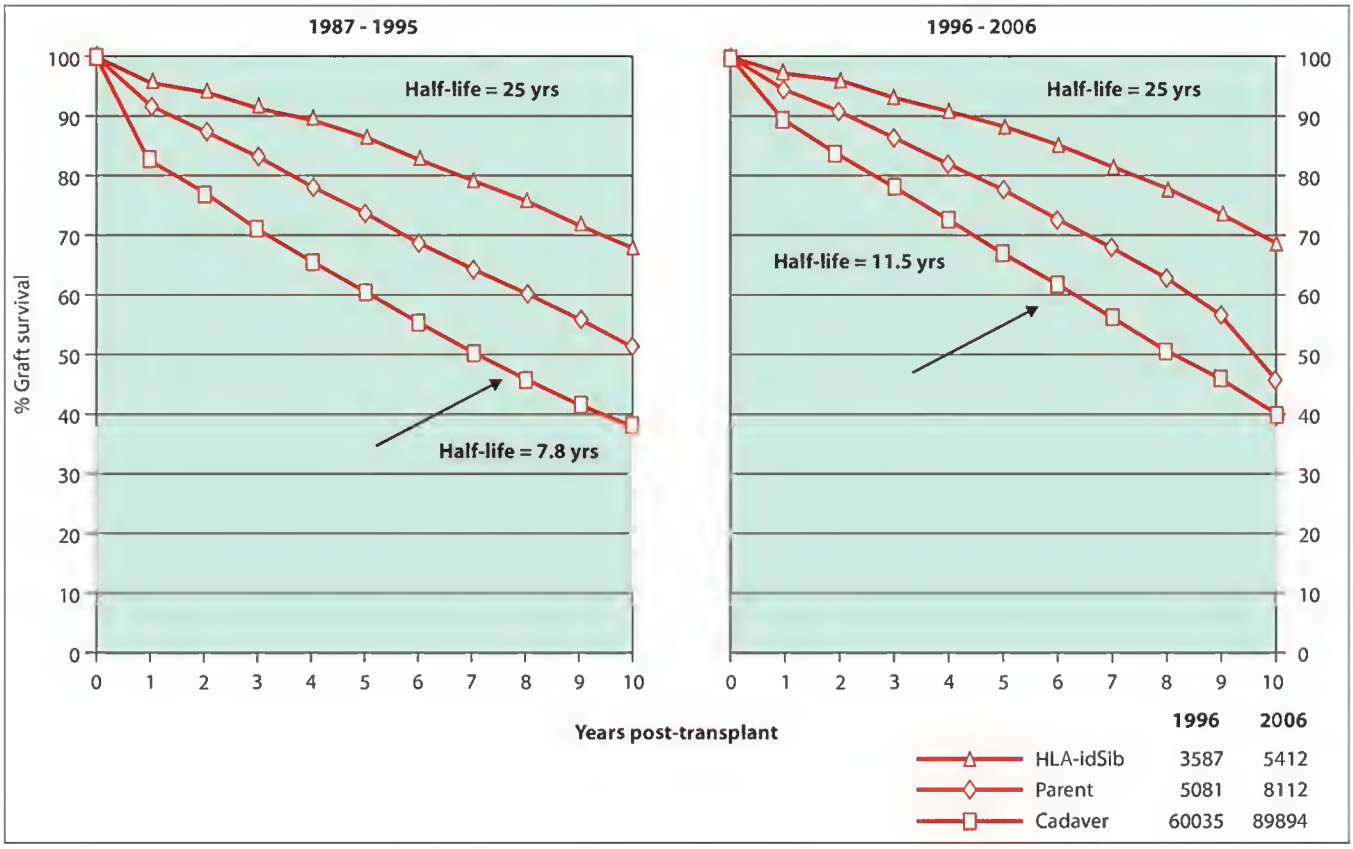
ALLORECOGNITION

Allorecognition refers to T-cell recognition of genetically encoded polymorphism between members of the same species. CD4+ recipient T-cells recognise donor alloantigens through either the *direct pathway* in which host T-lymphocytes recognise native MHC molecules expressed on graft-associated APCs or the *indirect pathway*, in which donor alloantigen-derived peptides are recognised in the context of self MHC molecules expressed on recipient APCs (**Figures 5A and B**). The direct pathway is of particular relevance during acute rejection. Donor derived APCs expressing donor alloantigens rapidly migrate from the graft and enter the secondary lymphoid tissues, where they can encounter and prime the allospecific T-cells. Cytotoxic T-lymphocytes, B-cells, macrophages and natural killer cells are recruited in a graft undergoing rejection. The main mechanisms implicated for graft destruction are cell-mediated cytotoxicity, delayed type hypersensitivity and antibody-dependent-cellular cytotoxicity.

GRAFT REJECTION

Efforts are always made to ensure that patient and donor are matched for HLA gene loci as completely as possible. However, this is difficult to achieve and immunosuppressive drugs are given to control the host immunity caused by HLA disparity. The aim is to prevent or control rejection and allow the recipient to develop long-term acceptance (or tolerance) of the graft. Rejection can be mediated by antibodies, lymphocytes or both and can manifest as hyperacute (in the early post-transplant period, within hours), acute (occur at any time) and chronic rejection (slowly developing process with progressive decline in graft function).

Hyperacute rejection is caused by preformed donor specific alloantibodies in a presensitised recipients. Humoral presensitisation may be caused by a previous transplant, blood transfusions or pregnancy. The alloantibody-mediated rejection is initiated by activation of the complement cascade leading to release of various inflammatory mediators and the initiation of the coagulation and fibrinolytic systems. Hyperacute rejection is manifested by rapid vascular constriction, oedema and thrombotic occlusion.



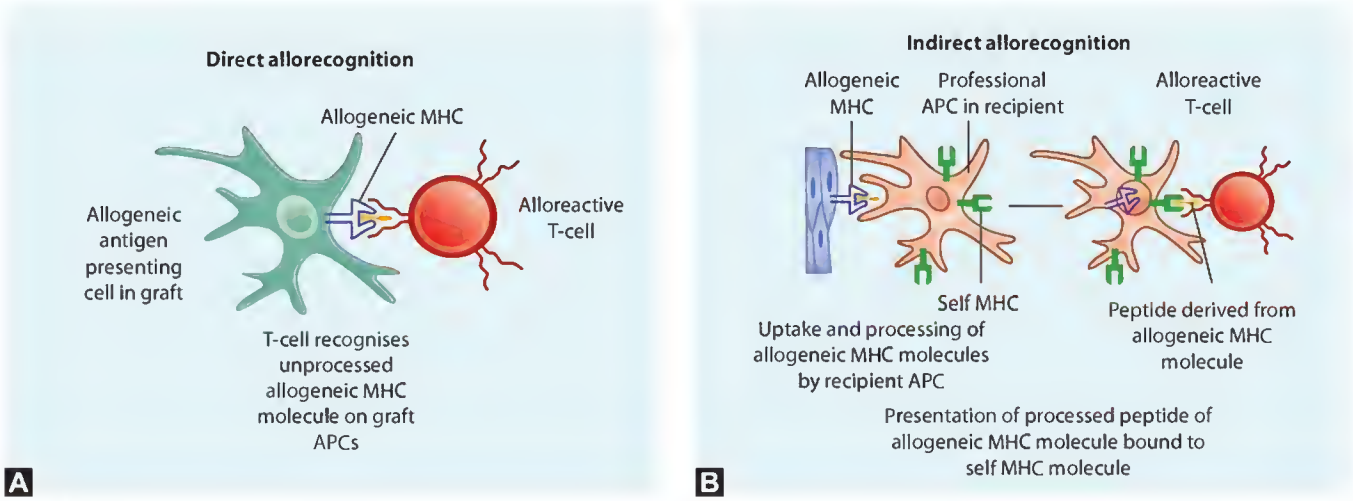


Figure 4: University of California Los Angeles (UCLA) data involving large series of kidney transplants showing the HLA matching effect followed for at least a 10-year period. The HLA-identical sibling donor transplants have 70% graft survival compared to 50% for haplo-identical parental grafts and < 40% for mismatched cadaver donor grafts. The half-life of the HLA-Id grafts is 25 years which drops significantly to 7.8 years (1987-95 block) and 9.3 years (1996-2006 block) for the cadaver donors.

Figures 5A and B: The pathways of allorecognition that cause problems in organ transplantation as a result of HLA mismatching. (A) Direct pathway. The alloreactive responses of recipient T-cells to donor APC expressing incompatible antigens. (B) Indirect pathway. Allogeneic HLA antigens are taken up and processed by the recipient APCs and presented in the context of autologous (self) HLA molecules to recipient T-cells. Antigen-presenting cell trigger CD4+ and CD8+ cells, and as a result local and systemic immune response develops. Cytokine recruitment and activation of specific T-cells, NK cells and macrophage-mediated mechanisms lead to cytotoxicity and finally the allograft destruction.

MHC = Major histocompatibility complex; HLA = Human leucocyte antigen.

The injury in acute rejection (AR) is caused by T-cells (T-cell mediated rejection) and antibodies (humoral rejection), either alone or together. It typically appears during the first 1-6 weeks after transplantation and declines sharply after the first 6 months. The allograft vascular endothelium is the primary target of the initial stage of cellular rejection and lymphocytes exert a direct cytotoxic effect on graft parenchymal cells, and mediate a delayed type hypersensitivity (DTH) response.

Chronic rejection, affects most long-term transplant survivors and is characterised by vasculopathy, fibrosis and a progressive loss of the organ function. Chronic rejection is mediated by low-

grade, persistent DTH response and activated macrophages secrete mesenchymal cell growth factors leading to fibrosis. Persistent viral infections also induce cellular immune responses. The donor-specific alloreactive T-cells and the chronic ischaemia secondary to injury of the blood vessels by antibody or cell-mediated mechanisms also contribute. Vascular occlusion may occur as a result of smooth muscle cell proliferation in the intima of the arterial walls.

PRE- AND POST-TRANSPLANT ANTIBODY SCREENING

A meticulous '*crossmatch test*' for possible occurrence of anti-donor antibodies is always performed before any transplantation. This is similar to the direct crossmatch done prior to blood transfusions; donor lymphocytes instead of red cells are tested with patient serum. Several improved cross-match assays have been developed to increase the sensitivity and specificity of the test and include the anti-human globulin test (AHG), flow cytometry, and solid phase assays like enzyme linked immunosorbent assay and luminex systems. Serum treatment with dithiothreitol is used to distinguish clinically less relevant IgM type antibodies.

HLA antibodies that develop *de novo* post-transplantation and not necessarily donor specific, are associated with poor graft survival. It is, therefore, advisable to monitor routinely the post-transplant development of such antibodies, as a predictive marker for allograft function.

CONCLUSION

Recent advances in immunological techniques promise improved management of transplant patients by predicting rejection episodes before the onset of irreversible and terminal damage. HLA matching is beneficial in both short as well as long-term survival of the renal allograft and in live related as well as deceased donors. The poor match status between donor and recipient is frequently associated with more vigorous antibody response. Molecular approaches for clinical monitoring of the post-transplant immune status and identifying the best functionally matched donor before the transplant procedures are among the key areas of futuristic research in the area of clinical transplantation. Continuing progress in understanding molecular mechanisms of graft rejection may lead to the ultimate goal of long-term acceptance of organ allograft through tolerance induction.

6.1 Introduction to Medical Genetics

Shyam Swarup Agarwal

DEFINITION

Genetics is the science of study of genes, a field devoted to understanding principles and mechanisms of heredity and variation. Gene—a segment of deoxyribonucleic acid (DNA) that codes one polypeptide chain—is the basic unit of inheritance that transmits characters from generation to generation. Collectively genes are responsible for uniqueness of each species as well as each individual. Studies in genetics deal with decoding the structure, function and transmission of genes that determine the development and differentiation of a single cell zygote into a whole human being, and also, the functioning of various organs and systems of the body from conception to death. In addition, genetics also includes the study of genesis and selection of variation which determines survival of the fittest, and thus, evolution. Classically, genetics had dealt with study of one gene at a time, both for sake of simplicity and lack of tools to study multiple genes or the genome as a whole. It needs to be appreciated that the normal structure (anatomy) and function (physiology) of genes that determines health (Genetics in Medicine) is as important as the study of their aberration that leads to genetic disease (Medical Genetics as a speciality).

GENETICS AND GENOMICS

With recent advances in molecular biology leading to successful completion of the Human Genome Project in 2003, and emergence of technologies enabling study of whole genome, transcriptome, proteome and metabolome of the cell, in one go, a new era of medicine has dawned. In the words of Victor McKusick, "... Biomedical research in the future would be progressively more integrated and integrative; that families of genes, not single genes, and physiologic systems, not single reactions will be the objects of study....". This approach when applied to the study of genes in health translates into "Integrated Systems Biology", and in patient care to "Genomic Medicine". Literally, genomics can be defined as the study of the 'genome' as a whole, the sum total of all the genes and non-coding genetic material as well. This includes study of gene-gene and gene-environment interaction.

HISTORY

Although occurrence of familial disorders (such as, haemophilia, colour blindness, polydactyly, etc.) and resemblance of children to their parents was known for a long time, it was Mendel's classic experiments in 1865 on transmission of *discrete* characters in sweet-pea plants that laid the foundation of genetics (the term 'genetics' was coined by William Bateson in 1906). It was remarkable that Mendel deduced the laws of inheritance much before the discovery of chromosomes. The contributions of Mendel remained unnoticed till the turn of the 19th century when they were independently rediscovered by de Vries, Tschermak and Correns. But very soon the application of Mendelian laws was found for alkaptonuria, albinism, cystinuria and pentosuria—the inborn errors of metabolism—identified by Sir Archibald Garrod in 1909. As a parallel activity, around the same time (1879 onwards), diploid nature of the chromosomes in eukaryotic cells and mitotic and meiotic cell divisions were delineated that provided the physical basis for Mendelian inheritance (Sutton 1902). The correct number of human chromosomes, however, was not known until 1956 (Tjio and Levan 1956).

Next major milestone in genetics was the study of variation in *Drosophila melanogaster*, the fruit fly, which led to identification of spontaneous mutations and their induction by radiation and chemicals (Muller and Morgan). Studies on fruit flies also led to the discovery of linear arrangement of genes on a chromosome, the linkage of closely located genes on the same chromosome, and mechanism of determination of sex and meiotic re-combination. The first inkling about the biochemical functioning of genes came from the studies of Beadle and Tatum (1941) on auxotrophy in the fungus neurospora. It led to the hypothesis of 'one gene-one enzyme (polypeptide chain)' as the basis of inheritance. The chemical nature of genetic material was discovered by Avery, Macleod and McCarty in 1944 who showed that the 'transforming principle' of pneumococcus was DNA [in some organisms the genetic material was later shown to be ribonucleic acid (RNA) instead of DNA]. Subsequently, in quick succession, the molecular structure of DNA was delineated by Watson and Crick in 1953, and the processes of DNA replication, transcription and translation were delineated leading to unravelling of the genetic code. The holy trinity of DNA-RNA-Protein became the gospel truth of life, until Baltimore and Temin discovered the enzyme 'reverse transcriptase' in onco-RNA viruses providing a mechanism for reverse transcription of RNA into DNA, that gets integrated into host genome.

A totally new chapter in the field of human/medical genetics has been written with the advent of genetic engineering in 1970s. The discovery of restriction endonucleases (Smith 1968) enabled cutting and pasting of different DNAs leading to engineering of 'new' DNA. The 'new' DNA can be cloned in plasmids giving rise to millions of copies of the desired DNA (unique single copy genes). Combined with the technique of DNA sequencing, genetic engineering has paved the way for the Human Genome Project (1995-2003) that led to mapping and sequencing of the entire human genome. The completion of the Human Genome Project in 2003 is likely to be as revolutionary as the discovery of Mendelian principles of inheritance at the turn of last century.

MAJOR DIVISIONS OF THE FIELD OF GENETICS

Genetics as a whole encompasses a wide field of study. It has many sub-divisions. On basis of tools used for the study, there are four classical sub-divisions of genetics, viz., (1) Mendelian or

pedigree genetics, (2) cytogenetics, (3) biochemical genetics, and (4) molecular genetics. To this list, another specialised area of statistical genetics, bioinformatics and computational genetics has been added in recent years which is going to dominate the scene of genomic medicine in the years to come. The above terms are self-explanatory and are covered in separate chapters under this section. With regards to the area of study, the discipline of genetics can be divided into the following categories: (1) human genetics, (2) medical genetics, (3) clinical genetics, and (4) community genetics. These are interrelated areas which run into one another. A brief description of each follows, giving some idea about the scope of each domain. In addition, there are other areas of application as well, such as developmental genetics, population genetics, evolutionary genetics, and forensic genetics, etc.

Human Genetics

Human genetics may be broadly defined as study of the role of genes in health and normal variation. While identity of all the genes has been unravelled with successful completion of the Human Genome Project, their detailed function—giving rise to the ultimate phenotype—still remains to be delineated to a large extent (Functional genomics and Phenomics). Even more importantly, we need to understand regulation of temporal and spatial expression of genes, gene-gene interaction and gene-environment interaction. Some examples include production of different haemoglobins during embryonal, foetal and adult life; regulated secretion of insulin and other hormones to achieve glucose homoeostasis—after and in-between meals; regulation of reproductive cycles from puberty to menopause; senescence and even life span, characteristic of each species. It needs to be realised that the basis of life has now been reduced from cell to molecule, and we have to understand the entire anatomy, physiology, pathology and pharmacology at the molecular level—the so called "Molecular Medicine".

Human genetics deals with not only understanding of normal structure and function, but also of normal variation such as height, weight, colour of the skin and eyes, intelligence, etc. Unravelling of the human genome sequence has led to identification of millions of SNPs, CNVs and STRs among normal healthy individuals, some of which may contribute to quantitative variation—giving rise to characteristic Gaussian distribution curve for these genetic traits.

Human genetics is as relevant to medicine, as anatomy, physiology and biochemistry are.

Medical Genetics

Medical genetics is an extension of human genetics. It deals with the study of the role of genes in causation of the disease. In this context, genes play a dual role. On one side chromosomes, genes and DNA constitute the 'genetic system' in anatomical sense that is the site of lesion for genetic disease, and on the other, the gene acts as an aetiological agent contributing to causation of disease. In the latter context, genetic make-up of the individual determines susceptibility/resistance to environmental pathogens, giving rise to complex, multifactorial polygenic disorders. The defects of nuclear DNA, because of their presence in gametes, follow Mendelian segregation, whereas mitochondrial DNA defects follow maternal inheritance. More than 3,000 genetic disorders are listed in the *Online Mendelian Inheritance in Man* (OMIM) database which collectively affect approximately 2% to 3% of all births (excluding congenital malformations which account for another 1.5% to 2.5% of all live births). The genetic defect acquired in somatic cells may give rise to malignant transformation (leading to cancer), or senescence, without being transmitted to the next generation.

The studies in medical genetics include understanding of the pathophysiology of genetic diseases, i.e. how the abnormal gene gives rise to disease. The most classical example is of sickle cell disease where substitution by 'T' for 'A' at codon 6 of beta globin gene leads to substitution of glutamic acid by valine resulting in formation of a slow-moving haemoglobin (Hb S). The latter, under hypoxic conditions, gives rise to sickling of red cells which are responsible for all the manifestations of sickle cell disease. This knowledge allows for definitive diagnosis of the disease, antenatal diagnosis, as well as screening of the disorder in newborns for better prevention of various complications. Efforts are also being made to correct the defect by gene therapy, and designing of pharmacophores for treatment of genetic diseases.

Besides causation of disease, the genetic make-up of an individual may also modify its response to drugs – both safety and efficacy (Pharmacogenomics), toxins (Toxicogenomics) and nutrients (Nutrigenomics). This information can be used for personalising therapy as well as for prevention of disease.

Clinical Genetics

Clinical genetics deals with application of the knowledge of genetics to patients with genetic disorders in the clinic and at the bedside. It includes diagnosis, management and prevention of genetic disorders. To begin with, the role of genetic clinic was limited to genetic counselling. With the development of the technique of amniocentesis in the 1960s to obtain foetal cells, antenatal diagnosis could become possible, providing the couple an opportunity to choose reproductive options in a child at risk of genetic disorder. Simultaneously, the development of Guthrie's technique for newborn screening of phenylketonuria and other inborn errors of metabolism on one hand, and diets for treatment of these disorders on the other, has revolutionised the treatment of genetic disorders to the extent that screening of newborns has been made mandatory by law in a number of countries in the developed world. With the advent of DNA diagnostic tests, the scope of antenatal diagnosis has expanded to cover several hundred disorders. In addition to antenatal diagnosis and newborn screening, several other interventions have been developed for management of patients with genetic disorders. This includes replacement therapy such as AHG in haemophilia, high-dose vitamin therapy in homocystinuria, bone marrow transplantation for thalassaemia and others. More recently, recombinant DNA technology has allowed large scale manufacture of enzymes for enzyme replacement therapy for lysosomal storage disorders, though the cost of treatment remains high. There is also a ray of hope that gene therapy and other forms of molecular and cellular therapies may develop for some genetic disorders in the future. All theses developments have necessitated that the speciality of clinical genetics be developed for the benefit of patients with genetic disorders and primary care physicians (PCPs) be knowledgeable to suspect, counsel and refer these patients to speciality centres.

The core competencies required by PCPs have been published by the National Coalition for Health Professional Education in Genetics.

Community Genetics

Community genetics is an extension of clinical genetics for the public at large. One of the earliest examples was the screening of Ashkenazi Jews for Tay-Sachs disease carrier state and the offer of antenatal diagnosis to the couple at risk. Application of the same principle to thalassaemia screening in the Cyprus island has virtually eliminated the birth of even a single thalassaemic child in that country. It is one of the most radical and successful implementation of primary prevention of genetic disorders. In more recent years, periconceptional folic acid supplementation has led to marked reduction in the birth of children with open neural tube defect. Likewise, identification of several high-risk markers for Down's syndrome and other chromosomal disorders has led to universal counselling and screening of all pregnancies (irrespective of maternal age) with triple/quadruple test. For many of the strategies of antenatal diagnosis, it is desirable that the couples at risk should seek genetic advice before conception. It is strongly recommended that obstetric care should commence with preconception clinics. Cost-benefit analyses have shown that many of the screening programmes deserve to be taken up as national public health programmes. One of the new areas that are emerging is that of cancer genetics. Association of BRCA1/BRCA2 gene mutations with familial breast-ovarian cancer, and APC/MSH mutations with familial colon cancer have shown the utility of predictive screening for prevention of cancer. With increasing recognition of genetic markers for various polygenic-multifactorial disorders, such as diabetes, hypertension, coronary artery disease, etc., community genetics is bound to become a major component of public health programmes.

CURRENT STATUS AND FUTURE PROSPECTS: INDIAN SCENARIO

It needs to be considered under 3 headings, viz., teaching, practice and research. As far as teaching is concerned, most medical colleges in India do not have any teaching-training programme in human and medical genetics at present, mainly because of lack of trained medical faculty in this discipline. As mentioned above, we now need to tune ourselves to the molecular basis of health and disease. As far as clinical practice is concerned, there has been some introduction of services in this area as a by-product of clinical research programmes in this field. However, its penetration is limited mainly due to absence of adequate diagnostic laboratory facilities. There is an urgent need to establish quality assured laboratories, with adequate counselling support, to provide to our people (at least to those who can afford) what is already available elsewhere. Since clinical genetics is still largely a preventable programme, it would be better to take it up in the public health, national programme mode. As far as research is concerned, we are better than the other two areas. Most of our biomedical research labs have adequate infrastructure and expertise to be competitive in this field. What is needed is innovation in our approach and competition in spirit to make use of the opportunity. This will, however, require well-defined clinical material for exploration as well as validation which also needs to be addressed.

6.2 Mendel and Beyond

Ratna Dua Puri

INTRODUCTION

The roots of understanding of genetics can be traced back to 1865 when the Augustinian monk Gregor Mendel described the principles of inheritance based on his meticulous and painstaking cross-breeding experiments with the sweet pea *(Pisum sativum)* plants which he grew in his monastery garden in Brno. After 8 years of tedious experimental work with hybrid plants, Mendel proposed the basic principles of inheritance which are enumerated in **Table 1**.

Table 1: Basic Principles of Mendelian Inheritance

- Each individual inherited trait, including its alternate form, is determined by a pair of factors, later called genes by Wilhelm Johannsen in 1909.
- Each member of the pair of factors is inherited from one parent (the members of the pair segregate during gametogenesis—so that each gamete contains only one factor).
- The gene determining the alternative form of the trait is called 'allele'. The genes may be dominant or recessive, depending on their expression in the hybrid state. In the F1 hybrid only the dominant form is expressed. The recessive gene is neither lost, nor blended. It remanifests in the F2 generation in a ratio of 3:1.
- Genes determining different traits (now identified to be located on different chromosomes) segregate independently of each other.

The observations of Mendel are summarised in two laws which form the basis of inheritance of unifactorial traits.

The Law of Segregation

For any particular trait, the pair of alleles of each parent separate during meiosis so that the gamete receives only one allele. Only one allele passes from each parent to an offspring.

Principle of Independent Assortment

This law states that different pairs of alleles determining different traits are passed to offspring independently of each other. Today, we know this is true only for those genes which are located on different chromosomes, or quite far from each other if located on the same chromosome. The genes located close to each other are inherited together (linkage).

A Mendelian trait is one which is controlled by a single gene, follows Mendel's laws of inheritance, and mutation in the gene leads to altered/diseased phenotype.

Life is not simple, and so is the relationship of phenotype to the genotype. Heterogeneity of genetic disorders, both intra-family and inter-family, is the rule rather than an exception. This led to invocation of the phenomenon of 'penetrance' and 'expression'. The next challenge was to account for anticipation and various anomalous patterns of inheritance. At first, the very validity of the Mendelian laws was challenged, but with better understanding of the molecular basis of gene function, such as genomic imprinting, instability of triplet repeats, mitochondrial gene structure, function and phenomenon of homo-heteroplasmy, uniparental disomy, epigenetic modulation of gene expression, etc. our appreciation of the Mendelian principles of inheritance has enhanced rather than diminished. The next challenge is to unravel and understand the phenomenon of polygenic inheritance. Interestingly, even the monogenic disorders are greatly influenced by multiple genes-so called modifier genes. There is a growing realisation that no gene functions in isolation. The effect of every gene may be influenced by gene-gene interaction and gene-environment interaction. The fuzziness will give way to more clarity as we know more.

As a clinician, to identify individuals at risk for a genetic disorder, and to counsel the families with a child suffering from genetic disease, it is important to ascertain the mode of inheritance. This requires recording of the family history. The following discussion of the art of pedigree drawing and then its analysis to deduce the pattern of inheritance of the disease under consideration is of great importance.

PEDIGREE DRAWING

The initial step in any genetic consultation is the collection of relevant family data. A pedigree or a family tree is a diagrammatic representation of the relationships amongst family members and record of relevant medical information about each of them by employing a combination of internationally accepted symbols and lines. The index case, or proband, is the affected person who brings the family to notice and his position in the pedigree is depicted by an arrow. From this start point the brothers/sisters, parents, offspring and maternal and paternal relatives are recorded using the symbols as shown in **Figure 1**.

By convention, a three-generation pedigree is used in clinical practice. More extended family trees may be drawn if needed.

The importance of the pedigree chart is to record concisely and pictorially complete family history with names and dates of birth, their health and disease status, etc. from which the mode of inheritance of the disorder can be deduced. For example, limb girdle muscular dystrophy can be inherited as an autosomal dominant or recessive trait and this can be differentiated by pedigree analysis. It can also be used to identify the risk of transmitting an inherited condition to the offspring, to identify family members at risk of the disorder, or carriers of the disorder.

MENDELIAN INHERITANCE/SINGLE GENE DISORDERS

This refers to a group of disorders occurring as a result of a defect/mutation in one or both alleles of a gene. Autosomal pattern of inheritance is due to a mutation of a gene on an autosome and in sex-linked inheritance/trait, the relevant gene

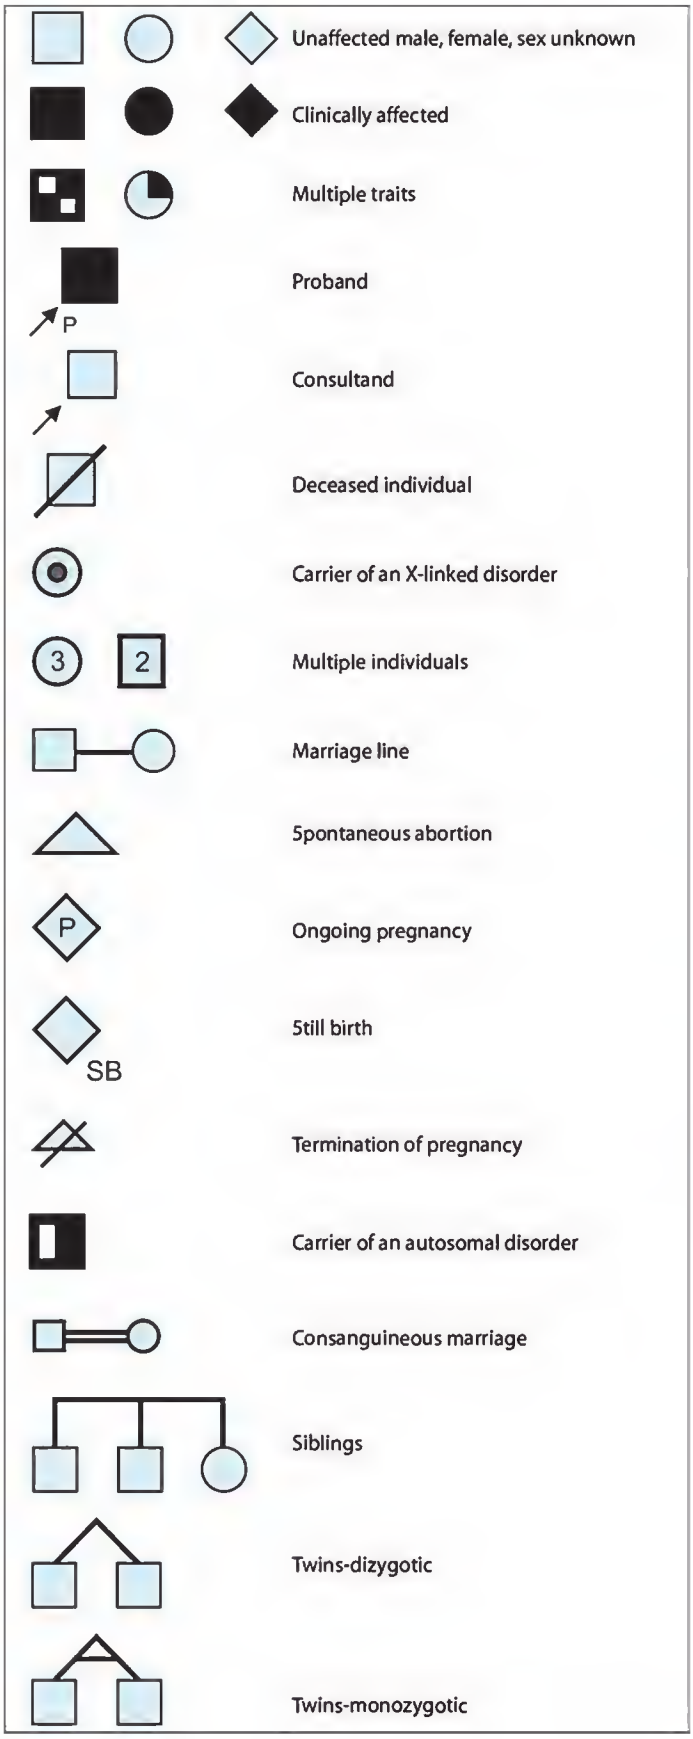

Figure 1: Pedigree symbols.

is on the X or Y chromosome. An individual with identical alleles of the gene is homozygous, and one whose alleles are not identical is heterozygous.

CONCEPT OF DOMINANCE AND RECESSIVENESS

Dominance is defined in terms of expression of the gene (disease or trait) in the heterozygous state. This occurs as a result of gain of function mutation where the abnormal gene product (even in the presence of normal product of the other gene) is sufficient to lead to altered state, e.g. Huntington chorea, Charcot-Marie-Tooth disease. Oncogenes are classical example of dominant genes. On the other hand, a recessive gene manifests as loss of function. It gives rise to disease/trait only when both the copies of the gene are knocked out, i.e. in homozygous state, e.g. thalassaemia. A dominant negative mutation results in a gene product that is non-functional, but it interferes with the function of the normal allele, so that it manifests even in the heterozygous state, e.g. osteogenesis imperfecta.

Autosomal Dominant Inheritance

The disorder occurs due to a mutation in one copy of a gene present on autosomes. Hence, these disorders manifest in the heterozygous state where the affected individual has one abnormal (mutated) and one normal allele (**Figures 2 and 3**). The characteristics of autosomal dominant inheritance are listed in **Table 2**.

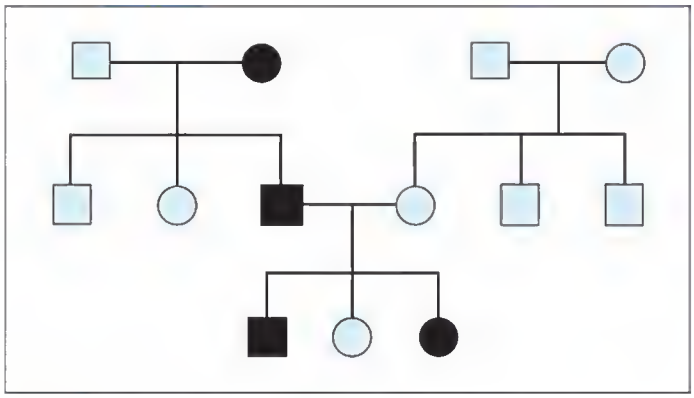

Figure 2: Autosomal dominant inheritance.

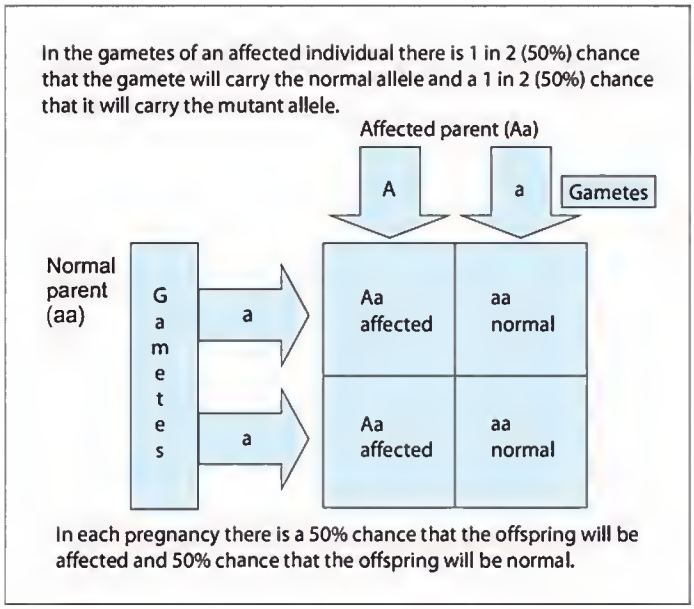

Figure 3: Punnett square showing segregation of alleles in a family with an autosomal dominant disorder.

Table 2: Characteristics of Autosomal Dominant Inheritance

- Vertical mode of transmission with expression in more than one generation
- Males and females are equally affected
- Father to son transmission present
- The risk to the offspring of an affected individual is 50% in each pregnancy
- Family members, who are unaffected, themselves do not transmit the disorder

Examples: Huntington disease, achondroplasia, autosomal dominant polycystic kidney disease, facioscapulohumeral dystrophy, neurofibromatosis I and II, tuberous sclerosis.

It is not unusual to see deviations from the typical characteristics of autosomal dominant pattern of inheritance described above. These have significance while counselling families.

Penetrance

In some disorders, the individual who carries the mutant gene does not manifest any sign or symptom of the disease, i.e. the gene is non-penetrant. This phenomenon may result in skipped generation in the pedigree chart (**Figure 4**). For disorders that show incomplete penetrance, the unaffected individual cannot be completely reassured that his or her children will not be affected unless molecular tests are done, e.g. hereditary non-polyposis colorectal cancer, acute intermittent porphyria.

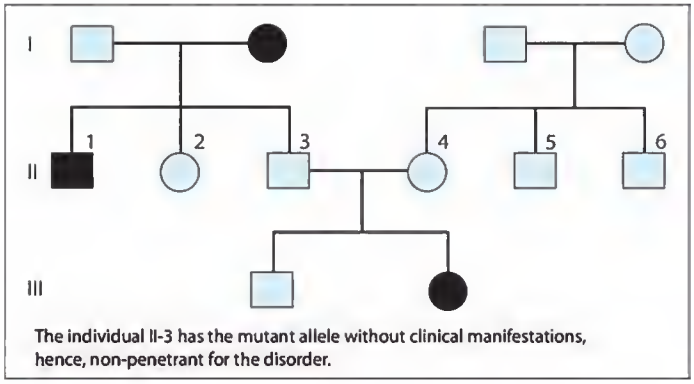

Figure 4: Autosomal dominant inheritance with non-penetrance.

Variable expression and pleiotropy

Individuals in the same family who carry an identical mutation can have varying clinical features and severity of the disorder, e.g. tuberous sclerosis—a mildly affected parent with only minor skin lesions can have a child with severe infantile spasms and mental retardation. Such intra-familial variability is difficult to explain on the basis of monogenic inheritance, as all the affected members in the family carry the same mutation. But now it is understood that no gene functions in isolation and the disease manifestations may be modified by interaction with other genes and the environment. Now, more and more information about genes which modify the phenotype of so-called monogenic disorders is becoming available. The phenomenon of gene-gene interaction is known as epistasis. Pleiotropy refers to multiple effects of a single gene/mutation in several tissues or organs of the body, e.g. neurofibromatosis type 1 can cause skin pigmentary changes, neurofibromas, short stature, mental subnormality and Lisch nodules in the eyes.

Onset

The onset of genetic disorders can be variable, e.g. Huntington chorea, spinocerebellar ataxias, etc. In these disorders, it is difficult to counsel at what age a person will develop the disease, or the quantum of risk of transmitting the disorder to the offspring if the person has not developed symptoms yet. In majority of these diseases, this dilemma may be overcome by the availability of DNA diagnostic tests.

New mutations

In some autosomal disorders, an affected person may be born to normal parents and there may be no history of similar disease in previous generations. In this clinical situation a new change in the gene (*de novo* mutation during gametogenesis) is responsible for the disease phenotype. The affected offspring would have 50% risk of transmitting the disease gene, but the risk to siblings will be nil, e.g. achondroplasia, Marfan's syndrome. It is important to exclude variable expression/non-penetrance and non-paternity as other possible reasons for an apparent new dominant mutation. In some cases there may be gonadal mosaicism—where the risk of recurrence cannot be excluded. *De novo* mutations are more likely to occur if paternal age is more than 45 years.

Homozygosity in an autosomal dominant disorder

In some autosomal dominant disorders, the severity of the disease increases in homozygotes, e.g. homozygosity for mutation causing achondroplasia may result in severe skeletal dysplasia that is lethal in the intrauterine or perinatal period. There is a 25% risk of lethal achondroplasia in the offspring if both the parents are affected with achondroplasia.

Recurrence risks

If one parent is affected by an autosomal dominant disorder and the other is normal, the risk of recurrence for their offspring in each pregnancy is 50%. Each pregnancy is an independent event and the probability remains the same with every conception, independent of the disease status of any previous children (**Figure 3**).

If both parents are affected by an autosomal dominant trait, then the risk of an affected child is 75% in each pregnancy. There is a 25% chance that they will have a child with both alleles mutated, e.g. achondroplasia.

Autosomal Recessive Inheritance

These disorders manifest when both alleles of a gene present at a locus are mutated. This disorder manifests only in the homozygous state. Most metabolic disorders due to enzyme deficiency follow the autosomal recessive mode of inheritance. This is because; being a catalyst, even half the product in a person with mutation in only one copy of the gene (carrier) is sufficient for the normal functioning of the cell (**Figures 5 and 6**). The characteristics of autosomal recessive inheritance are summarised in **Table 3**.

Recurrence risks

In each pregnancy, carrier parents have a 25% risk of having an affected child.

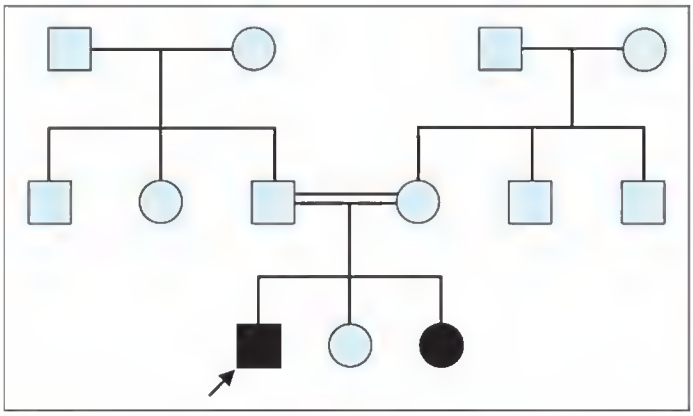

Figure 5: Autosomal recessive inheritance.

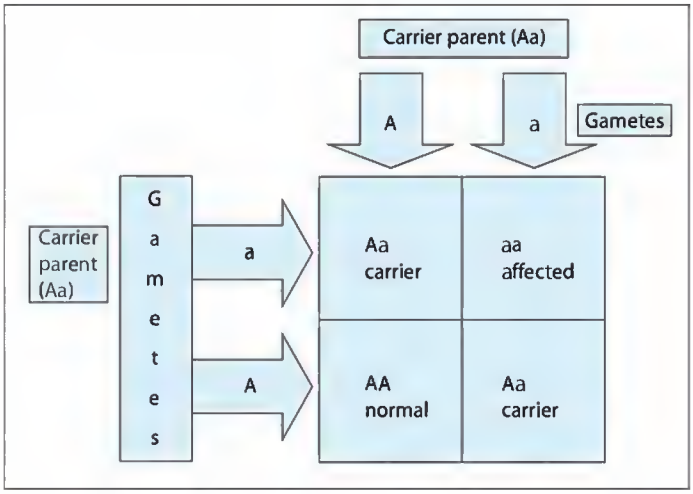

Figure 6: Punnett square of gametes and offspring for autosomal recessive inheritance.

Table 3: Characteristics of Autosomal Recessive Disorders

- Horizontal mode of transmission. All affected individuals are in one generation
- Parents of an affected individual are obligate, unaffected carriers
- The risk of recurrence to the siblings of an affected individual with carrier parents is 25% in each pregnancy
- Healthy siblings of an affected individual have a two-third risk of being a carrier
- Consanguinity among parents is more common in these disorders

Examples include beta-thalassaemia, sickle cell anaemia, Wilson's disease, cystic fibrosis, Fanconis anaemia, autosomal recessive polycystic kidney disease, oculocutaneous albinism.

X-linked Disorders

These disorders occur due to mutations in genes present on the X chromosome. X-linked disorders can be recessive with expression only in males, or dominant with expression in both the sexes. The characteristics of X-linked disorders are listed in **Table 4**.

X-linked recessive inheritance

Only males manifest the disease and it is transmitted through healthy female carriers (**Figure 7**).

Rarely, manifestations in a carrier female of an X-linked recessive disorder can occur in the following situations: Turner's syndrome with 45, X karyotype and mutation in a gene on the X chromosome, carrier female marrying an affected male giving birth to a daughter with mutation on her both X chromosomes, skewed inactivation of the X chromosome, and X-autosome translocation.

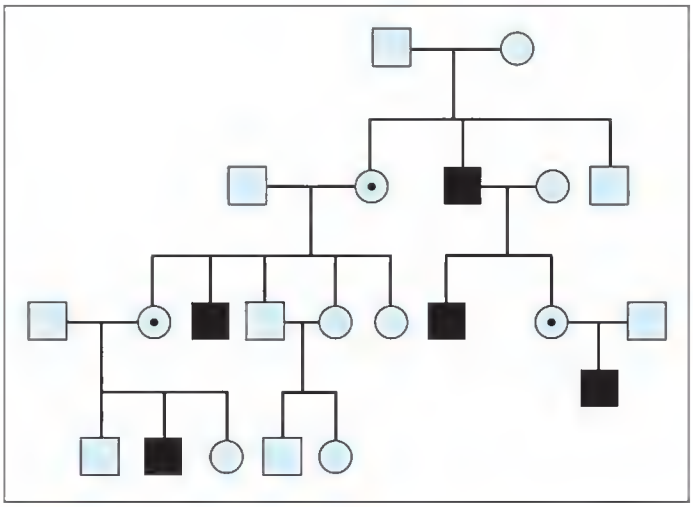

Figure 7: X-linked recessive inheritance.

Table 4: Characteristics of X-linked Disorders

- No father to son transmission
- All daughters of an affected male have the mutant gene, hence, are carriers
- Unaffected males never transmit the disease to their offspring
- Carrier women will transmit the disease to 50% of their sons
- Carrier women transmit the mutant allele to 50% of their daughters

Examples: Haemophilia A and B, Duchenne's muscular dystrophy, G6PD deficiency, X-linked ichthyosis, X-linked agammaglobulinaemia.

There are some X-linked recessive disorders where a heterozygous female can manifest a mild phenotype in the absence of above situations, e.g. Fabry's disease, X-linked hereditary nephrogenic diabetes insipidus, fragile-X mental retardation.

Recurrence risks

In each pregnancy, a woman with a mutation in one X chromosome has a 50:50 chance of having an affected son, and a 50:50 chance to have a daughter who carries the mutation. In the situation of marriage between an affected father and a non-carrier spouse, all sons are normal whereas all daughters are carriers.

In mating between a carrier female with an affected male, 50% daughters are affected, and 50% are carriers; whereas 50% sons are affected and 50% are normal.

X-linked dominant inheritance

Looks similar to an autosomal dominant pedigree with both males and females affected (**Figure 8**). Differences are summarised in **Table 5**.

Y-linked Inheritance

Only males are affected as these disorders are due to genes on the Y chromosome. An affected male will transmit the trait to all his sons but none to his daughters, e.g. hairy ears. Genes involved in spermatogenesis are present on the Y chromosome, but as they are associated with infertility, the inheritance

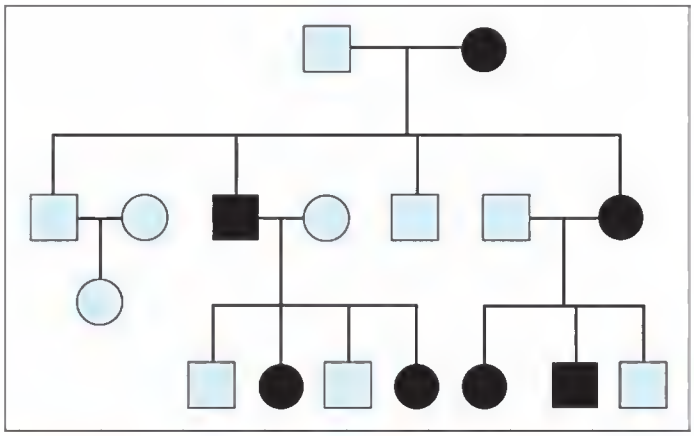

Figure 8: X-linked dominant inheritance.

Table 5: Differences of X-linked Dominant Inheritance

- Affected males transmit the disorder to all daughters but none to their sons
- Some of these disorders are lethal in males (hemizygous state), thus showing false predominance of affected females
- No direct father to son transmission
- Females (being heterozygotes) may be less severely affected

Examples of X-linked dominant disorders are Rett syndrome, X-linked hypophosphataemic rickets, incontinentia pigmentii.

pattern, may only come to light with the use of modern assisted reproductive techniques like intracytoplasmic sperm injection.

NON-MENDELIAN PATTERNS OF INHERITANCE

These are disorders due to mutations in single genes but they do not conform to the above Mendelian patterns of inheritance.

Mitochondrial Inheritance

Each cell has several copies of mitochondrial DNA which is capable of replicating independently of the nuclear genome. Mutations in the mitochondrial genome, and some nuclear genes controlling mitochondrial function, result in mitochondrial disorders (**Figure 9**). The pedigree of mitochondrial disorders is peculiar—both sexes are affected but the disease is exclusively transmitted through females. The division of mitochondria from parent to daughter cells during cell division is random, giving rise to wide variations in wild type and mutant type mitochondria in different cells, different tissues, and at different times (heteroplasmy). Due to this unique behaviour of mitochondria, these diseases display extensive phenotypic variability (**Table 6**).

Epigenetics

Epigenetics refers to modifications in the genetic material that do not change the nucleotide sequence, but result in functional changes in the DNA molecule. It is a heritable change, as far as somatic cells are concerned, and may lead to alterations in gene expression. As a result of this, the phenotype can vary even though the nucleotide sequence does not differ. The common epigenetic changes occur as a consequence of cytosine methylation of DNA and histone modifications. DNA methylation occurs in the cytosine residue of the CpG islands which are most commonly located in the promoter region of protein coding genes. This process causes alteration in gene transcription.

A special category of genes called imprinted genes are subject to epigenetic re-programming during gametogenesis or during

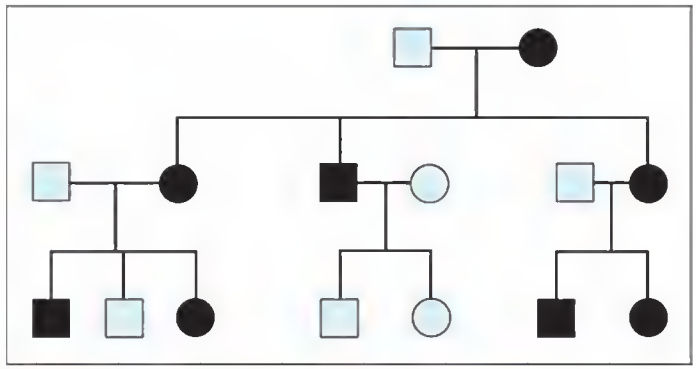

Figure 9: Mitochondrial inheritance.

Table 6: Characteristics of Mitochondrial Disorders

- Maternal transmission as mitochondria are exclusively maternal in origin
- Both males and females are affected
- Offspring of affected male will not manifest the disorder
- All offspring of the affected female have the risk of being affected
- Homoplasmy and heteroplasmy: In a cell with two populations of mitochondria, with wild type DNA and mutant mitochondrial DNA, during cell division the proportion of wild type and mutant type mitochondria may drift towards a pure type, either wild or mutant (homoplasmy), or may remain mixed (heteroplasmy)
- Threshold expression: When the mutant mitochondrial DNA crosses a threshold level, phenotypic expression results. This accounts for the variability in the clinical manifestations of mitochondrial disorders in different individuals and also the tissues affected in one individual

Examples of mitochondrially inherited disorders are Leber hereditary optic neuropathy, Leigh disease, MELAS (mitochondrial encephalopathy, lactic acidosis, stroke), MERRF (myoclonic epilepsy, ragged red fibres), Kearns-Sayre syndrome.

early embryogenesis in a predetermined fashion. Lyonisation of one of the two X chromosomes in females is an example of the same.

Genomic Imprinting and Uniparental Disomy (Table 7)

Parent-of-origin-dependent transmission of some diseases, such as Prader-Willi and Angelman syndrome was first described in the 1980s.

Table 7: Genomic Imprinting

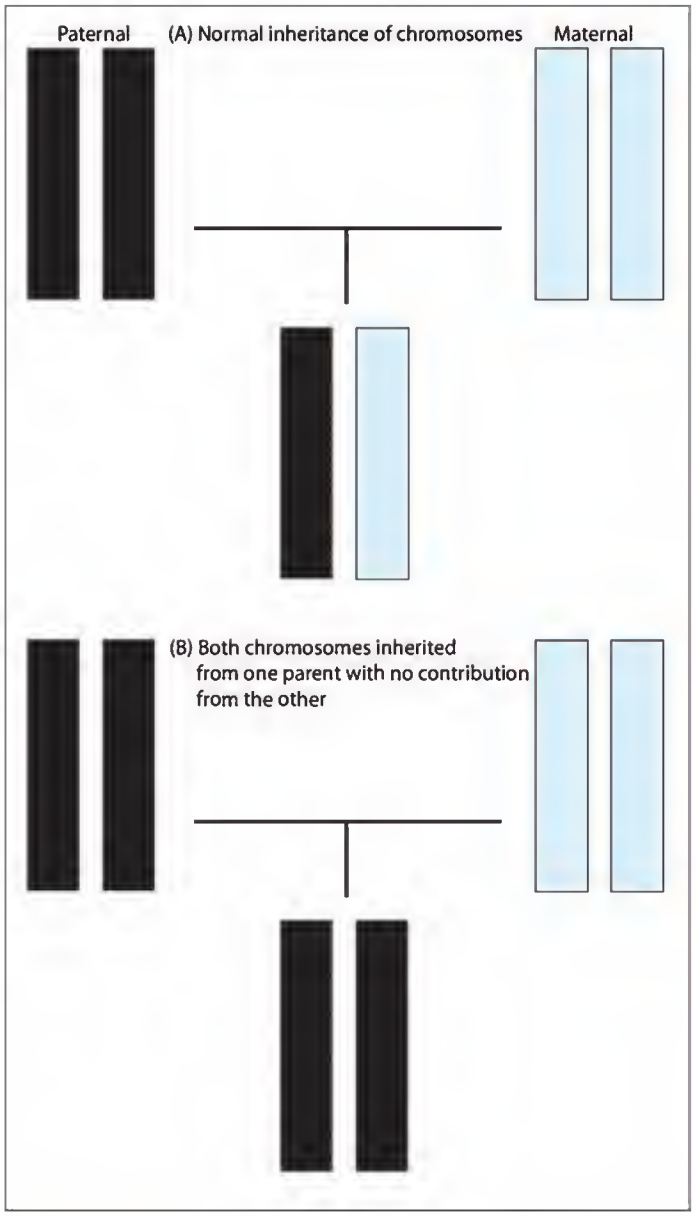
Salient features of the imprinting are:

- It occurs before fertilisation
- It confers transcriptional silencing
- It is stably transmitted through mitosis in somatic cells
- It is a reversible process during passage though the opposite parental germline so that the sex appropriate imprint can be established

For every gene on a chromosome there are two copies, one inherited from the father and the other from the mother. Usually both copies are active and used for protein synthesis. However for some genes, their expression in the cells depends on the parent of origin. This is referred to as genomic imprinting whereby the parent of origin of the gene is stamped on it and the phenotype of the disorder depends on the parent of origin of the allele. For this group of genes, a functional hemizygous state is normal, with expression of only the paternal or maternal allele. A gene is maternally imprinted if the allele derived from

the mother is inactive, and paternally imprinted if the allele from the father is inactive. Best examples of imprinting are Prader-Willi syndrome and Angelman syndrome which can also occur due to deletion of chromosome 15q11-13 region, or uniparental disomy (UPD).

Uniparental disomy is the condition where both copies of a particular chromosome are inherited from one parent and none from the other. Usually UPD has no clinical consequence unless the involved chromosome has one or more imprinted genes. The disease phenotype in UPD occurs as a result of loss of the normally functioning gene where both chromosomes are inherited from the parent where the gene is imprinted, and hence, non-functional. In Prader-Willi syndrome (hypotonia, mental retardation, obesity, hyperphagia, and characteristic facies), the paternal allele is the active gene and the maternal counterpart is normally inactive. Any condition resulting in the absence of the active paternal allele results in the disease. This could occur as a result of microdeletion of the gene on the paternally inherited chromosome, or both chromosomes being inherited from the mother (maternal uniparental disomy). The reverse situation occurs in Angelman syndrome characterised by hypertonia, inappropriate laughter, mental retardation and seizures. The active allele in this case is present on the maternal chromosome, hence maternal 15q 11 deletion, or paternal uniparental disomy results in the disorder (**Figures 10A and B**).



Other disorders due to genomic imprinting are Beckwith-Wiedemann syndrome, Russell-Silver syndrome, neonatal diabetes mellitus, etc. Majority of these disorders are sporadic with negligible risk of recurrence.

Dynamic Inheritance/Trinucleotide Repeat Sequence Mutation–Anticipation

Some genetic disorders express a more severe phenotype, and an earlier age of onset in successive generations. This phenomenon is called anticipation. It is observed in many autosomal dominant neurological disorders like myotonic dystrophy, spinocerebellar ataxias, and Huntington disease, etc. Spinobulbar muscular dystrophy and fragile-X mental retardation are X-linked triplet repeat disorders.

Genes of the above disorders carry trinucleotide repeats (e.g. CGG, CAG) in them. When the number of repeats increases beyond a critical size threshold, the repeat sequence becomes unstable with a tendency for repeat numbers to increase in each successive generation. This phenomenon is known as dynamic mutations. Premutation(s) are intermediate sized alleles, between alleles with normal range of trinucleotides and larger ones (mutation) which is associated with the disease phenotype. The premutation is the harbinger of full mutation during meiosis.

For some disorders the sex of the transmitting parent influences the degree of expansion of the repeat, and thus, the occurrence of the disease in the offspring, e.g. fragile-X mental retardation is usually transmitted through a female with mutation developing during oogenesis, whereas Huntington disease is more often severe if transmitted through an affected father.

Figures 10A and B: Uniparental disomy and genomic imprinting.

In myotonic dystrophy, an autosomal dominant disorder, the mildest form manifests as cataract in late life, but as the repeat number increases in successive generations, neuromuscular manifestations like myotonia and dystrophic features occur at an early age. At the most severe end of the spectrum, the disease manifests at birth and presents with respiratory distress, hypotonia and mental retardation. This usually occurs when the mutation is transmitted from an affected mother.

Somatic/Gonadal Mosaicism

The presence of two genetically different cell lines, derived from a single zygote in an individual is called mosaicism. This can be present in somatic, gonadal, or both cells. Somatic mosaicism usually results in a milder and partial phenotype. Gonadal mosaicism does not lead to any phenotypic abnormalities in the individual, but may be responsible for a clinically unaffected individual to have two or more affected offspring, e.g. facioscapulohumeral dystrophy, Duchenne's muscular dystrophy, osteogenesis imperfecta type II.

Digenic Inheritance

In digenic inheritance mutations in two different genes together give rise to the affected phenotype. Disease does not occur when the individual carries mutation only in one gene, e.g. Bardet-Biedl syndrome, retinitis pigmentosa, sensorineural hearing loss, Hirschsprung disease.

Polygenic-Multifactorial Inheritance

This includes conditions where multiple genes, and also the environment, play a role in expression of the disease phenotype. In these disorders the pedigree chart usually shows familial aggregation but the disease phenotype does not segregate in Mendelian proportions. The risk of recurrence in these disorders is derived empirically from population studies, and is influenced by the number of affected individuals in the family. Also, closer the relation of the individual at risk to the proband, higher is the risk of recurrence. It has to be kept in mind that familial aggregation may also occur simply due to sharing of the same environment.

Examples of polygenic inheritance: congenital malformations like neural tube defects, pyloric stenosis, etc., and complex multifactorial disorders like hypertension and coronary artery disease, etc.

CONCLUSION

Pedigree analysis is a very useful tool for elucidation and interpretation of family history. It should be incorporated as a standard practice in clinical medicine and should be learned by all clinicians. Besides its role in genetic counselling, it can greatly help in making the diagnosis, e.g. haemophilia in a child with bleeding, and also as a tool for risk assessment in familial disorders, like diabetes, hypertension, autoimmune disorders, etc.

6.3 Clinical and Molecular Cytogenetics

Ashutosh Halder

INTRODUCTION

Cytogenetics is a branch of genetics that is devoted to the study of structure and function of cellular constituents concerned with heredity. A chromosome, as seen at metaphase, consists of two identical strands of chromatids. The chromatids are joined at the centromere, which appears as a constriction. The centromere divides the chromosome into a short arm (p), and a long arm (q). Individual chromosomes differ in size. Depending on the position of the centromere, chromosomes are categorised as metacentric (at the centre), submetacentric (slightly away from the centre), acrocentric (near the end) and telocentric (at the end). Human chromosomes are classified into different groups, viz., Group A (chromosome 1-3), Group B (chromosome 4-5), Group C (chromosome 6-12, X), Group D (chromosome 13-15), Group E (chromosome 16-18), Group F (chromosome 19-20) and Group G (chromosome 21-22,Y). Chromosomes of Groups D and G are acrocentric and their p arms do not contain important genes. Chromosomes 1-22 are in pairs (autosomes). Chromosome X and Y are sex chromosomes. A karyotype is a full set of chromosomes from an individual (**Figures 1A and B**). Homologous chromosomes (members of each pair) in meiosis (cell division during gametogenesis) exchange (recombine) DNA segment at crossing-over. It is responsible for genetic variation.

Chromosomal study is carried-out from living nucleated cells through *in vitro* culture methods using cell culture medium containing growth-stimulating agents. A mitotic inhibitor (colchicine) is added to stop cell division at mitosis. The cells are then treated with a hypotonic solution to swell the cells and then fixed in Carnoy's fixative (3:1 methanol to acetic acid). The cell suspension is then dropped onto slides, air-dried and banded using trypsin and Giemsa stain. Other chromosome-banding techniques practiced are quinacrine banding, reverse banding, C-banding, nucleolar organising region staining, etc. High-resolution banding involves analysing chromosomes during prophase or early metaphase (prometaphase), wherein the number of bands increases from about 300 to 800. Analysis of banded chromosomes is done under a microscope by a trained cytogeneticist. Generally, 20 metaphases are analysed from each individual (enough to rule-out mosaicism at clinical significance). The results are reported as per the guidelines of an International System for Cytogenetic Nomenclature (ISCN).

NUMERICAL ABNORMALITY

Normal chromosome complement of 46 (46, XX in female and 46, XY in male) is known as diploid, while one set of 23 chromosomes seen in gametes (23, X in female or 23,Y and 23, X in male) is known as haploid. Error in segregation of chromosomes during cell division leads to gain or loss of chromosome, which is called aneuploidy. It includes missing of a member of the pair (monosomy) or presence of more than two chromosomes in a pair (trisomy for 3 numbers, tetrasomy for 4 numbers, etc). Errors in mitosis result in mosaicism, i.e. two types of cells originated from single cell. Sometimes an individual may have an additional set of haploid (triploidy; 69) or diploid (tetraploidy; 92) chromosomes.

STRUCTURAL ABNORMALITIES

In structural abnormality, the appearance (morphology) of the chromosome is altered. Structural anomalies are classified into the following types:

Deletion

A portion of the chromosome is missing, resulting in loss of genetic material.

Figure 1A: Metaphase cell.

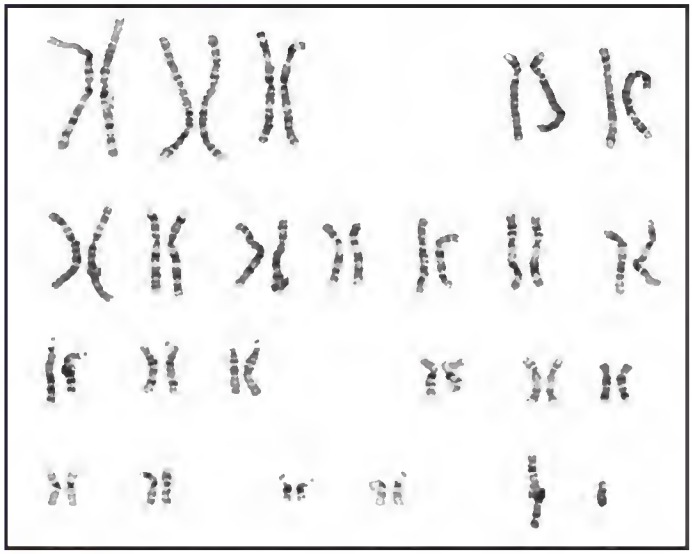

Figure 1B: Karyotyped chromosomes.

Duplication

A portion of the chromosome is duplicated, resulting in extra genetic material.

Translocation

A portion of one chromosome is transferred to another chromosome. There are two main types of translocations, i.e. reciprocal and Robertsonian. In reciprocal translocation, segments from two (or more) different chromosomes are exchanged. In Robertsonian translocation, the long arm of one acrocentric chromosome is translocated to the long arm of another acrocentric chromosome with loss of short arms of both the chromosomes, resulting in one chromosome, derived from two chromosomes. Translocations can be balanced (no gain or loss of genetic material) or unbalanced.

Inversion

A portion of the chromosome breaks, flips around and rejoins, resulting in change of orientation (physical position) of the genetic material.

Ring

Chromosomal ends break (near the tip) and rejoin each other to form a ring. This can happen with or without the loss of genetic material.

Isochromosome

Isochromosome is an abnormal chromosome with two identical arms, i.e. either two short (p), or two long (q) arms. It is formed by faulty chromatid separation during segregation.

Polymorphism

Chromosome polymorphism is a normal variation in appearance (heterochromatin, satellite, etc.) which occurs frequently (5%). It does not give rise to any phenotypic or reproductive problems.

OTHER ABNORMALITIES

Chromosomal Breakage/Instability/Fragility

It is characterised by spontaneous/induced chromosomal instability, breakage, constriction or fragility.

Uniparental Origin

Normally, each member of the pair of chromosomes is derived from each parent. Sometimes, both members of the pair (part or whole) of chromosome may be derived from one parent. Occasionally the entire set of chromosomes may derive from one parent as in molar pregnancy.

CLINICAL EFFECTS OF CHROMOSOMAL ABNORMALITY

The phenotype due to chromosomal abnormality depends on gain or loss, fusion, rearrangement, or altered parental inheritance of genes located on the chromosome. Most aneuploidies of autosomes, unbalanced structural abnormalities of autosomes, triploidies, tetraploidies and other polyploidies are spontaneously aborted. Remaining aneuploidies and unbalanced structural abnormalities of autosomes produce mental retardation and varying degree of dysmorphism. Sex chromosome aneuploidies often produce hypogonadism.

Trisomy 21 Down's Syndrome (DS)

Trisomy 21 is the commonest autosomal aneuploidy in live births (1 in 800 to 1000). It is caused by presence of all or part (21q21-22) of extra chromosome 21 leading to over expression of chromosome 21 genes (amyloid beta A4 precursor protein, microRNAs, etc). It is characterised by mental sub-normality, developmental disability, facial dysmorphism (round face, epicanthic fold, up-slanting palpebral fissures and macroglossia; **Figure 2**), cardiac malformations, and often duodenal atresia, thyroid dysfunction and early onset of Alzheimer's disease. Fertility is reduced; males are usually unable to father children. Majority of cases of DS are due to trisomy 21 where the risk of recurrence in the siblings is negligible. About 4% cases are due to translocation. The risk of recurrence in translocation cases varies depending on the chromosomes involved and sex of the carrier parent (more if mother is the carrier and may be up to 100% with chromosome 21:21 translocation). Birth of a child with DS is preventable through maternal serum screening, prenatal diagnosis and selective termination of pregnancy. Parental age at conception, in particular maternal age above 35 years, increases the risk of DS.

Figure 2: Facial profile in Down's syndrome.

Trisomy 18 (Edward Syndrome)

It is the second most common autosomal trisomy in live births (1 in 3,000). It is more in female births. The incidence increases with maternal age. The affected newborns have a low rate of survival. The syndrome is characterised by multiple congenital malformations of heart, kidneys, central nervous system (CNS), gastrointestinal tract (GIT), etc. besides low-set malformed ears, hypertelorism, cleft lip/palate, clenched hands, underdeveloped thumbs, Rocker bottom feet and joint contractures.

Trisomy 13 (Patau Syndrome)

It affects approximately one in 10,000 live births. It is associated with severe growth retardation and major congenital anomalies. The typical features are holoprosencephaly, microcephaly, microphthalmia, spinal defect, omphalocoele, cleft palate, polydactyly, overlapping of fingers and rocker-bottom feet. Trisomy 13 cases usually do not survive beyond a few months of life.

47, XXY Male (Klinefelter Syndrome)

It is seen in one out of every 1,000 males. The patient is usually tall, and presents with small testicles, reduced fertility and gynaecomastia. About 50% cases of Klinefelter syndrome have mosaicism, where 47, XXY cell line is present along with 46, XX; 46, XY; 48, XXYY or 48, XXXY cell lines.

Other Trisomy of Sex Chromosomes (47, XYY male and 47, XXX Female)

About 1 in 1,000 boys are born with a 47, XYY karyotype. 47, XYY boys may have increased growth velocity, learning difficulty and acne at puberty. Testosterone levels are normal with normal sexual development and fertility. 47, XXX female (triple X syndrome) occurs one in 1,000 girls. It does not cause any unusual features due to lyonisation of the extra X chromosome (leaving only one X chromosome active). However, females with this condition may have menstrual irregularities, including early onset of menarche and early menopause.

Monosomy X (Turner Syndrome; 45, X)

Turner syndrome occurs once in 2,500 female births. Approximately 98% of Turner syndrome conceptuses end up with miscarriage (**Figure 3**). Turner syndrome cases present with short stature, broad chest, low hairline, low-set ears, webbed neck, increased carrying angle of the elbow and gonadal dysfunction. Major systemic problems are also frequently present, including congenital heart defect (bicuspid aortic valve, coarctation of the aorta), kidney defect (horse shoe kidney), hypothyroidism, diabetes mellitus, vision problems, hearing defect, etc.

Figure 3: Turner syndrome abortus with cystic hygroma.

Translocations and Disease

Translocation is caused by rearrangement between parts of nonhomologous (usually) chromosomes. In the process, a fusion gene may be created by joining of two separated genes. This is a common event in cancer, infertility and congenital malformation. Reciprocal translocations are usually harmless. However, if a gene is disrupted or disregulated at the breakpoint, it is likely to cause symptoms like autism, intellectual disability, congenital anomalies, etc. Besides, it can give rise to gametes with unbalanced chromosomes leading to miscarriages or malformations. Robertsonian translocations also increase risk of unbalanced gametes.

Triploidy/Polyploidy Syndrome

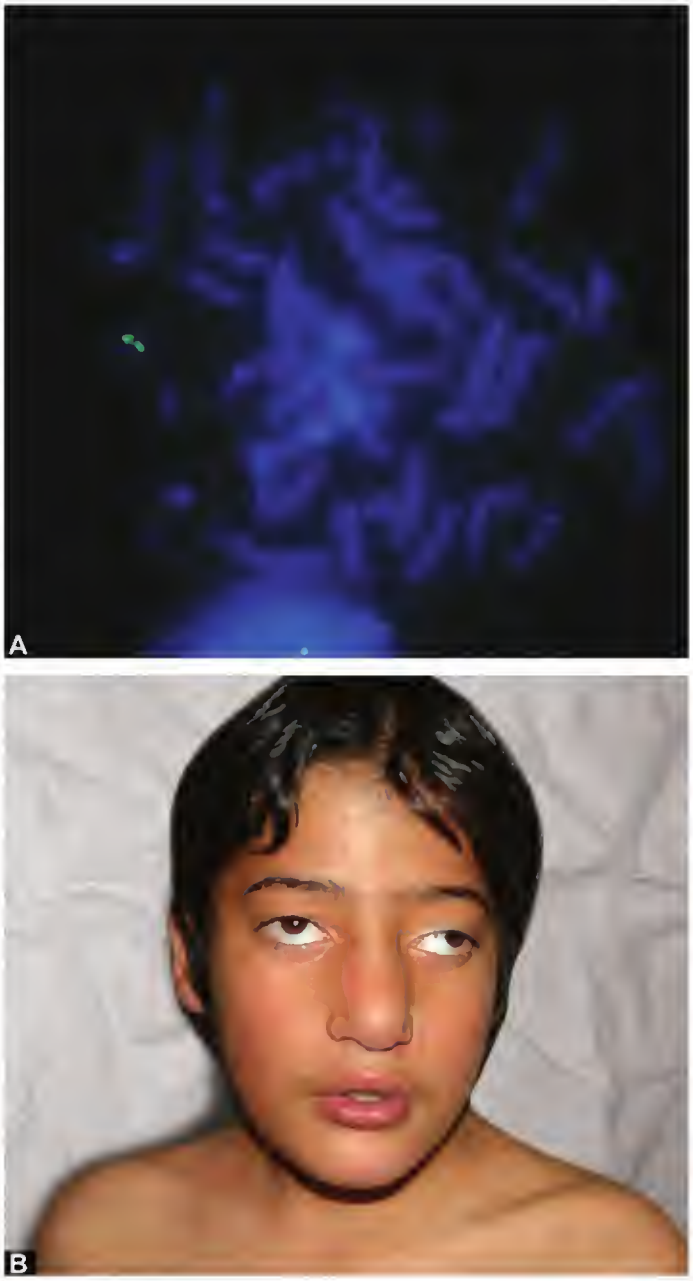
Triploidy accounts for 2% of all conceptions, but only one in 50,000 are live births. Triploid newborns die immediately after birth. They present with growth retardation, relative macrocephaly, cleft lip, low-set ears, agenesis of corpus callosum, heart defects, dysgenetic kidney and omphalocoele. The polyploidies generally lead to miscarriage, still birth or partial hydatidiform mole and are often associated with cancer.

Chromosomal Breakage/Instability/Fragile Syndrome

Chromosomal breakages may occur either spontaneously, or be induced by DNA damaging agents like radiation, ultraviolet light or alkylating agents. The examples include Fanconi anaemia, Bloom syndrome, ataxia telangiectasia, xeroderma pigmentosum, etc. These diseases are caused by the defects in DNA repair genes, and have a high-risk of developing malignancies.

Sometimes chromosomal fragility/stricture occurs at defined sites known as fragile sites. One of the common abnormalities is Fragile-X syndrome. These patients have characteristic facial appearance, mental retardation, and may have large testes.

MICRODELETION/MICRODUPLICATION SYNDROMES



Microdeletion/microduplication syndromes are characterised by small (< 5Mb) chromosomal deletions/duplications in which one or more genes are involved. They are frequently associated with multiple congenital anomalies or neuropsychiatric disease. The phenotype is the result of haploinsufficiency/over-expression of genes in the critical interval. The examples of microdeletion syndromes are Velocardiofacial syndrome (22q11.2), Prader-Willi syndrome/Angelman syndrome (15q11-13), Williams syndrome (7q11.23), Smith-Magenis syndrome (17p11.2), Cri-du-chat syndrome (5p15.2), Miller-Dicker syndrome (17p13.3), WAGR syndrome (11p13), Hereditary neuropathy with pressure palsy (17p12), Wolff Hirschhorn syndrome (4p 16.3), Tricho-rhino-pharyngeal syndrome (8q 24.1) and ATR 16 (16 p 13.3). The examples of microduplication syndromes are Charcot-Marie-tooth neuropathy 1A (17p 12), Alzheimer disease (21q 21.3), Spinocerebellar ataxia type 20 (11q 12), Pelizaeus-Merzbacher disease (Xq 21-22), Parkinson disease (4q 21), etc.

Velocardiofacial/DiGeorge Syndrome

It is the commonest microdeletion syndrome. It is seen with a frequency of 1 in 4,000 births. Almost all cases have 22q11.2 microdeletion (involving *COMT*, *TBX1*, *UFD1L*, *HIRA*, etc. genes; **Figure 4A**). Most deletions are the result of a *de novo* event, though 5% to 10% cases are inherited. The major clinical features are facial dysmorphism (long broad nose with bulbous tip, hypertelorism, low-set ears, etc. **Figure 4B**), palatal abnormalities (velopharyngeal incompetence, submucous cleft palate, etc.), hypocalcaemia, T-cell immunodeficiency, cono-truncal heart defects (tetralogy of fallot, truncus arteriosus, etc.) and learning disabilities.

William Syndrome

Its prevalence is estimated to be one in 7,500-10,000 births. Individuals with this syndrome have periorbital fullness, long philtrum and prominent lips (**Figure 5A**). Cardiovascular anomalies like supravalvular aortic stenosis and pulmonic

Figures 4A and B: Velcardiofacial syndrome: hemizygous deletion of 22q11.2 (A) and facial profile (B).

valvular stenosis are common. Other symptoms include dental malocclusion, hypercalcaemia, hyperacusis and a hoarse voice. Over 90% cases of William syndrome are due to microdeletion of 1.6 Mb size in 7q11.23 locus involving elastin gene.

Prader-Willi and Angelman Syndromes

These are seen with prevalence between 1 in 10,000 to 25,000 births. Prader-Willi syndrome is recognised by almond-shaped eyes and inverted V-shaped upper lip (**Figure 5B**). Neonates present with hypotonia, weak cry, poor sucking and hypothermia. Children present with voracious appetite, obesity, decreased pain, disturbed thermoregulation, psychomotor retardation, and impulsivity. Adolescence cases present with absence of pubertal growth spurt, hypogonadism, small hands and feet, diabetes mellitus and hypercholesterolaemia. Many symptoms of Prader-Willi syndrome are related to hypothalamic dysfunction. The clinical features of Angelman syndrome are microcephaly, large mouth, mandibular prognathism, hypopigmentation and mental retardation (**Figure 5C**). Patients later show truncal ataxia and hypertonia of limbs. Episodes of prolonged laughter, hyperactivity, sleep disorder and seizure are also common. Both Prader-Willi and Angelman disorders result from loss of 15q11-13 (SNRPN, MKRN3, MAGEL2, necdin, UBE3A, etc. genes) – the difference being that Prader-Willi syndrome is of paternal origin while Agelman syndrome AS is of maternal origin in 70% to 75% cases.

Figures 5A to C: Facial profile of William syndrome (A); Prader-Willi syndrome (B); and Angelman syndrome (C).

Charcot-Marie-Tooth Disease Type 1A (CMT 1A)

This is one of the most common inherited neurological disorder that affects one in 3,000 individuals. It is associated with

duplication (in 90%) of 17p11.2 *(PMP22;* **Figure 6***)*. Clinical presentation comprises of toe walking, pes cavus, claw hand, slapping gait, foot drop, absent or decreased deep tendon reflexes, nerve hypertrophy and loss of touch sensation predominantly in feet and legs.

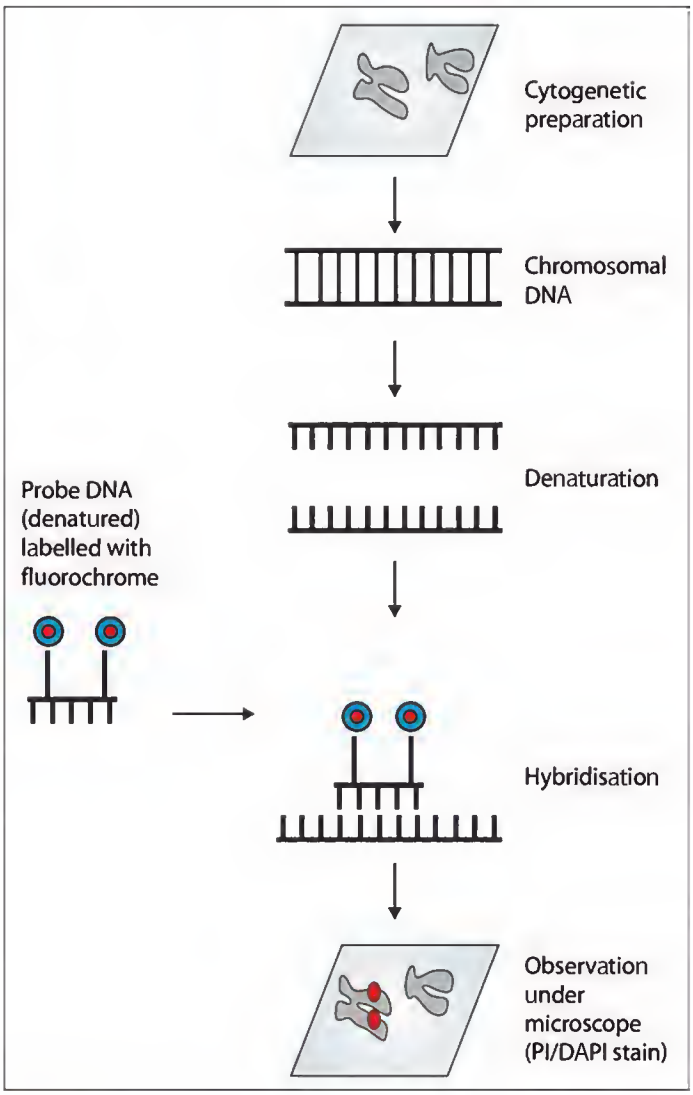
GENOMIC DISORDERS

Genomic disorders are a group of diseases that result from genomic rearrangements, such as insertions, deletions, duplications, inversions, etc. Human genome is a highly dynamic structure. Approximately 5% (~800 genes) of the human genome is structurally variable in the normal population. Genome architecture makes the genome susceptible to rearrangements through recombination mechanisms. Non-allelic recombination between low-copy repeats (LCRs) results in loss or gain of genomic segments. LCR DNA spans 10-400 kb, shares ~97% sequence homology and provides the substrate for recombination, thus predisposing the region to rearrangements. The mechanisms by which rearrangements contribute to various phenotypes (such as diversity, traits, susceptibility, behaviour or disease like microdeletion/duplication syndromes, schizophrenia, autism, etc.) are diverse and include gene dosage alterations, gene disruption, gene fusion, position effects, mutations, etc. Rearrangements introduce variation into our genome and serve as evolutionary function.

FLUORESCENCE *IN SITU* HYBRIDISATION (FISH)

FISH is a molecular cytogenetic technique used to detect and localise presence or absence of specific DNA sequence on chromosomal/nuclear DNA. It uses fluorescent probes (labelled nucleic acid sequence) that bind to DNA that have sequence homology. There are two types of FISH techniques—direct and indirect. In the direct method (**Figure 7**), fluorescent molecules (FITC, Cy3, etc.) are directly attached (enzymatically or non-enzymatically) to the probe so that probe-target hybrid can be visualised under fluorescent microscope immediately after hybridisation. In the indirect method, reporter molecules (biotin or digoxigenin) are attached to the probe and the probe is detected by either affinity cytochemistry with fluorescent dyes (indirect FISH) or chromogenic dyes (chromogenic *in situ* hybridisation or CISH). The probe can be cloned DNA sequence, or generated by polymerase chain reaction (PCR) from flow-sorted chromosomes, micro-dissected chromosomes or even whole genome. Probes may be from alphoid sequence of centromeres (150-250 bp repeats), telomeric/subtelomeric sequence (5-6 bp repeats), or unique sequence (100-500 Kb), etc. FISH is highly sensitive and can detect cell-cell heterogeneity and mosaicism. Further, FISH has been modified to spectral karyotyping, Rx FISH, or Multiplex FISH to identify all 24 chromosomes in one experiment; fibre FISH to characterise break points or Padlock probe FISH to improve resolution to single nucleotide level.



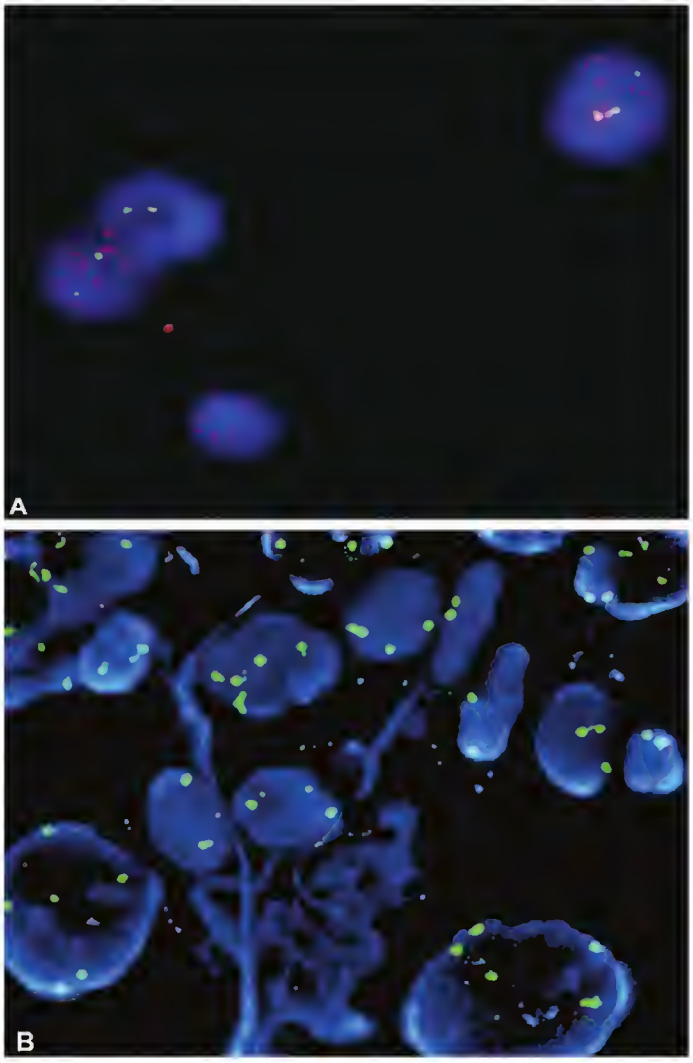


Figure 7: Various steps of FISH procedure.

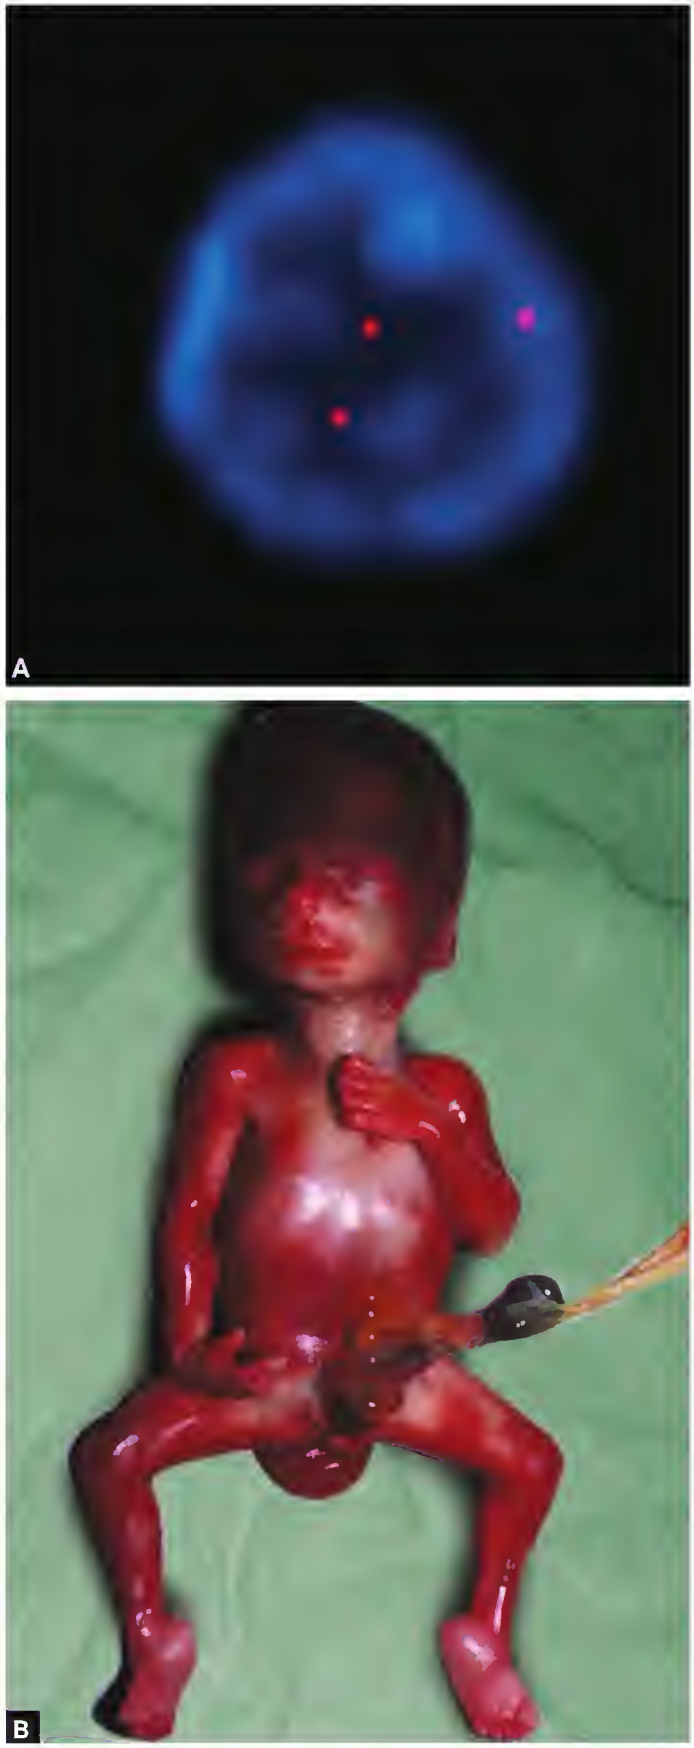
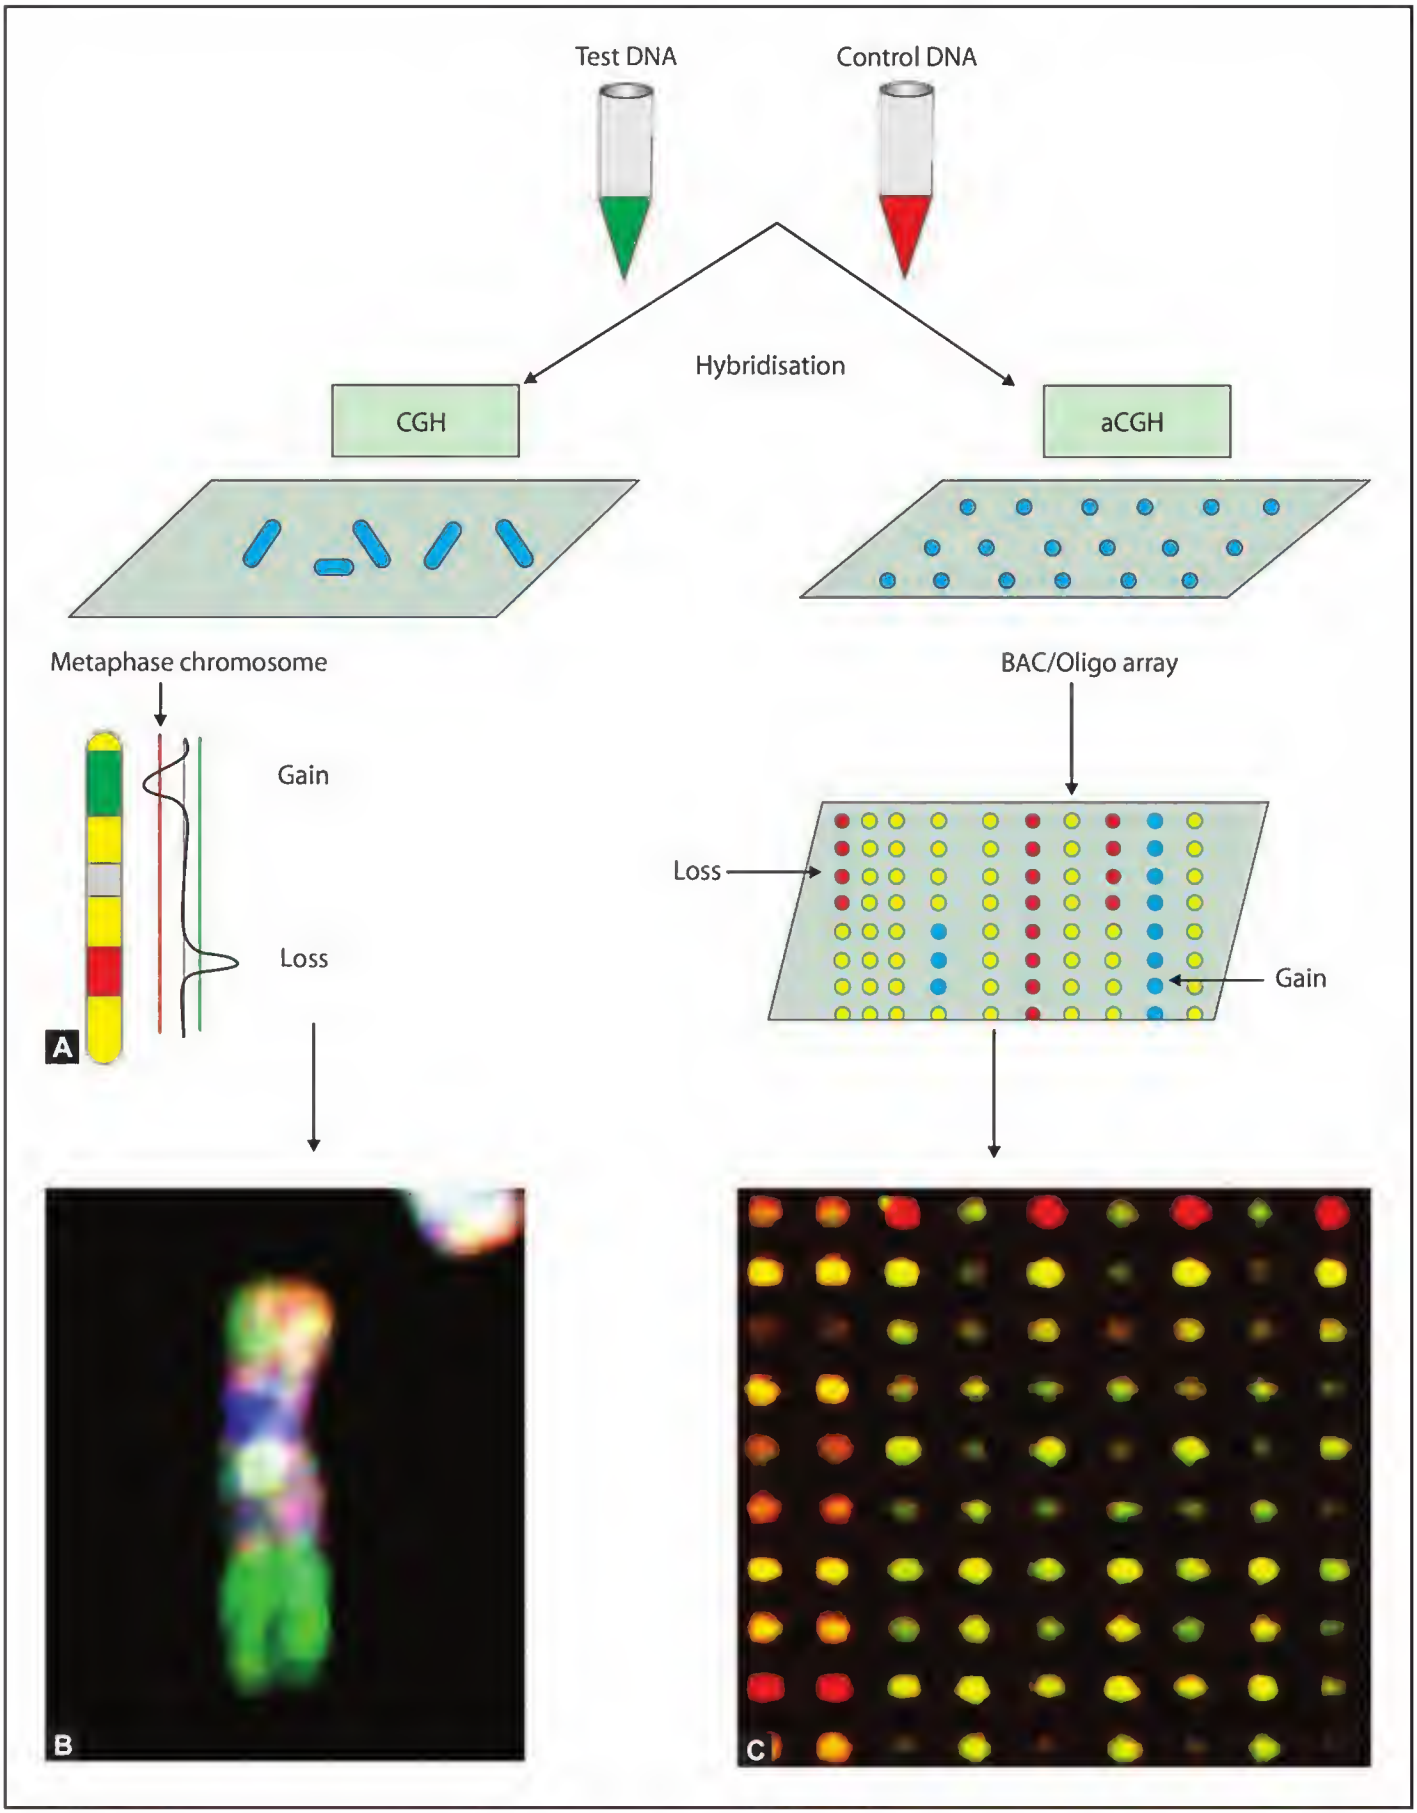
The major application of FISH is in the field of cancer (**Figures 8A and B**) followed by prenatal diagnosis (PND), preimplantation diagnosis (PGD), microdeletion-microduplication syndrome diagnosis, specific postnatal diagnosis and meiotic segregation error study. Detection of cancer-specific chromosome abnormality such as Philadelphia chromosome (bcr-abl fusion gene) assists in diagnosis/sub-classification of disease and selecting appropriate treatment besides monitoring of minimal residual disease, early relapse and engraftment of sex-mismatched allogenic bone marrow transplant. Rapid prenatal diagnosis can be made using FISH (**Figures 9A and B**) that



Figures 8A and B: Interphase FISH on tumour cells showing gene amplifications C MYC and cells-to-cells heterogeneity (A); copy numbers 1 to 6 with chromosome 1 FISH (B).

reduce parental anxiety and guide obstetric management quickly. In PGD, typically one or two blastomeres are biopsied from embryo and subjected to FISH for aneuploidy screening or specific translocation identification. FISH is capable of doing rapid sexing in a situation like ambiguous genitalia at birth where immediate assignment of sex is required for not only social reason but also for appropriate management. It has similar value in an acutely sick baby with congenital malformation syndrome suggestive of aneuploidy or microdeletion syndrome requiring urgent intensive care. FISH is the main modality of chromosome analysis for meiotic chromosome segregation and microdeletion syndrome besides the study of chromosome function and behaviour in interphase cells.

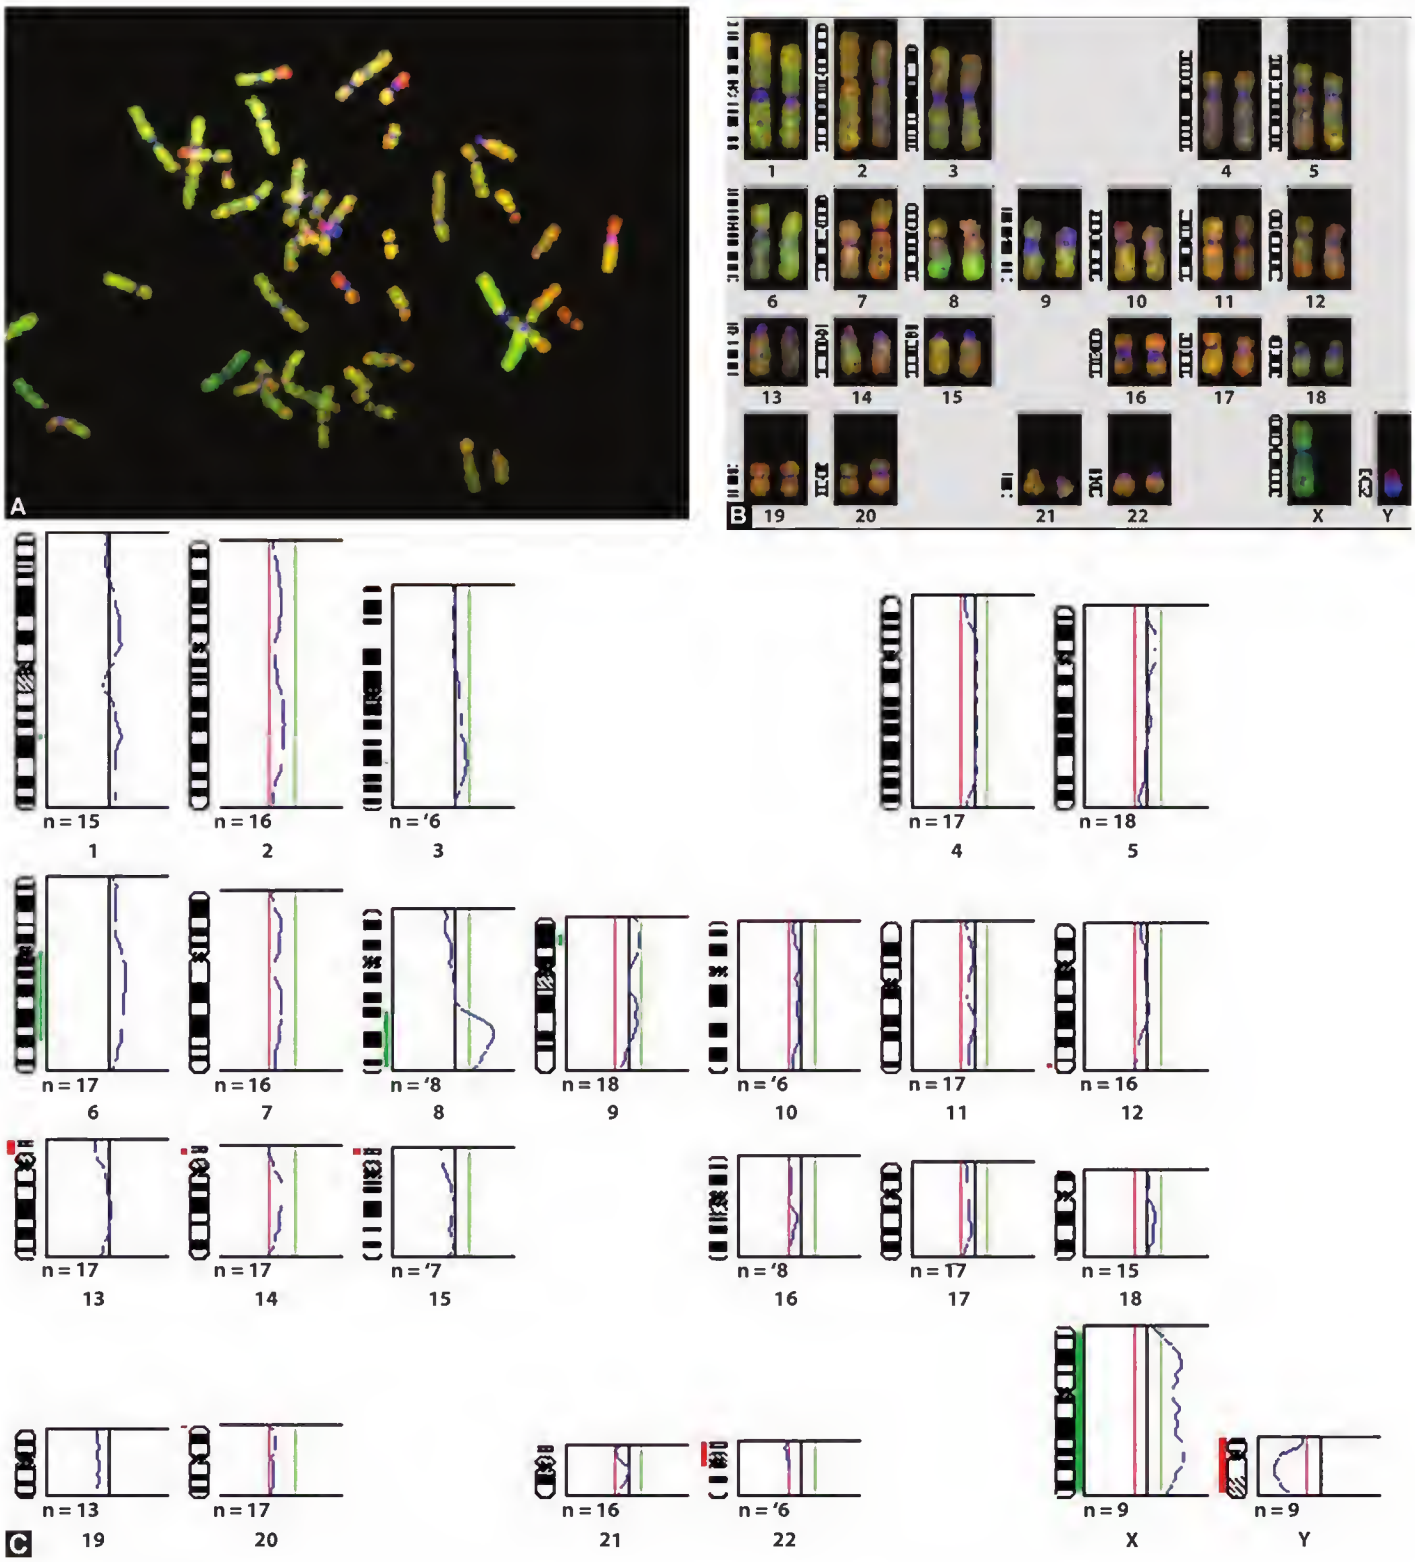


COMPARATIVE GENOMIC HYBRIDISATION (CGH)

CGH is a FISH technique that allows comprehensive analysis of chromosomal imbalance (relative copy number) in entire genome (molecular karyotyping at cytogenetic resolution; ~5 Mb) by single test without metaphase preparation and cell culture of the test samples. The strategy of CGH is based on co-hybridisation of differentially labelled whole genomic test and control DNA in equal ratio on normal metaphase spread, like dual FISH (**Figures 10A to C**). The slide is visualised using epifluorescence microscope. Image processing along with

Figures 9A and B: Interphase FISH on amniotic fluid cells showing 3 copies of chromosome 18 (A); leading to termination of pregnancy with trisomy 18 foetus (B).

quantification of fluorescence intensities of each karyotyped chromosome is done by computer software. Hybridisation results into general staining of all chromosomes. If the test DNA



Figures 10A to C: Showing principles of CGH and high resolution molecular karyotyping (aCGH) procedure (A); CGH binned view of chromosome 8 showing C MYC amplification (B); and magnified view (C) of array showing DNA amplifications (green spots), deletion (red spots) and no change in copy numbers (yellow spots).

contains additional copies of DNA material, hybridisation will reveal higher signal intensity of test DNA (if labelled with green, then more green) at the corresponding target region of the hybridised chromosome. Similarly, deletion/monosomy will give rise to lower signal intensities (**Figures 11A to C**). The CGH cannot detect mosaicism of less than 40%, balanced translocation and tetraploidy. CGH is labour intensive, difficult (karyotyping of DAPI banded chromosome) and time consuming. This technique is getting replaced by high resolution molecular karyotyping.

HIGH RESOLUTION MOLECULAR KARYOTYPING (ARRAY CGH)

High resolution molecular karyotyping is an extension of CGH. It is carried-out on the principle of CGH (**Figures 10A to C**), though with some modifications (co-hybridisation is carried out on DNA spots/arrays rather than metaphase chromosomes). Following hybridisation of differentially labelled test and reference genomic DNA to the target sequences on the microarray, the slide is scanned to measure

Figures 11A to C: Showing CGH metaphase (A) green as amplification, red as deletion, yellow as no change in copy numbers and blue as heterochromatin karyotype (B); and profile/analysis (C) from tumour samples (green amplification and red deletion).

fluorescence intensities at each target on the array. The fluorescent ratio for the test and reference DNA is then plotted against the position of the sequence along with the chromosomes. Gains or losses across the genome are shown by values higher or lower than normal 1:1 ratio (as in CGH). The resolution depends on the size, number of targets and position of targets on the genome. It also depends on the platform used (BAC based arrays have lower resolution than SNP based arrays). The molecular karyotyping result is presented using the ISCN, along with a written description and interpretation of the result. Molecular karyotyping (aCGH) procedure is rapid (24-36 hours). It provides whole genome view at a very high resolution (up to 100 Kb), and does not depend on live cell, or cell culture. It detects majority of microscopic as well as sub-microscopic chromosomal changes from any DNA source in a single experiment without prior knowledge of abnormalities. The only limitation is its inability to detect polyploidy or balanced chromosome abnormalities. It has the potential of diagnostic application in the evaluation of multiple malformations, mental retardation, prenatal diagnosis and cancer. Now disease-specific (microdeletion syndrome), chromosome-specific, or other (sub-telomeric) arrays are available for specific applications.

6.4 Genetic Tests

Ashwin Dalal

Advances in the field of genetics have made it possible to detect genetic abnormalities in increasing number of genetic disorders. This has brought the field of medical genetics to the forefront of clinical practice.

DEFINITION

Genetic testing is defined as 'the analysis of human DNA, RNA, chromosomes, proteins, and metabolites to detect heritable disease-related genotypes, mutations, phenotypes, or karyotypes for clinical purposes'. It includes a broad range of techniques that can be used for diverse applications, including diagnosis of genetic disease in foetuses, newborns, children, and adults; identification of future health risks to the individual; and prediction of drug responses, etc.

HISTORY

Genetic testing before 1959 was limited to biochemical tests like G6PD test, sickle cell test, etc. since necessary tools for direct genetic analysis were not available. Lejeune for the first time discovered the chromosomal cause of Down's Syndrome in 1959 which led to application of genetic testing in humans. Since then the field of cytogenetics has blossomed to cover a wide range of disorders, particularly genetic syndromes, mental retardation, congenital malformations and cancer *(see chapter on cytogenetics)*. Direct detection of genetic mutations in humans had to wait till the 1970s when discovery of restriction endo-nucleases, cloning of human genes and blotting techniques made it possible to amplify and probe human DNA. The completion of Human Genome Project in 2003 has heralded a new era of 'molecular genetics'. The number of genetic tests for human diseases has increased to several thousand in the last 20 years.

CLASSIFICATION OF GENETIC TESTS

Genetic tests can be classified into the following categories based on the purpose for which these are conducted:

1. Diagnosis including prenatal diagnosis (PND) of human genetic diseases
2. Predictive testing for genetic markers associated with polygenic disorders, and presymptomatic diagnosis; and
3. Forensic testing for establishment of identity, paternity testing, and zygosity testing, etc.

Diagnosis and Prenatal Diagnosis of Human Genetic Disease

Genetic tests are commonly employed for the diagnosis and prenatal diagnosis of human single gene disorders. Many of the single gene disorders can be diagnosed based on typical clinical features (tuberous sclerosis, neurofibromatosis), or investigations like muscle biopsy and immunohistochemistry (Duchenne muscular dystrophy), haemoglobin electrophoresis (beta thalassaemia), factor VIII level determination (haemophilia A), etc. In these cases, however, knowledge of genetic mutations is a prerequisite for prenatal diagnosis. Presence of DNA from at least one affected member in the family can be of great assistance in identifying the mutation in the family for counselling and PND. In contrast, there is another group of diseases where genetic testing is the only way to conclusively diagnose the disease condition as there is no other diagnostic test available, e.g. Huntington disease, spinocerebellar ataxias, Friedreich's ataxia, etc. This also includes use of genetic tests for carrier testing and preimplantation genetic diagnosis (PGD). Genetic tests can also be used for diagnosis and classification of tumours, prognostic prediction and diagnosis of cancer predisposing conditions, e.g. familial adenomatous polyposis *(see chapter on Cancer Genetics)*.

Predictive Testing

Predictive testing is done where the person is not having any signs or symptoms of the disease but is likely to develop the condition in future. This information can be used to prevent or delay onset of the disease, if appropriate medical or lifestyle interventions are available. Predictive testing includes pre-symptomatic and predisposition testing.

In pre-symptomatic genetic testing, a healthy person is tested for diseases with delayed onset. A positive result indicates that the patient will develop the condition but does not indicate when this will occur. Evaluating a healthy person with a family history of Huntington disease is an example of pre-symptomatic genetic testing. Although there is no cure for this disease, a positive result can be used for life planning, including reproductive planning, etc. However, it is essential to provide adequate and appropriate pre-test and post-test counselling to the patient in these cases.

Predisposition genetic testing informs individuals of increased or decreased risk of developing a particular disease, however, the degree of certainty is unknown. This most often applies to cancer predisposition testing (e.g. BRCA1, BRCA2 in breast-ovarian cancer families, etc.) in which a positive result indicates need for increased surveillance, while a negative result implies risk similar to the general population. Eventually, this area is likely to include risk estimates for a wide range of common disorders like hypertension, diabetes mellitus, coronary artery disease, etc. and response to drugs and other treatments (pharmacogenetics).

TECHNIQUES IN GENETIC TESTING

Genetic testing by molecular genetic methods involves various techniques designed to amplify and probe the DNA so that meaningful information can be obtained. All molecular DNA tests need DNA to be extracted from a patient's sample containing some nucleated cells. DNA is commonly extracted from peripheral blood leukocytes or tissue samples in cases of cancer. The DNA once extracted can be stored for long

periods in a stable condition and subjected to various tests as required.

Southern Blotting

Southern blotting is a method of detection of mutations in which genomic DNA is isolated from peripheral blood leucocytes or solid tissue samples and digested with a restriction endonuclease. Restriction endonucleases are nucleolytic enzymes which cut the DNA at a specific sequence. This is followed by size separation by electrophoresis. The size-fractionated DNA is transferred to a solid membrane support by means of capillary action and target sequences are detected by hybridisation with sequence-specific probes labelled with radioisotopes. Although, Southern blotting remains a useful technique for detecting large deletions or genomic rearrangements, it is seldom used in clinical laboratories due to its labour intensive and cumbersome nature. Southern blotting is rapidly being replaced by assays based on fluorescent dyes which eliminate the risk of radiation. However, Southern blotting still remains the gold standard in testing for certain diseases like triplet repeat disorders, e.g. fragile-X syndrome.

Polymerase Chain Reaction and Its Applications

Polymerase chain reaction (PCR) was discovered by Kary Mullis in 1983. This technique allows selective amplification of specific target nucleic acid sequences from total DNA using a pair of 15-25 nucleotide long forward and reverse primers specific for the target region to be amplified. The main components of a PCR reaction include a heat stable DNA polymerase, four nucleotide triphosphates (dATP, dGTP, dCTP and dTTP) and a suitable buffer containing magnesium ions. The basic steps of a PCR cycle are shown in **Figure 1**. They include the following:

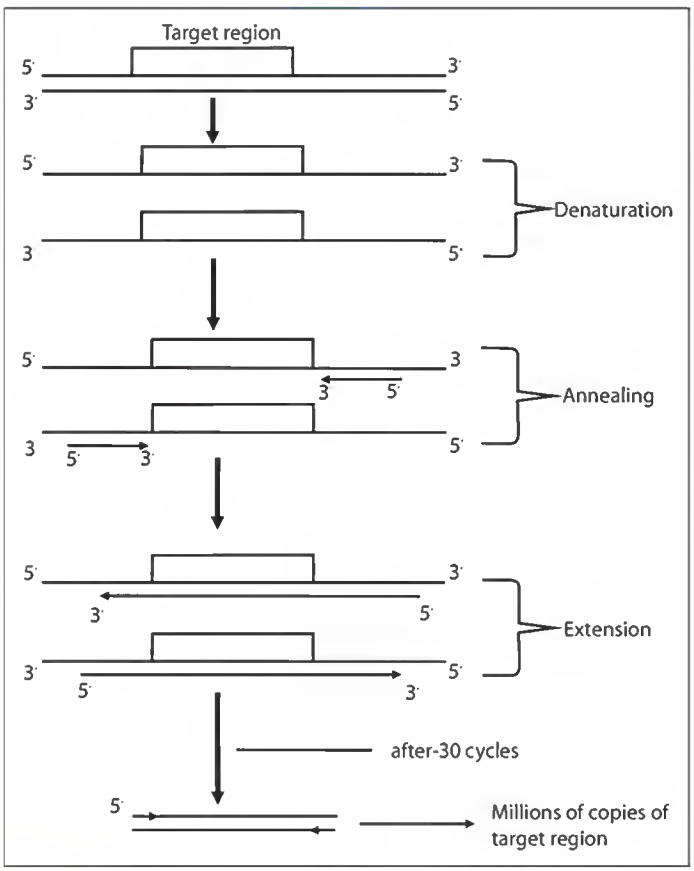

Figure 1: Principle of polymerase chain reaction.

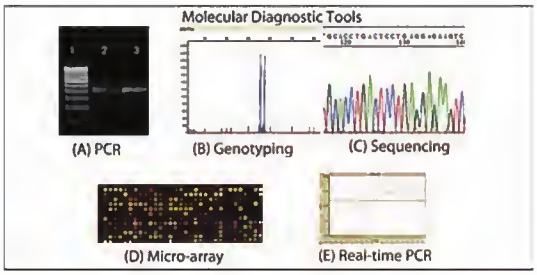
1. *Denaturation:* The template DNA which is double-stranded is separated to single strands at a temperature of around 92-96°C;
2. *Annealing:* Primers bind to the specific target regions of the single-stranded DNA at a temperature of around 50-65°C (exact temperature is specific for each primer pair); and
3. *Extension:* The primers are extended at a temperature of around 68-78°C in the presence of DNA polymerase, dNTPs and Mg^{2+} ions. The concentration of Mg^{2+} ions is critical for each PCR reaction. It is determined empirically.

The newly synthesised DNA strand acts as a template for the next cycle, which is repeated around 25 to 30 times, leading to formation of millions of copies of the specific target DNA. In order to retain the activity of DNA polymerase enzyme at such high denaturation temperature, *Taq* DNA polymerase, extracted from a micro-organism called *Thermus aquaticus* is used in the PCR reaction. This particular enzyme has an optimum working temperature around 80°C.



Applications of PCR

PCR is the starting point in most of the molecular genetic tests. Some important clinical applications of PCR are as follows (**Figures 2A to E**):

1. *Mutation detection for genetic disorders:* Genetic mutations can be detected by PCR alone (e.g. Huntington disease), PCR followed by digestion with restriction endonucleases (for detection of restriction fragment length polymorphism) (e.g. diagnosis of spinal muscular atrophy), PCR followed by dot-blot hybridisation (e.g. thalassaemia mutation detection), PCR followed by capillary electrophoresis for genotyping (e.g. detection of triplet repeat disorders), etc.
2. *Sequencing:* PCR is used as first step for DNA amplification for all methods of DNA sequencing.
3. *Detection of pathogens:* PCR is used to detect small quantities of pathogen DNA in human samples, e.g. PCR for *Mycobacterium tuberculosis*. PCR can also be used to detect viruses, including use of reverse transcriptase enzyme for RNA viruses, and real-time PCR (RT-PCR) for quantification of viral load in diseases like hepatitis B and C, human immunodeficiency virus (HIV), etc.
4. *Forensic genetics:* PCR is used in forensic laboratories to identify DNA sequences that are unique to each individual.

Real-time PCR and its applications

The RT-PCR is a type of PCR which allows quantification of the PCR product in 'real-time'. It is used to quantify the amount/number of copies of input DNA/RNA. The method utilises 5'-exonuclease activity of *Taq* polymerase, and a dual-labelled internal non-extendable probe with reporter dye at one end and quencher dye at the other end. The probe emits fluorescence signal on cleavage, based on the principle of fluorescence resonance energy transfer (FRET). To start with, the primer binds to the DNA and is extended by *Taq* polymerase. As the extended end of the primer approaches the probe already bound to specific region of the template DNA, the 5'-exonuclease activity of the polymerase enzyme cleaves the reporter dye present at 5' end of the probe resulting in increase of reporter fluorescence emission (e.g. FAM at 518 nm) in

Figures 2A to E: Molecular diagnostic tools used in the molecular genetics laboratory. every cycle. The RT-PCR is used for a broad range of applications including quantitative gene expression analysis, single nucleotide polymorphism (SNP) genotyping, point mutation detection, copy number analysis, quantification of viral load, and drug target validation, etc.

DNA Sequencing

DNA sequencing is a PCR-based technique in which sequence of the DNA can be determined at single nucleotide level. Various methods employed in the past used radioactivity for detection of sequences. More recent methods are based on fluorescent dyes. Some of these methods include:

1. *Chain termination method:* It was developed by Sanger in the 1970s. In this method, PCR is carried out in presence of small amounts of dideoxynucleotides (ddNTPs), in addition to usual constituents of the reaction mixture. Each ddNTP is labelled with a different fluorescent probe. Incorporation of ddNTP, which lacks the 32-hydroxyl group on the ribose sugar, required for continuation of the polymerisation process, blocks further elongation of the DNA chain. For example incorporation of ddATP in place of dATP at sites where thymine is present in the template DNA will lead to formation of DNA fragments of different sizes ending with ddATP. Correspondingly, DNA fragments of different sizes ending with ddTTP, ddCTP and ddGTP are produced. All the different sized fragments are then resolved by capillary electrophoresis and resulting electropherogram is analysed by software, such as Chromas 2.0, etc. which calls the sequence of individual bases in the DNA.
2. *Micro-array:* In this method small oligonucleotides with varying combination of nucleotides are used and the sequence is detected based on hybridisation of the template DNA with the immobilised oligonucleotides.
3. *Next generation sequencing:* The present methods of sequencing using capillary electrophoresis can be used for sequencing of limited number of base pairs at a time. These are being replaced by high throughput sequencing methods called next generation sequencing methods which can sequence the entire human genome of 3 billion base pairs for less than $5,000. It is hoped that the newer technologies will bring down the cost to less than $1,000 in the near future.

Forensic Genetic Testing

Forensic testing uses DNA sequences to identify an individual for legal purposes. This type of testing can identify crime or catastrophe victims, rule-out or implicate a crime suspect, or establish biological relationships between people (for example, paternity).

Association Studies in Complex Disorders

Complex disorders or multifactorial disorders are conditions resulting from interplay of genetic susceptibility and environmental influences. Very little is known about the genetics of these disorders. Traditional genetic methods like linkage analysis cannot be used for deciphering the genetic factors in these disorders. Hence, we have to resort to association studies, similar to the ones conducted for deciphering the environmental factors involved in these diseases, e.g. smoking and lung cancer. Genetic association studies look at the association of SNPs with occurrence of a particular disease, using a set of cases and controls from specific ethnic populations. When such a study is conducted by looking at thousands of SNPs throughout the genome, these studies are termed as Genome Wide Association Studies (GWAS). These types of studies need high throughput methods which can detect multiple SNPs in a single assay. This type of high throughput data can be generated using micro-arrays which can detect millions of SNPs in a single assay.

Microarrays

Microarray is a collection of small oligonucleotides spotted on to a glass slide or silicon chip. The micro-array technique is based on complementary hybridisation of nucleic acids. In this technique, sequence complementarity leads to the hybridisation between two single-stranded nucleic acid molecules, one of which is immobilised on a matrix like glass slide or silicon chip. There are two types of the chips: cDNA micro-arrays and oligonucleotide arrays. They differ in the size of the arrayed nucleic acids. In cDNA micro-arrays, relatively long DNA molecules are immobilised on a solid surface such as membranes, glass or silicon chips. These types of arrays are used for large-scale screening and expression studies. The oligonucleotide arrays are spotted with short nucleic acids (oligonucleotides up to 25 nucleotides) and are useful for the detection of mutations and expression monitoring, gene discovery and mapping.

Applications of cDNA arrays: expression profiling

cDNA arrays are used for expression profiling by hybridising cDNA obtained from specific samples/tissues to look for up-regulation or down-regulation of genes in disease states so that this knowledge can be used to develop new biomarkers and treatment strategies. Expression profiling has been used extensively for various cancers and has resulted in development of novel drugs for treatment of various cancers, e.g. monoclonal antibody (trastuzumab) treatment in cases of breast cancers with HER2/neu gene amplification.

Applications of oligonucleotide microarrays

Oligonucleotide microarrays are used for typing of alleles at different loci throughout the genome. They can be used for:

1. Detection of mutations in human genetic disorders
2. Detection of microdeletions/microduplications and copy number changes throughout the genome.

3. Genotyping of SNPs: The data obtained from typing of these polymorphisms can be used for genome-wide association studies in multifactorial disorders like hypertension, diabetes mellitus, etc. and mapping of genes for single gene disorders by linkage analysis.

SPECIAL CONSIDERATIONS IN HUMAN GENETIC TESTING

Genetic test results not only apply to the individual across his/her entire lifespan, but have implications to other family members as well. Hence, special considerations need to be kept in mind while ordering a genetic test.

1. *Confidentiality:* It is very important to maintain confidentiality regarding the results of genetic tests since they have a bearing on various issues like insurance, job security, etc.
2. *Quality assurance:* As newer and newer methods and assays are available for genetic testing, proper quality control needs to be maintained by the testing laboratories. Accreditation of laboratories and practice of internationally recognised standards and guidelines needs to be ensured.

LIMITATIONS OF GENETIC TESTING

The patient needs to be counselled regarding limitations of genetic tests before conducting the test. Some limitations of genetic tests include:

Multiple Mutations

Different types of mutations can result in a single phenotype/disease, e.g. Duchenne muscular dystrophy can be caused due to deletion of any/some of the 79 exons in dystrophin gene or due to point mutations in the same gene. Thus, we have to use different genetic methods to look for deletions and point mutations to establish the genetic basis of this disorder.

Errors in Genetic Testing

Various errors can occur during genetic testing either due to human errors, machine related errors, reagent related errors, etc. All precautions need to be taken to prevent errors during genetic testing. It is recommended always to use a positive and negative control during assays like PCR so that errors due to contamination of foreign DNA can be avoided.

Limited Information

The genetic basis of some disorders is not completely understood and hence genetic testing in these diseases will give limited information regarding genetic etiology, e.g. retinitis pigmentosa, deafness, etc.

DIRECT-TO-CONSUMER TESTING

Direct-to-consumer (DTC) genetic testing is advertised and offered directly to the consumer without having to go through a health care professional. In this case the test can be ordered by the patient, family member at risk, or anyone from the population on-line themselves. While on one hand it offers the advantage of privacy and confidentiality, on the other it suffers from the danger of creating confusion due to misinterpretation of genetic information. A variety of DTC tests are being offered by different companies, ranging from testing for breast cancer risk, macular degeneration risk, adverse drug reaction risk, etc. to ancestry analysis. The DTC testing is not under any regulation regarding marketing claims, and quality of services provided. Advertising of DTC has been criticised for conveying exaggerated and inaccurate messages about connection of genetic test result and disease risk, utilising emotions as a selling factor. Truly speaking, we still do not have enough data to quantify the risks conferred by the risk alleles towards occurrence of various disease phenotypes. It would be advisable to defer the application of DTC tests until such data and knowledge is available.

Properly designed educational programmes are urgently needed to aid the medical fraternity and general public in understanding implications of molecular diagnostic studies. Judicious application of molecular genetic testing can go a long way in improving the health of populations in future.

6.5 Inborn Errors of Metabolism

Madhulika Kabra

Traditionally, management of patients with inborn errors of metabolism (IEM) has been a concern of paediatricians. Most of these disorders present exclusively in infancy and childhood, and due to their severity patients may succumb early in life. Paediatric forms of the disease are more severe, hence, more easily recognisable. Newborn screening programmes for several of these disorders exist in developed countries, and have helped in early diagnosis and prompt management. Early diagnosis, strict dietary management, biochemical interventions, and careful medical care have led to increasing number of patients with inherited biochemical defects surviving into adulthood.

In addition to increasing age of survival of children with early-onset biochemical disorders, some milder variants first present late as adult-onset disease. It is now clear that potentially every disorder has a milder form with a later onset and there is a distinct possibility that diagnosis in adults may be missed due to lack of awareness among physicians. Examples include adults with organic acidaemia and movement disorders, urea cycle disorders, late onset lysosomal storage disorders, etc. The age of onset is determined by the presence of variable activity of the defective enzyme that results from different genetic mutations. Adult female carriers of the X-linked ornithine transcarbamylase deficiency may have variable manifestations of hyperammonaemia after protein ingestion—confusion, ataxia, migraine headache, or even frank coma. Internists not only need to assume responsibility of taking care of surviving patients, but should also be competent to diagnose and manage adult-onset IEM.

DEFINITION AND EPIDEMIOLOGY

IEM are conditions caused due to a genetic defect related to synthesis, metabolism, transport or storage of various biochemical compounds. The genetic defect usually causes deficiency of one or more enzymes or transport proteins.

Worldwide incidence of IEM has been estimated to be about 3-4 per 1,000 live births. More than 300 such defects are known. Most IEM are inherited in an autosomal recessive manner, some are X-linked. Exact incidence of IEM in India is not known as no population based data is available. In one study, 5% of the cases of mental retardation due to genetic cause were due to IEM [Indian Council of Medical Research (ICMR) multicentric study]. In other studies from India, 0.5% to 2.4% of mentally retarded children have been reported to have an amino acid metabolism disorder.

AETIOPATHOGENESIS

IEM are disorders which are caused by deficiency of an enzyme that leads to a block in the metabolic pathway. This leads to: (i) deficiency of the end product, (ii) accumulation of the substrate, and (iii) generation of secondary metabolites through some alternate pathway. Symptoms are caused both due to deficiency of the product and accumulation of the substrate/alternate metabolite. **Figure 1** illustrates the mechanism.

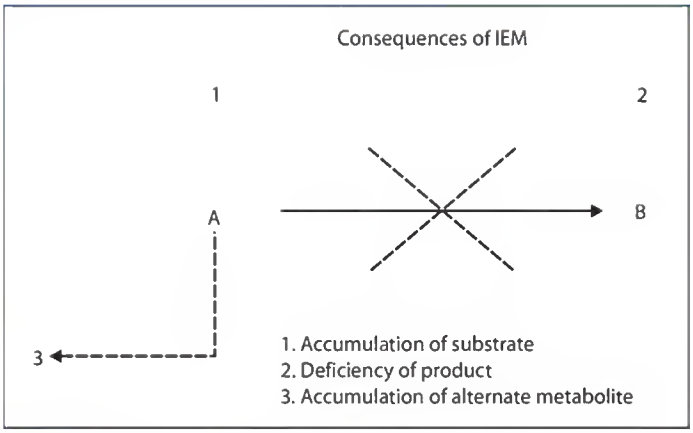

Figure 1: Consequences of enzyme deficiency in a metabolic pathway.

CLASSIFICATION

IEM are classified in two major groups—small molecule diseases and large molecule diseases (**Table 1**).

Table 1: Clinical Classification of Inborn Errors of Metabolism

Acute (generally present in infancy)	Intermittent (Precipitated by stress, infection, starvation, diet)	Chronic (generally present late in childhood/adults)
Due to small molecule defect (amino acids, organic acids, simple sugars, etc)	Caused due to milder metabolic derangement	Due to large molecule defect (storage disorders) (energy deficiency)
Poor feeding, vomiting, lethargy Convulsion, hypotonia Cataract Abnormal body odour Negative septic screen in a sick infant	Repeated episodes of Reduced level of consciousness Acidosis or ketosis or hypoglycaemia Weakness Ataxia/spasticity vomiting, Reye syndrome like episodes	Progressive central nervous system degeneration manifested as seizures, development delay or failure to thrive, mental retardation Hypotonia/spasticity, muscular weakness Associated organomegaly, abnormal fundus, coarse facies

The major categories of IEM which can present as an acute emergency include—organic acidurias (OA), fatty acid oxidation (FAO) defects, mitochondrial encephalomyelopathies, aminoacid disorders [phenylketonuria (PKU), maple syrup urine disease (MSUD), non-ketotic hyperglycinemia (NKH), tyrosinaemia], urea cycle defects (UCD) and disorders of carbohydrate metabolism (galactosaemia)].

CLINICAL PRESENTATION AND SUSPICION OF IEM

Infants and Children

The classical presentation in newborns is of an initial period of normalcy, followed by symptoms, usually getting precipitated

by feeding which resemble sepsis. In infants and older children, symptoms may get precipitated by intercurrent illness or dietary factors and may be intermittent. If untreated, patients may rapidly deteriorate and slip into encephalopathy. History of consanguinity, family history of developmental delay or sudden infant death syndrome, onset of symptoms with institution of feeds, unexplained growth disturbances, recurrent vomiting, poor feeding, seizures, apnoea, breathlessness may be important clues.

Physical findings

Clinical findings are non-specific and include tachypnoea, apnoea, lethargy, hypertonia, hypotonia, hepatosplenomegaly, ambiguous genitalia, jaundice, dysmorphic or coarse facial features, rashes or patchy hypopigmentation, ocular findings (cataracts, lens dislocation or pigmentary retinopathy), intracranial haemorrhage, and unusual odours. **Table 2** gives some important clinical markers for IEM.

Table 2 : Clinical Pointers to Specific Disorders

Cutaneous abnormality: Perioral eruption (multiple carboxylase deficiency), increased pigmentation (adrenoleukodystrophy), decreased pigmentation (phenylketonuria)

Abnormal urinary or body odour: Musty (phenylketonuria), maple syrup (maple syrup urine disease), sweaty feet (isovaleric acidaemia, glutaric acidaemia type II), cat urine (multiple carboxylase deficiency), sulphurous (homocystinuria)

Hair abnormalities: Alopecia (multiple carboxylase deficiency), kinky hair (Menkes disease), arginosuccemic aciduria, multiple carboxylase deficiency)

Dysmorphic features: Zellweger syndrome, glutaric acidaemia type II

Ocular abnormalities: Cataract (galactosaemia, Zellweger, homocystinuria), iris heterochromia/retinitis pigmentosa (Zellweger syndrome), KF ring (Wilson's disease)

Hepatomegaly: Galactosaemia, glycogen storage disease, tyrosinaemia

Hepatosplenomegaly: Storage disorders – Niemann-Pick, Gaucher disease, mucopolysaccharidosis

Renal enlargement: Zellweger, GSD I, tyrosinaemia

Laboratory findings

Laboratory findings which should raise a suspicion of IEM include metabolic acidosis with increased anion gap, primary respiratory alkalosis, hyperammonaemia, hypoglycaemia, ketosis or ketonuria, lactic acidosis, non-glucose reducing substance in urine, abnormal liver functions, unexplained neutropaenia and thrombocytopaenia. In general, IEM can have one of the following presentations:

1. *Neurologic syndromes:* These can present as acute encephalopathy, chronic encephalopathy, movement disorders, myopathy, and psychiatric problems.
   (a) Acute encephalopathy: Encephalopathy in acutely presenting IEM has certain characteristics. It usually occurs with little warning in a previously healthy individual and early signs may be taken as a behavioural problem. The condition often progresses rapidly and consciousness may fluctuate. History of recurrent similar episodes may be present.
   (b) Chronic encephalopathy: Psychomotor retardation/developmental delay are the commonest manifestation of IEM. The retardation tends to be global and progressive. History of regression of milestones may be present. Irritability, aggressiveness, hyperactivity and lack of night sleep are commonly associated. In addition, retardation is often associated with objective neurological signs, like tone changes, pyramidal or extra-pyramidal deficits. Seizures, visual failure, extra-pyramidal disturbances are signs of grey matter disease. Involvement of non-neural organs like hepato-splenomegaly gives important clues to diagnosis.
   (c) Movement disorders: In patients with IEM can be seen in a large variety of disorders and are usually associated with other neurologic signs. Movement abnormalities can be intermittent or progressive. These may occur in the form of ataxias, dystonia, choreoathetosis and Parkinsonism. Common examples of IEM presenting as movement disorder are organic acidurias, neuronal ceroid lipofuscinosis (late onset forms), lysosomal storage disorders and urea cycle disorders, etc.
   (d) Myopathy: IEM presenting with myopathy are usually due to defects in energy metabolism. The myopathy can be progressive, e.g. glycogen storage disease, mitochondrial disorders.
2. *Hepatic syndromes:* Liver involvement is seen in a number of IEM. There are four possible presentations: (i) Jaundice (unconjugated—G6PD deficiency, Gilbert, Crigler-Najjar, and conjugated—galactosaemia, tyrosinemia, fructose intolerance); (ii) Hepatomegaly (asymptomatic hepatomegaly is common, e.g. GSD); (iii) Hypoglycaemia galactosaemia, GSD); and (iv) Hepatocellular dysfunction galactosaemia, GSD (IV and III), Niemann-Pick type B, α_1 antitrypsin deficiency, etc.
3. *Cardiac syndromes:* Serious cardiac disease has been found to be associated particularly with fatty acid oxidation defects, mitochondrial disorders, GSD II, Fabry's disease and MPS.

Clinical Presentation in Adults

A history of intermittent attacks triggered by feeding or fasting or some stress may suggest milder intermittent forms of small molecule diseases like disorders of urea cycle, amino acid metabolism, or fatty acid oxidation. A slow progressive course may suggest a lysosomal storage disease or a peroxisomal disorder. Often detailed questioning may disclose evidence of problems in childhood or adolescence. A positive family history may also give a clue. A detailed enquiry for mild clinical symptoms at an early age is warranted as those symptoms may be passed off as non-specific and unrelated. These features often remain unrecognised, as they may be mild and often intermittent in nature. Specific neurological findings such as vertical supranuclear ophthalmoplegia or a cherry red spot may suggest a lysosomal storage disorder. Alternatively, there may be abnormalities affecting other organ systems. The internist may confront a group of disorders caused by mutations in mitochondrial DNA that express themselves as disorders of cellular energy metabolism secondary to electron transport chain defects. The manifestations may involve single organ system or may be these disorders may mimic an idiopathic,

organ-specific, degenerative disease. Affected persons may present at any age with variable features of myopathy, ophthalmoplegias, encephalopathy, strokes and cardiac manifestations. The cardinal biochemical feature is lactic acidaemia; lactic acid elevation in the cerebrospinal fluid may be the sole abnormality. **Table 3** gives brief information about inherited metabolic disorders with adult onset forms.

Table 3: IEM with Adult Onset

Disease	Presentation
Lysosomal storage diseases	
Pompe's disease	Muscle weakness, cardiomyopathy
Fabry's disease	Peripheral nerve pain, renal failure, angiokeratoma, cardiomyopathy, stroke-like episodes
Gaucher's disease type III	Horizontal supranuclear gaze defect, developmental delay, skeletal abnormalities, psychosis, organomegaly
Gaucher's disease type I	Anaemia, splenomegaly, thrombocytopaenia
GM1 gangliosidosis	Extrapyramidal signs, sometimes with psychosis
Krabbe's leukodystrophy	Pes-cavus, spastic tetraparesis, leukodystrophy, visual problems
Metachromatic leukodystrophy	Loss of cognitive function or behavioural abnormalities, neuromuscular weakness with impaired nerve conduction, leukodystrophy
Niemann-Pick's disease type C	Psychomotor retardation, ataxia, dystonia
Amino acid disorders	
Arginase deficiency	Disorientation, coma
Citrullinaemia	Disorientation, coma, restlessness
Hartnup's disease	Dementia, ataxia ± skin lesions
Homocystinuria	Occlusive cerebrovascular disease, dislocated lenses, osteoporosis, psychiatric disturbances
Hyperornithinaemia	Gyrate atrophy of the retina and choroid
Ornithine transcarbamylase deficiency	Behavioural disturbances, coma episodes, sleep disorders
Fatty acid oxidation defects	Muscle weakness, easy fatigability ± liver disease ± cardiomyopathy ± hypoglycaemia
Organic acid disorders	
Glutaric aciduria type 1	Dystonia ± hypoglycaemia, may present with Reye-like syndrome
Propionic acidaemia	Chorea, dementia, recurrent vomiting
Peroxisomal disorders – X-linked ALD	Onset at 20-30 yrs in males, gait disturbance, spastic paraparesis, intellectual function usually intact, impotence ± Addison's disease, occasionally cerebral symptoms
Mitochondrial disorders	Encephalopathy, stroke-like episodes, muscle weakness, multisystem disease (NARP, MELAS, MERRF, Kearns-Sayre syndrome, LHON)
Glycogen storage diseases	Muscle weakness, cardiomyopathy, hepatomegaly, hypoglycaemia, myopathy
Homocystinuria and methylmalonic aciduria	Megaloblastic anaemia, dystonia, stroke
Juvenile Batten's disease	Seizures, visual loss, dementia
Porphyrias	Limb, neck, and chest pain, muscle weakness, sensory loss, seizures, behavioural abnormalities
Refsum's disease	Retinitis pigmentosa, peripheral polyneuropathy, cerebellar ataxia, abdominal symptoms, photosensitivity
Segawa disease	Cyclical dystonia
Wilson's disease	Dystonia, pseudobulbar palsy, Parkinsonian features, liver disease
Lesch-Nyhan syndrome	Choreiform movements, dysarthria ± renal problems

LABORATORY APPROACH TO SUSPECTED IEM

Screening and Definitive Diagnosis

Based on history and suspicious clinical course, an investigational plan for IEM should be followed. Initial screening investigations will help in disease classification and instituting presumptive therapy. **Figure 2** gives step-wise approach to a suspected IEM. **Figures 3A and B** give details of evaluating a child with metabolic acidosis and **Figures 4A and B** give differential diagnosis of hyperammonaemia. **Figure 5** gives details of evaluation of a patient presenting with hypoglycaemia. For definitive diagnosis a combination of investigations is required. These include tandem mass spectrometry (TMS), gas chromatography mass spectroscopy (GCMS, primarily for organic acidurias) and high performance liquid chromatography (HPLC for amino-acidopathies). Enzyme assays are required for the diagnosis of lysosomal storage disorders. DNA-based diagnosis for causative mutations is the most reliable diagnostic modality but is difficult due to limited availability and heterogeneity in different populations.

Definitive diagnosis may not be available promptly; hence, treatment has to be started empirically in most situations. **Table 4** gives details of workup which is required for acutely presenting IEM. Routine tests such as blood sugar, serum calcium, liver function tests, blood counts and urine tests (**Table 5**) may give some clues to diagnosis. Four laboratory tests are particularly useful in broad classification of IEM and instituting empirical therapy—arterial blood gas analysis, blood lactate, blood ammonia, and urine ketosis (**Table 6**).

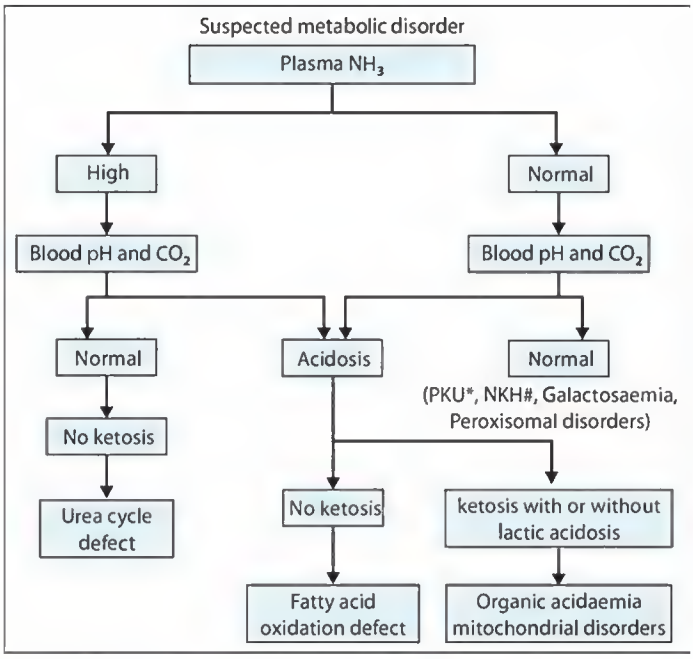

Figure 2: Approach to a case of suspected IEM.
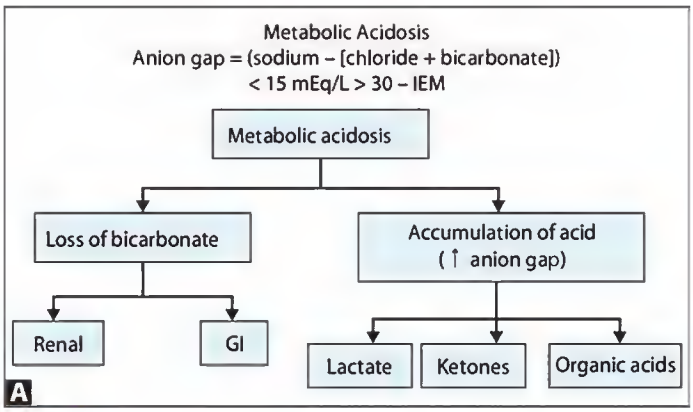
**Phenylketonuria, # Non-ketotic hyperglycinaemia*



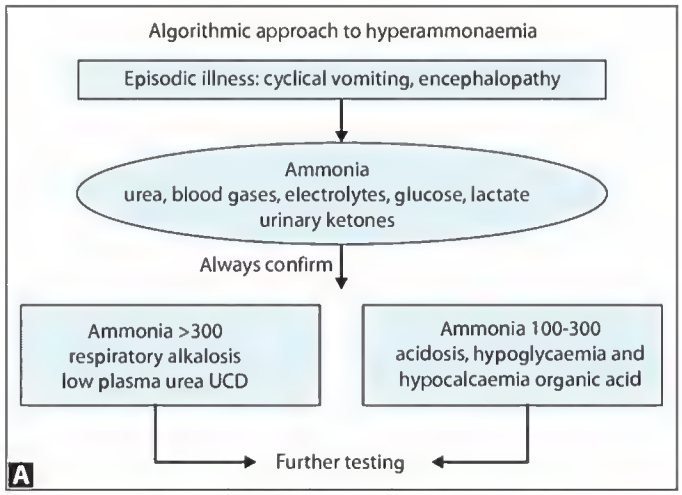


Figure 3A: Approach to a patient with metabolic acidosis.

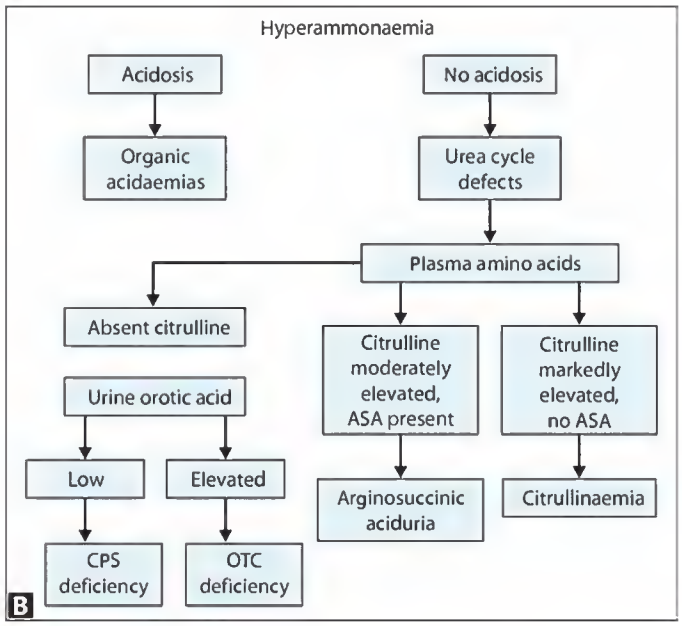

Figure 4A and B: Approach to a patient with hyperammonaemia.

Table 4: Investigations for Acutely Presenting IEM

	Investigations	Sample storage for specific investigations
Urine	Smell (special odour)	*Urine collection:* Collect each fresh micturition
	Look (special colour)	separately and put it in the refrigerator
	Acetone (acetest, ames)	*Freezing:* Freeze at -20 °C, samples collected
	Reducing substances (clinitest, ames)	before treatment and, afterward, an aliquot
	Keto acids (DNPH)	of 24-hour collection on treatment
Blood	Blood cell count	Plasma, heparinised, 5 mL at -20 °C
	Electrolytes (for anion gap)	Blood on filter paper (as 'Guthrie test')
	Glucose, calcium	Whole blood 10 to 15 mL collected in EDTA vial
	Blood gases	(for molecular biology/enzyme studies)
	Uric acid	
	Prothrombin time	
	Transaminases (and other liver tests)	
	Ammonia	
	Lactic and pyruvic acids	Arterial blood sample
Miscellaneous	Lumbar puncture	Skin biopsy (fibroblast culture)
	Chest radiograph	Cerebrospinal fluid, 1 mL frozen
	Echocardiography, EMG	*Post-mortem:* Liver, muscle biopsies
	Cerebral ultrasound	(macroscopic fragment frozen at -70 °C)
	CT, MRI, EEG	
Specialised investigations	HPLC, GCMS, TMS	

Table 5: Urine Metabolic Screen

Disorder	Ferric Chloride	DNPH*	Reducing Substances	Nitroprusside	MPS Spot Test**
Phenylketonuria	+	+	–	–	–
Galactosaemia	–	–	+	–	–
Organic aciduria	+	+	–	–	–
Amino aciduria	–	+	–	–	–
Homocystinuria	–	–	–	+	–
Mucopolysaccharidosis	–	–	–	–	+

** DNPH = Dinitrophenyl hydrazine ** MPS spot test = Mucopolysaccharidoses spot test*

Table 6: Four Basic Tests for Inherited Metabolic Disorders

Group	Acidosis	Ketosis	Lactate	Ammonia	Diagnosis
I	–	+	–	–	MSUD
II	+	+	–	–	Organic aciduria
III	+	+	+	–	Lactic acidosis
IV	–	–	–	+	Urea cycle disorder
V	–	–	–	–	NKH, sulfite oxidase, Peroxisomal, PKU galactosaemia

Points to Remember when Collecting Samples

Samples should be collected before specific treatment is started or feeds are stopped, as tests may be falsely normal if the child is off feeds. Samples like serum ammonia and lactate should be immediately tested. Lactate level should be arterial and collected after 2 hours fast. For children ammonia sample is to be collected approximately after 4–6 hours while in adults it should be collected after a longer period of fasting. Detailed history including drug details should be provided to the laboratory.

Investigation for a Dying Child (Biochemical Autopsy)/Post-mortem Investigations

If a child (suddenly) dies of an unknown, possibly metabolic disease, it is essential to collect representative post-mortem samples and discuss the analysis with a metabolic specialist. Without diagnosis, genetic counselling of the parents and reliable risk assessment for future children is not possible. The following should be collected for post-mortem analysis if a metabolic disorder is suspected but specific investigations have not yet been performed:

1. Serum and plasma (centrifuge several millilitres immediately, freeze in separate fractions).
2. Guthrie-card (dried blood spot on filter paper).
3. Urine (10-20 mL, freeze immediately, consider bladder wash with NaCl).
4. DNA (3-10 mL EDTA blood, freeze without centrifuging), and
5. Consider CSF (several 1 mL fractions, freeze immediately, if possible at -70°C).

Consider fibroblasts (skin biopsy may be stored 1 to 2 days at 4°C in culture fluid).

Biopsies

The acquisition of organ biopsies depends on the clinical picture and should be discussed with the laboratory/metabolic specialist (samples are usually frozen immediately in liquid nitrogen): muscle (skeletal, consider heart), liver, kidney and brain.

TREATMENT

Immediate Management of Acutely Presenting Disorders

Initial emergency treatment should be started empirically even on suspicion of IEM, and even without knowledge of the specific metabolic diagnosis or disease category.

1. General measures:
   (a) Airway, breathing and circulation should be established,
   (b) Treat precipitating/associated conditions like septicaemia.
   (c) Seizures: These should be managed as per the protocols. Pyridoxine should be given to neonates with seizures unresponsive to conventional anticonvulsants. Valproate and phenobarbitone are preferably avoided as they interfere with mitochondrial metabolism.
2. Correction of metabolic abnormalities
3. All oral intake should be stopped to reduce levels of potentially harmful proteins and sugars. Treat hypoglycaemia and prevent catabolism. Maintain fluid and electrolyte balance. Treat acidosis. For intractable acidosis, haemodialysis/peritoneal dialysis is required.
4. Removal of toxic metabolites: Abnormal metabolites are removed by restricting intake of the offending substrate, or by promoting renal excretion of toxic metabolites. In severe cases, dialysis (preferably haemodialysis) is required. Although haemodialysis has advantages over peritoneal dialysis (PD), vascular access remains the primary technical problem and PD is, therefore, usually offered.

SPECIFIC MANAGEMENT

Hyperammonaemia

Kidneys clear ammonia poorly. Its removal is hastened by formation of compounds other than urea, hence, decreasing load on the urea cycle. Compounds used are sodium benzoate, phenyl

acetate and arginine. Intravenous preparations of sodium benzoate and phenyl acetate are not available in India. Oral sodium benzoate is available and can be used in the same dose.

Ammonia level more than 200 µmol/L to 350 mg/dL

Protein intake is to be stopped, and catabolic state is interrupted by high-calorie infusion (>120 kcal/kg/day). Arginine hydrochloride 360 mg/kg, carnitine 50 mg/kg, Na-benzoate 350 mg/kg and Na-phenylbutyrate or Na-phenylacetate 250 mg/kg should be started. The patient should be transferred to a referral centre. Citrulline may be used in the dose of 170 mg/kg per day in CPS and OTC deficiency. Anticonvulsants like sodium valproate should be avoided.

NH_3 level more than 400 µmol/L

In addition to the above measures, extracorporeal detoxification should be started as soon as possible. Use haemodialysis, if possible; otherwise, peritoneal dialysis.

Long-term treatment of urea cycle defects

Start low-protein diet containing essential amino acids early. Na-benzoate orally in a dose of 250-400 mg/kg/day and Na-phenyl-butyrate orally in a dose of 250-500 mg/kg/day is also to be administered. Supplement vitamins (e.g. folic acid 500 µg/day) and trace elements. If carnitine is low, supplement carnitine in the dose of 30-50 mg/kg. Consider lactulose as it binds intestinal ammonia due to acid pH. The target value of NH_3 is less than 80. Essential amino acids should be in the normal range.

Organic Acid Disorders

Emergency treatment in the hospital includes the following:

(a) *Interrupt catabolic state:* High-dose energy substitution, usually glucose intravenous (exceptionally via nasogastric tube), if necessary with intravenous insulin.

(b) *Stop protein intake:* In some disorders, the accumulation of toxic metabolites can be reduced by intestinal antibiotic treatment (metronidazole, colistin).

(c) *Ensure adequate fluid and electrolyte intake:* Aim for a sodium concentration >140 mmol/L to reduce the risk of cerebral oedema.

(d) *Carry-out detoxifying measures depending on the disease and laboratory findings:* Increased diuresis, dialysis, haemofiltration.

(e) *Consider specific drug treatment* (vitamins, carnitine, etc.) depending on the disease and laboratory findings.

Long-term treatment includes the following: (a) Diet: protein restriction, (b) If indicated give specific vitamins or co-factors, (c) Carnitine (50-100 mg/kg/day), and (d) Regular laboratory monitoring (depending on the disease).

Disorders of Fatty Acid Oxidation

The main therapy is prevention of fasting and catabolic states. In acute situations, intravenous glucose infusion (8-10 mg/kg/min) should be started without delay. In contrast, in patients with defects in LCAD metabolism, low fat diet supplemented with medium chain triglycerides may be beneficial. Avoid valproate as an antiepileptic drug if possible.

Mitochondrial Disorders

Most approaches used for the treatment of mitochondriopathies have not been scientifically evaluated, and success is limited. General measures include avoidance of drugs that inhibit the respiratory chain, e.g. valproate, barbiturates, tetracyclines, chloramphenicol. L-Carnitine 50-100 (up to 200) mg/kg/day in 4 doses; avoid lactic acidosis by limiting excessive physical exercise, controlling fever, early and efficiently, and early treatment of seizures.

Treatment regimen in acute lactic acidosis and suspected mitochondriopathy includes: coenzyme Q_{10} + riboflavin (in the neonate: 100 mg/day), vitamin C, carnitine, biotin (20 mg/day), phylloquinone or menadione and thiamine.

Specific long-term treatment, though of uncertain efficacy, includes: coenzyme Q_{10} 4-5 mg/kg/day in 2 doses, riboflavin 3-20 mg/kg/day in 4 doses, thiamine 25-100 mg/kg/day, tocopherol (vitamin E) 100-300 (up to 1,000) mg/day and Creatine 4-10 g/day (stop every 4th month), e.g. in mitochondrial myopathy. Corticosteroids are not indicated.

Vitamin/Cofactor Therapy

In certain IEM, enhancement of the activity of a mutant enzyme can be achieved by giving mega-doses of a vitamin cofactor required for enzyme's action. One-third of the cases of homocystinuria due to cystathionine b-synthetase deficiency are pyridoxine responsive. Deficiency of multiple biotin-dependent carboxylases responds to 10 mg of biotin given daily. Some cases of methylmalonic acidaemia respond to pharmacological supplementation of intramuscular hydroxycobalamin in a dose of 1 mg per day. A diet low in fat and protein together with a trial of oral riboflavin (200-300 mg per day) and carnitine may be helpful in some patients with glutaric aciduria type I and II.

Dietary Therapy and Enzyme Replacement

Specific therapy will depend on the final diagnosis. Dietary therapy is required for PKU, MSUD, galactosaemia, homocystinuria, etc. Cost of the special diets is high and critical monitoring is required for effective management. Enzyme replacement therapy is available for many lysosomal storage (e.g. Gaucher's, MPSI, MPSII, GSDII, Fabry's, MPSVII) disorders with excellent results. Bone marrow/stem cell transplantation is another option for lysosomal storage disorders.

Newborn Screening

Newborn screening is a well-tested strategy for secondary prevention of IEM. Most developed countries test for IEM using TMS in addition to screening for congenital hypothyroidism and congenital adrenal hyperplasia. Samples are collected by heal prick 48 to 72 hours after birth. Early diagnosis and timely management prevents neurological sequelae and mortality. India does not have a national newborn screening programme presently. The ICMR has initiated a multicentric pilot project for newborn screening of 100,000 babies for congenital

hypothyroidism and congenital adrenal hyperplasia to study the incidence of these disorders and also the feasibility of introducing such a programme in India. The Governments of Chandigarh and Goa, India have also initiated newborn screening programmes recently.

Genetic Counselling and Prenatal Diagnosis

As most IEM are autosomal recessive, the risk of recurrence in subsequent pregnancies is 25%. For X-linked disorders recurrence risk is 50% for male offspring. Prenatal diagnosis is possible by enzyme assay in chorionic villous biopsy or amniotic fluid cells. Mutation analysis on DNA extracted from chorionic villous sample or amniotic fluid cells is a more robust and preferred modality if causative mutations are known.

6.6 Molecular Genetics, Human Genome Project and Genomic Medicine

Girisha KM

The understanding of the structure, function, regulation and variations in DNA is the key to the understanding of human health and disease. This chapter discusses the molecular basis of life, gives insight into genetic variation between individuals and its clinical implications.

STRUCTURE OF DNA

Deoxyribonucleic acid (DNA) is a long polymer of nucleotides. Each nucleotide is made up of a nitrogenous base [purines: adenine (A) and guanine (G); and pyrimidines: cytosine (C) and thymine (T)], a deoxyribose sugar, and a phosphate group. Ribonucleic acid (RNA) differs from DNA in having a ribose sugar in place of deoxyribose, and pyrimidine uracil (U) in place of thymine. Watson and Crick (1953) demonstrated how deoxynucleotides are assembled to form the double stranded helical structure of DNA, where sugar and phosphate molecules form two sides of the ladder that are held by strong phosphodiester bonds, and rungs of the ladder are formed by nitrogenous bases facing inside, being held together by hydrogen bonds that are weaker and separate during replication and transcription. The two strands run anti-parellel to each other with one strand having the orientation of 5′ to 3′ direction and the other of 3′ to 5′ direction (**Figure 1**).

In human nucleated cells, approximately 2 metres of DNA is condensed about 10,000 times and packaged into chromosomes. The DNA is first wound around a histone protein core to form a nucleosome, which in turn forms a helical solenoid. The solenoids are organised into chromatin loops, which are attached to a protein scaffold and further packaged into chromosomes.

DNA REPLICATION

Replication of DNA is the key event for transmission of genetic information from parent cell to its progeny. The process leads to formation of two identical copies of the original DNA that get segregated into two daughter cells during cell division. The replication begins with uncoiling and separation of two strands of the DNA molecule by the enzyme helicase. Each strand of the DNA directs synthesis of its complementary copy through complementary base pairing (adenine pairs with thymine and cytosine pairs with guanine) resulting in formation of two DNA molecules (semi-conservative synthesis) identical to the original parent molecule. This process conserves the genetic information, and transmits it unchanged to each daughter cell. The key enzyme that carries out DNA synthesis is DNA polymerase. The process initiates at several sites simultaneously during the S (synthetic) phase of cell cycle. The synthesis of a new DNA strand proceeds in 5′ to 3′ direction. This leads to formation of one continuous strand (leading strand) which is the copy of the 3′ to 5′ strand; and the other strand is synthesised in parts (Okazaki fragments) that are later joined together by the enzyme DNA ligase.

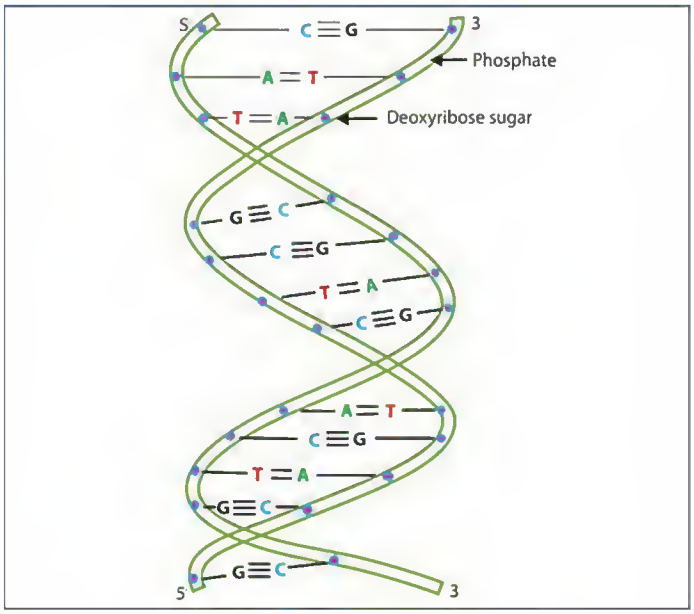

Figure 1: Helical structure of the DNA showing the sugar-phosphate backbone and the nitrogenous bases. The DNA resembles a ladder with the sides formed by the phosphodiester bond between phosphoric acid and deoxyribose sugar and the rings formed by hydrogen bonds in-between the nitrogenous bases. Two hydrogen bonds are formed between adenine (A) and thymine (T) and three hydrogen bonds between guanine (G) and cytosine (C).

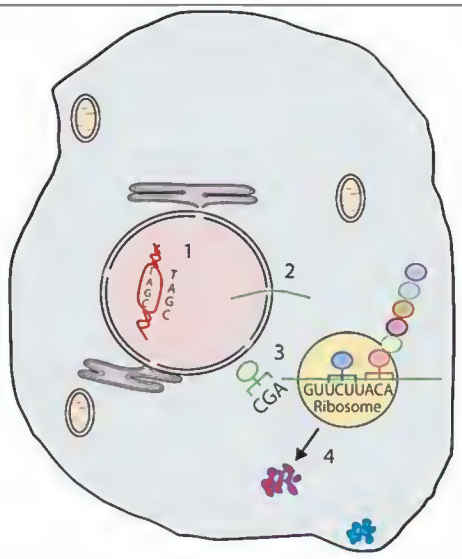

TRANSCRIPTION AND RNA PROCESSING

Transcription is the process whereby genetic information stored in DNA is utilised for gene function. It leads to formation of RNA which migrates to cytoplasm for synthesis of proteins. The transcript of the coding DNA is known as messenger RNA. The mRNA is single stranded. It is synthesised by the enzyme RNA polymerase that adds complementary ribonucleotides to the RNA chain (uracil replaces thymine in mRNA). The particular strand of DNA that acts as a template for synthesis of mRNA is called 'antisense strand' so that the new molecule of mRNA is the copy of the other 'sense strand'.

The mRNA leaves the nucleus to cytoplasm after several processing events. The RNA processing includes removal of introns at specific splice sites in mRNA (splicing), addition of a methylated guanine nucleotide to the 5′ end of the molecule (5′ capping) and addition of about 200 adenylate residues at the 3′ end (polyadenylation). Now the mRNA molecule is ready to be translated.

THE GENETIC CODE

The 20 different amino acids in proteins are coded by the four different nucleotides (bases) in DNA (**Figure 2**). The sequence of triplet nucleotide bases in the DNA molecule that specifies the sequence of amino acids in the protein molecule is called the genetic code. The genetic code from DNA is transmitted to

1. DNA replicates to produce more copies so that it can be equally distributed to both the daughter cells.
2. Genetic information in the DNA is transcribed into the mRNA through the process of transcription. mRNA is then translocated into the cytoplasm.
3. In the cytoplasm, the information carried by the mRNA is translated into proteins by ribosomes and tRNA.
4. The protein then formed carries out various intracellular and extracellular functions and, thus, carrying out the complex functions pertaining to life.

Figure 2: Central dogma of molecular biology.

Figure 3: The genetic code: Triplet nucleotides in the mRNA form codons and code for specific amino acids. An amino acid may be coded by more than one codon and three codons stop the elongation of polypeptide chain.

codons of the mRNA during transcription which is then decoded into specific amino acids during translation.

The codons on mRNA are non-overlapping, and are read as per translational reading frame. Among 64 possible triplet codons from 4 nucleotides, some code for same amino acid (degeneracy, since there are only 20 amino acids). Three codons code for termination of the polypeptide synthesis (stop codons). The process of transfer of genetic information from DNA to RNA to protein is sometimes referred to as 'central dogma' or 'holy trinity' of molecular biology (**Figure 3**).

TRANSLATION

The genetic code in the DNA (of a gene) is transmitted on to the codons of mRNA and these direct the synthesis of polypeptide chain by incorporating specific amino acids during the process of translation. In the ribosomes, the site of protein synthesis, the mRNA molecules with the help of specific transfer RNAs (tRNA) carrying the 'anticodons' for individual amino acids synthesise the polypeptide chain, originally directed by the genetic code in the gene. The polypeptide chains, thus synthesised, undergo several post-translational modifications (hydroxylation, methylation, glycosylation, proteolytic cleavage, etc.) to become functional proteins that are transported to their specific cellular locations.

REVERSE TRANSCRIPTION

In most situations, the genetic information flows from DNA to RNA. However, in certain types of viruses (retroviruses) genetic information can flow in reverse direction from RNA to DNA. This is termed reverse transcription or RNA-directed DNA synthesis and involves the enzyme reverse transcriptase. Some regions of the DNA serve as templates for synthesis of RNA, which in turn act as templates for synthesis of DNA. This DNA may get integrated into nuclear DNA of other cells.

GENE: THE FUNCTIONAL UNIT OF DNA

A 'gene' may be conceptualised as the sequence of DNA that contains the information required for a functional product (**Figure 4**). The product encoded may be a polypeptide or RNA molecule. Previously, it was thought that the coding sequence of a gene lies in continuity, which is now known to be a rarity. Now, the 'gene' has been shown to consist of amino acid coding exons, intervening non-coding introns, promoter sequences at 5' region that initiate transcription and other regulatory elements like enhancers, silencers, and locus control regions. Genes may overlap, may be found within another gene, or even the same sequence may be transcribed in reverse direction to produce another product.

REGULATION OF GENE EXPRESSION

The estimated 23,000 genes in each human cell control all the cellular processes in the living being. Their expression varies at different stages of development, and depending on the type of the cell/tissue. Several complex pathways are involved in controlling temporal and spatial expression of genes.

Signalling molecules called transcription factors bind to regulatory sequences of DNA, nuclear receptors (hormones) or even specific ligands located at the cell surface for signal transduction. The transcription factors may bind to promoter elements (TATA, GC and CAAT boxes) of the specific genes located adjacent to the coding region (cis-acting) to regulate the pace of protein synthesis, or to enhancer or silencer elements located at a distance and act on both copies of the gene (transacting) to enhance or suppress the transcription. Transcription factors themselves are coded by genes and bind to DNA to regulate gene expression.

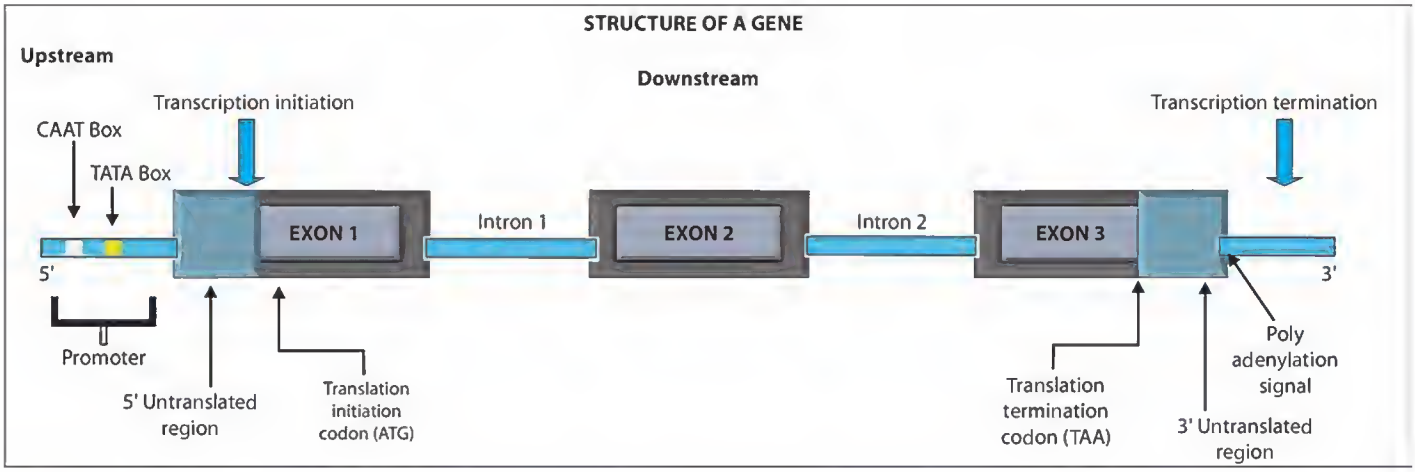

Figure 4: Structure of a gene: A typical gene is made up of a promoter, a transcriptional start site, exons, introns, translational stop site and a Poly A signal. The promoter facilitates the binding of RNA polymerase to the gene during transcription; the transcriptional start site contains the initiation codon ATG, which marks the start of transcription. Exons encode the information for a functional protein. The 5' and 3' untranslated sequences play a role in gene regulation.

Gene activity may also be related to patterns of chromatin condensation. Heterochromatin is usually highly condensed and is characterised by histone modification that makes it inaccessible to transcription factors, whereas euchromatin is decondensed and transcriptionally more active.

Though regulation of expression of most of the genes is mediated by transcription factors, regulation can also occur at various stages of protein synthesis, viz. RNA processing, transport, and translation. Alternative splicing is a mechanism where a gene can code for more than one protein or at varying rates.

STRUCTURE AND ORGANISATION OF THE HUMAN GENOME

The 'human genome' refers to the total genetic information in human cells. In simple terms, genome refers to the entire DNA content of the cell. It consists of the larger nuclear genome ($3x10^9$ bp) and the very small mitochondrial genome (16.6 kb). The nuclear genome encodes bulk of genetic information, most of which specifies synthesis of proteins of the body. Mitochondrial genome encodes its own transfer RNA, ribosomal RNA and few of its own polypeptides.

Nuclear Genes

It is estimated that there are about 23,000 genes in the entire nuclear genome. The size of the genes varies greatly, with small genes comprising of one to three exons (e.g. beta globin gene) and large genes with up to 79 exons (dystrophin gene, ~2.5 Mb).

Unique single-copy genes are present in single copy (in the haploid set of chromosomes). These encode the polypeptides that are involved in a wide variety of cellular functions: enzymes, receptors, regulators, etc. Some others are members of *multigene families*. These arise through gene duplication events during evolution. These may be found in physically close clusters like alpha and beta globin genes on chromosome 16 and 11, respectively or dispersed throughout the genome like the HOX gene family, which are important developmental genes. The genes which encode the ribosomal RNAs are clustered as tandem arrays at the short arms of the acrocentric chromosomes and those encoding the transfer RNAs occur in numerous clusters throughout the genome. These constitute *classic gene families*. Genes encoding the human leukocyte antigens (HLA) and the T-cell receptor genes belong to the immunoglobulin *gene superfamily*. *Pseudogenes* closely resemble known structural genes but do not express. They are thought to have arisen either by duplication of genes that have lost function due to mutations or by insertion of complementary DNA sequences lacking promoter sequences.

Extragenic DNA

The sequences that represent all the genes of the human body constitute around 1.5% of the genome. The rest of the human genome is made up of repetitive DNA sequences that are predominantly inactive. These have also been referred to as junk DNA, but have some uncertain regulatory role.

Tandem repeats

The non-coding DNA may occur in tandem repeats or may be interspersed in the genome. *Satellite DNA* is clustered around the centromeres of certain chromosomes and contains very large series of tandemly repeated sequences that are transcriptionally inactive. *Mini-satellites* consist of repetitive sequences found at the telomeres of chromosomes. Highly polymorphic short tandem repeats of core units made up of 10-100 base pairs are used in DNA fingerprinting. *Micro-satellite DNA* consists of tandem repeats of 1-4 base pair sequences located throughout the genome.

Highly repeated interspersed repetitive DNA

Approximately one-third of the human genome is made up of two main classes of short and long repetitive DNA sequences that are interspersed throughout the human genome. These include several lakhs of copies of short interspersed nuclear elements (SINEs) and the long interspersed nuclear elements (LINEs).

Mitochondrial DNA

Mitochondria contain their own 16.6 kb circular DNA (mtDNA). It encodes for 37 genes including 2 for ribosomal RNA, 22 for transfer RNA and 13 for polypeptide sequences. It may be noted that most of the protein component of mitochondria are product of nuclear genes.

DNA CLONING

Cloning refers to selective amplification of a specific DNA fragment of interest to produce it in a large quantity for further analysis. This can be done by either one cell based *in vivo* amplification, or via polymerase chain reaction *in vitro*.

To clone a segment of DNA, the first step is to generate DNA fragments. This can be done by various methods, the most popular being digestion with restriction enzymes that cleave the DNA into fragments at recognition sites specific to the enzyme. Enzymes that produce staggered (sticky) ends are used for DNA cloning. Next, a suitable vector (plasmid, bacteriophage, cosmid, bacterial or yeast artificial chromosome) is also digested with the same restriction enzyme. The sticky ends of the DNA fragment and the DNA of the vector are attached by the enzyme DNA ligase to generate a recombinant DNA molecule. The recombinant vector is then introduced into especially modified bacterial or yeast host cell that gets transformed. When the host cell multiplies, large quantities of DNA of interest or clones are also synthesised. The transfected cells are then screened for antibiotic resistance or sensitivity genes incorporated in the transforming vector or for the product of gene of interest. Specific clones containing the desired DNA inserts are then selected and cultured separately. This clone serves as the source of amplified DNA fragment of interest for further analysis.

DNA Libraries

DNA libraries contain a large number of clones representing entire repertoire of DNA/RNA derived from a given source. When whole DNA from nucleated cell is used as the source, the resultant product is called genomic DNA library. It may also be chromosome specific library if clones are prepared from sorted chromosomes. When mRNA is used to synthesise the DNA (complementary DNA (cDNAJ) and library is created from it, it is termed cDNA library. The cDNA library contains DNA sequences that are copies of transcribed mRNA. Specific clones from the library may be used for different purposes.

VARIATIONS IN HUMAN GENOME

Humans display a remarkable degree of genetic variation. The most obvious traits include height, blood pressure and skin colour. This also encompasses variation in disease traits and susceptibility to diseases, etc. Even though the sequence of human nuclear DNA is 99.9% similar between any 2 individuals; only 0.1% is sufficient for no. 2 individual to be alike.

Mutations and Polymorphism

Genetic variations originate from 'mutation' that is defined as a change in DNA sequence that is heritable. As a result of mutations, DNA sequences and genes may vary from person-to-person. Different sequences on a particular location (locus) of the chromosome are referred to as alleles. A homozygote has the same allele on both members of a chromosome pair, but alleles differ in a heterozygote. The genotype refers to the alleles present at a given locus.

If a locus has 2 or more alleles where the frequency of minor allele exceeds 1% in population, the locus is said to be polymorphic. Usually such alleles do not produce significant phenotypic effect (i.e. these are neutral in effect), but are presumed to be selected/maintained in the population. These can serve as a useful genetic marker.

Types of Mutations

The variations in the human genome may be at the genomic level as in aneuploidy, chromosomal level as in translocations, or at the gene level as in point mutations. A germline mutation affects cells that produce gametes and is transmitted from generation to generation, whereas a somatic mutation (that can lead to cancer) is confined to somatic cells.

Mutations in individual genes are classified on basis of sequence change and its consequence on protein product and its function. Substitution refers to replacement of a single nucleotide by another, and is the most common type of mutation. Transition refers to substitution of the same type of nucleotide (i.e. purine by purine, or pyrimidine by pyrimidine nucleotide). The reverse is transversion. Substitutions can result in a synonymous change (silent, with same amino acid retained in the protein product), or a non-synonymous change of amino acid. Non-synonymous mutations are missense when the altered amino acid affects protein function or stability, and nonsense when it leads to creation of a stop codon. A substitution may also affect the splice site leading to aberrant splicing of mRNA, or the promoter that leads to altered gene expression.

Deletions involve the loss of one or more nucleotides. If it occurs in the coding sequence, it may disrupt the reading frame (frame shift mutation), unless the deletion affects nucleotides that are a multiple of three (in frame). Larger deletions involving a part or whole of the gene also occur.

Insertion refers to addition of one or more nucleotides into a gene. Depending on the number of nucleotides inserted, the mutation may cause a shift in the reading frame. Expansion of triplet repeats is a form of insertion. It is described elsewhere in this section.

Substitution, insertion and deletion may affect the splice site, either by activating a cryptic splice site or by abolition of a regular splice site. This may result in exon skipping, retention of intronic sequences and frame shift.

Functionally, a mutation can lead to loss of function of a protein [deletion of dystrophin gene (some exons) in Duchenne muscular dystrophy], haploinsufficiency (50% of the protein product is insufficient for normal cellular function as in familial hypercholesterolaemia) or gain of function (as in achondroplasia), or rarely a dominant-negative effect where product of mutant gene in heterozygous state results in loss of activity of normal gene product of the corresponding allele as well.

Single Nucleotide Polymorphisms

Single nucleotide polymorphisms (SNPs, also pronounced as SNIPS) refer to single base differences in the DNA sequence, found throughout the human genome with a frequency of about 1 per 1000 bp, in more than 1% of the population. These are mostly biallelic and occur in both coding and non-coding regions of the genome. It is easy, fast and inexpensive to assay SNPs, and many sites can be assayed simultaneously and automated. They are almost always found near the genes of interest. Combination of SNPs can be used to construct haplotypes, or SNP profiles which serve as powerful tools to study linkage, genetic predisposition to multifactorial diseases, detection of submicroscopic chromosomal imbalances, pharmacogenetics, etc. More recently SNP microarrays have been extensively used for genome wide association studies.

Copy Number Variations

Being diploid, humans have two copies for any particular segment of DNA. However, in some areas, the number of copies of the particular segment varies between two human genomes (of two individuals). This phenomenon has now been termed

copy number variation (CNV) and more and more such copy number variants are being uncovered by the use of array comparative genomic hybridisation technique that is being used widely. A CNV may vary in size from 1 kb to several mega bases and can occur anywhere in the genome. Usually they result from deletion-duplication events and are heritable. It is estimated that approximately 0.4% of the genome of unrelated people typically differs with respect to copy number. Like any other genetic variation, CNVs have been found to be associated with disease susceptibility and resistance. CNVs encompass more DNA than SNPs. CNVs can be limited to a single gene or include contiguous set of genes. CNVs can result in having either too many or too few of the dosage sensitive genes, which may be responsible for substantial amount of human phenotypic variability, complex behavioural traits, and disease susceptibility. It is often difficult to determine whether a particular CNV that is uncovered in a chromosomal array is pathogenic or not. A CNV that arose *de novo* in an individual with abnormal phenotype is likely to be pathogenic whereas a CNV that is inherited from an asymptomatic parent or a CNV that is found in other unaffected individual is likely to be a polymorphism.

HUMAN GENOME PROJECT

It has been one of the most ambitious undertakings in the history of biomedical research. The Human Genome Project (HGP) began in 1991 and produced the first draft sequence of the human genome by 2001, well ahead of its scheduled date of completion. A completed, highly accurate sequence was unveiled in 2003. The entire data is now available in the public domain. In addition to sequencing of the entire human genome, the project had set several other objectives and areas of work as well: human gene maps and mapping of human inherited diseases, maps of model organisms, development of new DNA technologies, development of bioinformatics, comparative genomics and functional genomics. The project also had an ethical component to look into various issues arising out of genome research. The project has provided a map of genetic markers using many thousands of polymorphisms (variations) distributed throughout the genome. Additionally, more than 4 million SNPs have been identified in the human genome.

In addition to the human genome, genomes of several other organisms like *Escherichia coli*, *Haemophilus influenzae*, *Saccharomyces cerevisiae* (yeast), *Caenorhabditis elegans*, *Drosophila melanogaster* (fruit fly), mouse, rat, and zebra fish have also been sequenced. The genes in these organisms show significant homology to genes in humans and provide an opportunity to study candidate genes for human diseases *(comparative genomics)*. These model organisms are also invaluable tools to study expression of genes and function of their protein products in normal development as well as their dysfunction in inherited disorders. Developments in molecular techniques and computational abilities have made gene mapping easier and faster. But it has also thrown many ethical, legal and social challenges. Completion of HGP project represents the beginning of an era of scientifically exciting, but socially complex, biomedical research and molecular medicine.

POST-GENOMIC ERA OF 'OMICS'

The major goal of HGP was to provide entire structure of human genome *(structural genomics)*. But this is of limited use without knowing function of the genome. The emphasis has now shifted to methods suitable for study of functions of different genes identified in the genome. Functional genomics aims to study functions of a gene at biochemical, cellular and organismal level, including gene-gene interactions and gene-environmental interactions. The approach also takes into consideration the role of conserved genes in model organisms and human homologues. Transgenic (those which carry the gene of interest) and knock-out (where the gene of interest is absent or mutated) models provide invaluable insight into function of genes. *Transcriptomics* (study of total mRNA transcript of the cell) provides more scope for linking genes and their products into functional pathways and networks. Expression pattern also reveals how changes in gene expression coordinate the biochemical activities of the cell in health and disease. Development of microarray technology has provided useful means to study expression of thousands of genes at a time. The field of *proteomics* encompasses the analysis of protein expression, protein structure and protein interactions to understand the functions and interactions of genes. *Metabolomics* refers to the study of metabolites and metabolic networks (pathways).

GENOMIC MEDICINE

Each person has a unique genome, except for monozygotic twins, and hence different phenotype (physical traits). Its needs and responses with respect to nutrition, disease susceptibility, preventive care, disease phenotype, complications, treatment, response to drugs, are likely to be unique. All physicians will soon need to understand the concept of genetic variability, its interactions with the environment, and its implications for patient care. With sequence of the human genome now available and technology making it possible to sequence the whole genome of any individual, the practice of medicine will enter into a new era in which an individual patient's genome will help determine the optimal approach to care, be it preventive, diagnostic, or therapeutic.

With rapid progress in technologies to unravel the genome, proteome and even metabolome, there is a paradigm shift in the research focus from disease causing genes to modifier genes, structure to function, aetiology to pathogenesis, and disease diagnosis to susceptibility recognition. Though stem cell therapy and gene therapy still remain a dream despite over two decades of research, we are likely to see major discoveries demystifying human health and disease at an astonishing pace in the coming years. All the monogenic disorders and the underlying defects will be characterised enabling molecular diagnosis of all and prenatal diagnosis whenever indicated. This will open up new treatment options based on innovative strategies. Predictive testing is already possible for some disorders and the number is likely to increase in case of multifactorial diseases. The ultimate aim of understanding the human genome is to offer genomic medicine where the genetic make-up of an individual paves the way for a healthy lifestyle, prevention of disease, and optimal treatment of medical conditions. Simultaneously, progress in the medical field, in all likelihood will increase the debate on social and ethical issues involved.

6.7 Gene Therapy

Rita Mulherkar

INTRODUCTION

There are more than 3000 genetic disorders caused by single gene defects. In addition, there are many other multifactorial disorders where genetic variation plays a significant role in the aetiology of the disease. The strategies of conventional treatment for genetic disorders often require life-long treatment and are expensive. Besides, for many disorders there is nothing to offer. The possibility of curing the genetic disorder by replacing the defective gene or repairing the mutation *in-situ* appears to be much more logical. Recent advances in molecular biology have made gene therapy an achievable goal.

Gene therapy, as yet, is an experimental modality of treatment where a functional gene is introduced into a cell to take over the function of the defective gene. The first gene therapy trial in humans was approved in 1989. Since then more than 1500 trials in various conditions have been carried out. These studies have provided the 'proof of principle' but safe and effective gene therapy for genetic disorders is still a long way to go. In addition to monogenic disorders, clinical trials using gene therapy are also being carried out for disorders like cardiovascular disease, diabetes mellitus, cancer and infectious diseases like human immunodeficiency virus (HIV).

Gene therapy can be carried out to correct the genetic defect in a fertilised egg (Germline Gene Therapy), or in somatic cells (Somatic Gene Therapy). Due to fear of possible adverse effect on future generations and other social, ethical and legal issues, germline gene therapy is not permitted in any country at present. For somatic gene therapy, special guidelines for clinical trial protocols and permission of ethics committee and other regulatory bodies of the country may be essential.

REQUIREMENTS FOR GENE THERAPY

The prerequisites of successful human gene therapy (HGT), include selecting a therapeutically suitable gene (with a proven role in the pathophysiology of the disease), appropriate gene delivery system (e.g. viral and non-viral vectors to transfer the gene into the cells), efficacy and safety studies in appropriate animal models, and suitable manufacturing and analytical processes to produce well-defined HGT products for clinical investigations. It is only after successful pre-clinical trials for gene therapy in cell culture and animal models, that the therapeutic gene be tested in clinical trials.

In monogenic disorders, addition of the wild type gene has shown some promise in several clinical trials. The first successful gene therapy trial for severe combined immunodeficiency syndrome (SCID) due to adenosine deaminase (ADA) deficiency was carried out in 1990. In this disorder, the wild type ADA gene was introduced in T-cells of the patient and the transduced cells were transferred back to the patient. This resulted in dramatic improvement in immune competence of the patient, so much so that she could attend the normal school. Once the therapeutic gene is selected, the sequences which regulate expression of the gene, i.e. the promoter sequences also need to be selected. A tissue-specific promoter would regulate expression of the therapeutic gene in that particular tissue. A ubiquitous promoter, on the other hand, would express the gene in most tissues, e.g. a viral promoter such as cytomegalovirus (CMV) promoter. The choice of vector is equally important. Most efficient vectors are viral vectors which are modified in the lab to become non-pathogenic. Viruses have evolved over a period of time to efficiently utilise the cellular machinery for its own advantage and make numerous copies of itself in the cell. Thus a gene cloned in a viral vector also replicates itself along with the virus and either gets integrated in the host genome or remains in the nucleus as an episomal body. Adenoviral and adeno-associated virus vectors have been the most widely used vectors in clinical trials so far.

IN VIVO AND *EX VIVO* DELIVERY OF A THERAPEUTIC GENE

The therapeutic gene along with its regulatory sequences can be introduced into the patient either directly as naked deoxyribonucleic acid (DNA) or through a vector, which is injected intramuscularly or systemically. This is known as *in vivo* gene delivery. On the other hand, the therapeutic gene can be introduced into cells removed from patient's body and manipulated *in vitro* before injecting them back into the humans. This is called as *ex vivo* gene delivery. In *ex vivo* gene delivery, there is scope for selectively expanding the cells carrying the transgene, and carry-out quality assurance procedures before administering it to the patient. Stem cells, because of their capacity to survive indefinitely, are good candidates for *ex vivo* gene therapy.

Methods of Gene Delivery

Techniques for gene (DNA) delivery into cells in culture have been the crux of success of recombinant (DNA) technology. Various chemical and physical methods have been used to introduce DNA into cells *in vitro*, the process being called transfection of cells. The cheapest and most widely used method in the laboratory is transfection via calcium phosphate precipitation where DNA is trapped in a fine precipitate and layered onto cells in culture. The DNA enters the cell via endocytosis. Other chemical methods include the use of cationic (positively charged) molecules, such as liposomes, which bind both to the negatively charged DNA on one hand and the negatively charged cell membrane on the other, thereby, facilitating DNA entry into the cell. Physical method, such as electroporation, is another commonly used method for introducing DNA into cells in culture. It is a technique where cells are mixed with the DNA construct and then briefly exposed to pulses of high electrical voltage. This creates transient, reversible pores on the cell surface allowing foreign DNA to enter the host cell. However, the most efficient method for DNA delivery is the use of viral vectors. These include retroviruses,

such as Moloney murine leukaemia virus and adenoviruses which are the common cold viruses. Some important properties desired of an ideal vector are as follows: (a) should protect and deliver DNA into the cell without any alteration, (b) transit easily through cell membrane and from cytoplasm to nucleus, (c) persist in host cell nucleus, (d) be non-toxic (non-pathogenic, if viral) and non-immunogenic, and (e) be easy to produce in large quantities.

Depending on tropism, selected retroviruses can infect all dividing mammalian cells. They carry ribonucleic acid (RNA) as their genome which is converted to cDNA by the enzyme reverse transcriptase inside the infected cell. The cDNA of the virus along with the therapeutic gene, under appropriate regulatory sequences, gets incorporated in the host genome. Thereafter, the virus uses the host cellular machinery to make the therapeutic gene product. Adenoviruses, on the other hand, are DNA viruses; they enter the cell via membrane receptors and remain episomal (unintegrated in the host DNA) in the nucleus. The transduction efficiency (infectivity) of adenoviruses is much greater than that of retroviruses in human tissues. They also have the advantage of transfecting non-dividing cells. But they are immunogenic and do not last for long. Recently, vectors based on HIV lentivirus are being tested as they are the most efficient vectors. Viruses are made non-pathogenic by removing some structural genes from its genome.

STRATEGIES FOR GENE THERAPY

Gene therapy strategy for different diseases varies depending on the genetic information available for a particular disease. Various strategies employed for gene therapy are described below.

Gene Augmentation Therapy

For a disease caused by a mutation leading to loss of function, introduction of a functional copy of the gene into the patient's cells will restore normal function of the cell. However, sustained, long-term expression of the therapeutic gene in an adequate and regulated amount is a major problem. For diseases like severe combined immunodeficiency syndrome (SCID) due to adenosine deaminase deficiency, and haemophilias, expression of even a small amount of protein is sufficient to ameliorate the symptoms. Such diseases are good candidates for gene therapy.

Targeted Mutation Correction

If a mutated gene produces a defective protein which by itself has the harmful effect, i.e. dominant negative effect, then the mutation has to be repaired. In this situation, introduction of a normal copy of the gene will not be effective. For this purpose, a normal copy of the gene is required to be targeted to the same location as the defective gene by homologous recombination. This approach has not yet been possible, although much research is continuing in this area.

RNA Interference (RNAi) for Inhibiting Gene Expression

RNA interference is the technology by which expression of the gene can be inhibited, so that the protein it codes for is not made. The system depends on introduction of double-stranded RNA (dsRNA) inside the cell which activates a cascade of events leading to destruction of the specific RNA molecule. The dsRNA may be in the form of silencing RNA (siRNA) or short hairpin RNA, (shRNA) which is made synthetically and introduced into cells, like DNA, for gene therapy. The sequence of the dsRNA molecule is the same as the sequence of the RNA that is targeted to be destroyed. This approach could be of great benefit in diseases such as cancer, where proteins known to play a role in cell proliferation and anti-apoptosis can be manipulated by this technique. Also, knocking down of the genes which confer resistance to chemotherapy/radiotherapy could sensitise tumour cells to treatment. Numerous trials blocking gene expression at RNA level are in progress and have shown promise.

Gene Therapy for SCID

In 1990, the first genetic disorder to be treated by gene therapy was ADA-SCID. The ADA mini gene was transferred by retroviral vector *ex-vivo* into peripheral blood lymphocytes from 2 patients undergoing enzyme replacement therapy. Long-term survival of transfected T- and B-lymphocytes, marrow cells, and granulocytes expressing the transferred ADA gene was demonstrated and resulted in restoration of cellular and humoral immunity. Although the haemopoietic stem cell would have been the ideal target cell for somatic cell gene therapy of the haematopoietic system, the use of T-lymphocytes as gene therapy vehicle was chosen since they represent the affected cells and known to be long survivors. Subsequently, 8 out of 10 children with ADA deficiency have been successfully treated following infusion of autologous CD34+ cells transduced with the ADA gene.

More recently children with X-linked SCID have shown almost complete reconstitution of their immune system after receiving retrovirally transduced autologous $CD34^+$ haematopoietic stem cells carrying a functional gamma chain of multiple cytokine receptor genes. These children are able to lead a normal life, have responded to several childhood immunisations and have shown good antibody response to infections. However, five of the 20 treated children subsequently developed a leukaemia-like disease after 3.5 years, probably due to the undesired activation of an oncogene by retroviral integration in the host genome.

Gene Therapy for Lysosomal Storage Disorders

Gene therapy is an attractive alternative in many lysosomal storage disorder patients who have responded poorly to bone marrow transplantation or enzyme replacement therapy. The primary goal is to introduce a normal copy of the gene for the lysosomal enzyme into a depot organ such as liver or muscle, so that there is sustained production and reconstitution of therapeutic levels of the enzyme in the affected tissues. A mouse model of Gaucher disease has been developed. In this model, chemically induced deficiency of glucocerebrosidase (GC) is created which results in accumulation of elevated levels of glucosylceramide (GL-1) in lysosomes of Kupffer cells. When these animals were administered mannose-terminated GC (cerezyme) there was reduction of GL-1 levels in liver. Gene transduction of hepatocytes with a plasmid DNA vector encoding human GC (pGZB-GC) achieved similar results. Based on pre-clinical studies, clinical trials are being carried-out where gene coding for GC is transferred to the haematopoietic cells. In one of the clinical trials, the GC gene was targeted via retroviral vector to CD34+ progenitor cells. Preliminary results indicate engraftment of genetically corrected cells in the patient. Further results are awaited.

GENE THERAPY IN CANCER

The largest number of gene therapy trials have been done in patients with cancer (about 65%). It may be not only because cancer is a genetic disease at somatic cell level, but more so out of desperation. Several approaches have been tried for this purpose, viz. (a) introduction of a gene to convert a prodrug to active cytocidal drug in tumour cells causing selective tumour cell destruction, (b) introduction of a multidrug resistant (MDR) gene in normal bone marrow cells to protect them from toxic effects of chemotherapy, (c) introduction of genes for enhancing antitumour immune responses, and (d) introduction of tumour suppressor gene, such as p53, mutation of which is related to several cancers. The latter therapy has even been approved in China for the treatment of head and neck cancer.

FUTURE OF GENE THERAPY

So far four patients have died related to gene therapy. In addition, the occurrence of leukaemia in successfully treated children with X-SCID has been a big dampner. Generally, reaction of the scientific community has been to go back to the bench. This has also served as an impetus to improve vectors and lay greater emphasis on *in situ* gene correction. Successes continue to be achieved in experimental models. Recently, it has been possible to cure sickle-cell disease in an experimental animal using transduced induced pleuripotent stem cells. The unbridled enthusiasm of the nineties has given way to more sober and more realistic expectations. So far the promise continues and the efforts are on. The success in treating SCID, and understanding the molecular basis of leukaemogenesis indicates that the dream may still come true.

6.8 Genetic Counselling and Prenatal Diagnosis

Shubha R Phadke

For most of the genetic disorders there is no curative treatment at present, or the treatment is cumbersome, costly and associated with risks. Also, many genetic disorders are associated with decreased life expectancy, and mental or physical handicap. Due to these reasons, families with a genetic disorder or those at risk of having an offspring with a genetic disorder, need information about the disease to help them cope with the problem and ways to prevent the occurrence or recurrence of the disorder. The process of communication of this information is genetic counselling. It is aimed to answer the questions of the family, viz. 'Why did this happen to me?", and "Will it recur in my family?' As genetic disorders can involve any system of the body, it is important that clinicians in all specialities are able to identify clinical presentations which are due to, or can possibly be due to, genetic disorders, counsel them and refer them to a geneticist for appropriate investigations and advice where available. In this chapter the importance of genetic counselling in the management of genetic disorders is stressed and basic principles of genetic counselling are discussed.

DEFINITION OF GENETIC COUNSELLING

The American Society of Human Genetics defined genetic counselling as 'a communicative process which deals with human problems associated with the occurrence and/or recurrence of a genetic disorder in a family'. This process involves an attempt by one or more appropriately trained persons to help an individual or a family to: (i) comprehend the medical facts, including the diagnosis, probable course of the disorder and available management; (ii) understand the manner in which heredity contributes to the disorder, and the risk of recurrence in the family; (iii) understand the alternatives for dealing with the risk of occurrence or recurrence; (iv) choose a course of action which seems to them appropriate in view of this risk, their family goals, ethical and religious standards and to act in accordance with the decision; and (v) make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder.

It is clear from the above definition that the primary goal of the genetic counselling is to educate the concerned persons about the medical aspects of the genetic disorder in their family. The family can use the information in a meaningful way to cope with the disorder and the risk of recurrence in accordance with their psychosocial and religious background.

A person who seeks genetic counselling is called consultand or 'counsellee', and the person who gives the advice is called the counsellor. In association with a medical specialist, persons with various backgrounds such as nursing, sociology, psychology or genetics can be trained as genetic counsellor.

INDICATIONS FOR GENETIC COUNSELLING

The following clinical presentations indicate the need for referral to a clinical geneticist and genetic counselling:

1. Congenital malformation: Lethal or non-lethal, isolated or multiple, prenatal or postnatal.
2. Still births/perinatal deaths with or without malformation.
3. Developmental delay or mental retardation with or without malformations, facial dysmorphism and/or neurological deficit.
4. Neurodegenerative diseases presenting as focal neurological deficit, ataxia, spasticity, hypotonia, seizures or psychomotor regression.
5. Mypopathies and muscular dystrophies.
6. A neonate or an infant with acute sickness, or failure to thrive or has recurrent episodes of vomiting, acidosis and/or convulsions.
7. Ambiguous genitalia or abnormalities of sexual development like primary amenorrhoea and delayed puberty.
8. Infertility and poor obstetric history like recurrent spontaneous abortions and foetal losses.
9. Proportionate or disproportionate short stature.
10. Childhood deafness.
11. Known monogenic disorders like thalassaemia, Wilson disease, haemophilia A, mucopolysaccharidosis, etc.
12. Down's Syndrome and other chromosomal disorders.
13. Familial cancers or cancer prone disorders.
14. Relatives of an individual having a structural abnormality of a chromosome or chromosomes.
15. Any unusual disease of the skin, eyes, bones or unusual facial features.
16. Any disease which is familial.
17. Exposure to a known or possible teratogen during pregnancy.
18. Consanguineous marriage.
19. Advanced maternal age.
20. Carrier of a genetic disorder.
21. Positive screening test for a genetic disorder.

STEPS IN GENETIC COUNSELLING

The process of genetic counselling is quite complex. It requires correct diagnosis and latest information about medical and genetic aspects of the disorder. The steps of genetic counselling are as follows:

1. Accurate diagnosis of the proband
   (a) History taking
   (b) Pedigree drawing

(c) Clinical examination
(d) Biochemical, haematological, imaging and other necessary investigations.

2. Chromosomal or DNA tests, as needed.
3. Latest information about pathophysiology of the disease, available treatment, risk of recurrence, and availability of prenatal diagnostic test.
4. Communicating the information in simple, layman's language to the consultand and family members concerned.
5. Giving the consult and a written or typed case summary which includes the case details, diagnosis and details of genetic counselling.
6. Follow-up sessions may be needed to support the family, communicate new information, and observe any progression of the disease in the proband.

In addition to accurate diagnosis, consideration of many other issues like psychosocial, religious, educational and ethical are of paramount importance for effective genetic counselling. Success of genetic counselling depends on whether the consultand feels benefited by genetic counselling or not. Hence, it is important to assess the expectations of the consultand and to tailor the counselling accordingly, keeping in mind the psychosocial, religious and educational backgrounds of the consultand.

Genetic counselling for some common genetic disorders is discussed below. This is to illustrate the principles of genetic counselling and various issues involved in the process.

CASE-I

Down's Syndrome: A Common Chromosomal Syndrome and the Commonest Genetic Cause of Mental Retardation

A 3-month-old infant was brought to the clinic with rapid breathing, feeding difficulty and excessive crying. The child had a pansystolic murmur in the left parasternal region and typical facial features like flat face, hypertelorism, upslant of eyes and Simian crease on both hands. The diagnosis was Down's syndrome with ventricular septal defect with congestive cardiac failure.

In addition to echocardiography and treatment of cardiac failure, the karyotype from blood was recommended. Karyotype is needed not only to confirm the diagnosis of Down's syndrome but also to know the type of chromosomal abnormality. Ninety-five per cent of Down's syndrome cases are due to free trisomy 21 (47,+21) (**Figure 1**), and the risk of recurrence in siblings of such a child is 1%. Four per cent of Down's Syndrome cases are because of translocation of chromosome 21 to 14, 15, 21 or 22 (**Figure 2**). Karyotypes of both parents of such a case are essential. The risk of recurrence varies depending on the chromosome involved and sex of the carrier parent (**Table 1**). The karyotyping of parents of a child with free trisomy 21 is not indicated.

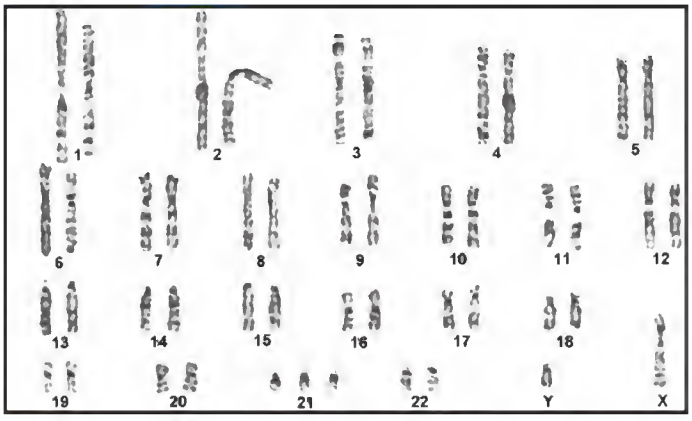

Figure 1: Karyotype showing free trisomy 21.

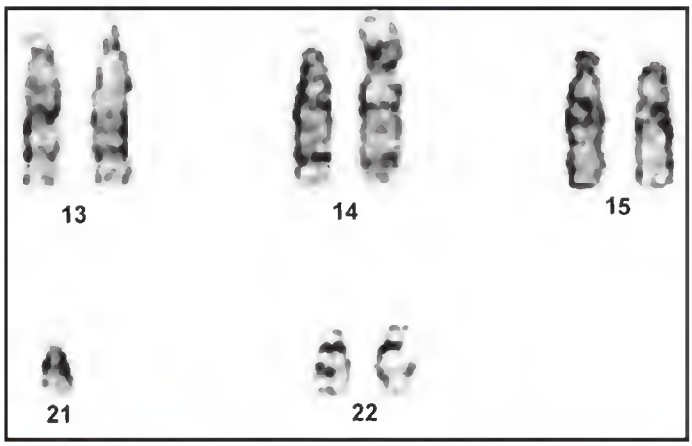

Figure 2: Partial karyotypes showing balanced translocation between chromosomes 14 and 21.

Table 1: Risk of Recurrence of Down's Syndrome in the Offspring of a Parent with a Balanced Translocation

Translocation	Carrier Father	Carrier Mother
t(14;21)	1% to 5%	15%
t(21;22)	1% to 5%	15%
t(21;21)	100%	100%

Genetic counselling

The challenge in this case is to break the news of the diagnosis of Down's syndrome to the parents. Further, the parents are to be advised regarding the need for surgical treatment of the cardiac defect, and associated problem of mental sub-normality and developmental delay which would become more pronounced as the child grows. Realistic information about mental abilities is essential. Though the intelligent quotient (IQ) of Down's syndrome cases varies from 40 to 70 or more, most of the cases with Down's syndrome are moderately retarded. Though late, they learn to walk, talk, carry-out self-care activities, and can also be taught to do simple repetitive tasks. They can work in a supervised and sheltered workplace. They can lead a loving, useful and happy life but need lifelong supervision. Importance of regular surveillance for hypothyroidism and hearing and ophthalmological problems needs to be stressed, but increased risk of leukaemia and atlanto-axial dislocation need not be told in the first visit as the risk of these conditions is very small. Risk of recurrence of Down's syndrome in any subsequent pregnancy should be discussed after the karyotype report is available. Prenatal diagnosis in the next pregnancy can prevent recurrence and the family should be provided the information before planning the next pregnancy.

Messages

1. The diagnosis of Down's syndrome is obvious at birth and should be communicated to the family soon after birth. This helps in screening for major malformations immediately

after birth and timely treatment. Of course giving the bad news of the birth of a child with mental sub-normality to the family, happy with the childbirth and an apparently normal looking neonate is a challenge to the paediatrician and obstetrician.

2. Chromosomal analysis of all children with Down's syndrome is important to provide the risk of recurrence and prenatal diagnosis.
3. Prenatal diagnosis of Down's syndrome is possible by doing karyotype analysis from chorionic villi or an amniotic fluid sample.
4. The primary care physician or a paediatrician can take up the responsibility of providing regular follow-up needed for children with Down's syndrome. This includes clinical examination for associated abnormalities, investigations for iron deficiency anaemia, hypothyroidism and ophthalmologic and ear examinations.

CASE-II

Prenatally Detected Mild Ventriculomegaly at 20 Weeks of Gestation on Routine Ultrasound Examination

A 32-year-old lady married for 8 years, who conceived after treatment for infertility, came for routine ultrasonography (USG) at 20 weeks of gestation. In the first year of her marriage, she had two spontaneous abortions at 10 weeks of gestation. The USG showed mild ventriculomegaly. Hence, she was referred for genetic counselling.

The first step of genetic counselling was to get a targeted ultrasonographic examination done to look for associated malformations. It showed mild dilatation of the lateral ventricles of the brain with open spinal defect and a large sac in the thoracolumbar region. There was no talipes equinovarus deformity or any major malformation of the heart, kidneys, abdominal wall, face, etc.

Genetic counselling

Meningomyelocoele is a major malformation which is often associated with Arnold-Chiari malformation and obstructive hydrocephalus. These defects are surgically treatable. But in spite of surgery after birth, many (50% or more) of the operated cases may have residual neurological defects including paraplegia, bladder-bowel incontinence and cognitive defects due to ventriculomegaly. In some cases hydrocephalus progresses rapidly, which may need destructive surgery for large head causing obstructed labour or may lead to stillbirth. The mother should be asked about the history of taking teratogenic drugs like anticonvulsants, and investigated for diabetes mellitus, as these are common risk factors for neural tube defect. Though the chance of chromosomal abnormality with isolated neural tube defect is low, prenatal chromosomal analysis by amniocentesis is recommended for proper counselling. If the family opts to continue the pregnancy regular follow-up USG examination, delivery at a good centre with good neonatal facilities, consultation with a paediatric surgeon or a neurosurgeon needs to be arranged.

If the family opts for termination of pregnancy, foetal autopsy, or after delivery detailed clinical and radiological examination of the baby is essential for counselling regarding risk of recurrence in a subsequent pregnancy. The risk of recurrence of isolated neural tube defect in the next pregnancy after the birth of one affected child is 5% and can be reduced by intake of folic acid by the mother during periconceptional period. If the meningocoele/meningomyelocoele is a part of a multiple malformation syndrome like spondylothoracic dysplasia or Meckel-Gruber syndrome then the risk of recurrence is 25%. Accurate diagnosis is also important to provide prenatal diagnosis during the next pregnancy which can be done ultrasonographically, as early as at 14 weeks. One USG at 16 to 18 weeks by an ultrasonographer with specialisation in prenatal diagnosis will be able to detect open neural tube defect with almost 100% sensitivity.

Messages

1. One routine USG examination should be offered at 16 to 18 weeks of gestation for prenatal diagnosis of malformations.
2. Accurate diagnosis of associated malformations and foetal chromosomal analysis is important for giving information about prognosis of malformation.
3. The information about possible outcomes of the malformation, especially if the malformation is treatable, will help the family in deciding about continuation or termination of pregnancy.
4. The uncertainties in providing exact outcome in each case should be truthfully shared with the family.
5. The genetic counselling should be non-directive. Possibilities of good and bad outcomes should be told with their likelihood. Many other factors like presence of previous normal or similarly affected children, age of mother, history of infertility may affect the family's decision. In this case, due to long period of infertility and two spontaneous abortions, the family may not take up the option of amniocentesis for karyotyping as it is an invasive procedure and associated with a small risk of abortion.
6. Autopsy of foetuses terminated after prenatal diagnosis of malformations is important not only for confirmation of prenatal diagnosis but also to look for associated malformations which may have been missed on USG, or may not be detectable on USG. Autopsy may change the diagnosis in about 30 to 50% foetuses, hence, essential for genetic counselling.

CASE-III

Pre-pregnancy Counselling for Family History of Huntington Chorea

A couple married for 2 years and planning to raise a family came for genetic counselling. The husband was 32-year-old and the wife was 27-year-old. The husband's brother who is 40-year-old had developed abnormal movements since the last 4 years and was diagnosed to have Huntington chorea. His father died at the age of 65 years, who suffered from similar problems for 10 years and had become bed-ridden. The couple wanted to know whether their child could have the same disease and whether it could be avoided.

Genetic counselling

The first step of genetic counselling is to draw a pedigree chart and confirm the diagnosis. A 3-generation pedigree chart was

drawn which showed that two of the uncles of the consultand (husband in this case) were similarly affected and one of them was seen as an out-patient at the Department of Genetics. The family was asked to get the medical records of the affected uncle with his permission. The records confirmed the diagnosis of Huntington chorea by a neurologist as well as by DNA-based mutation analysis. The DNA test showed that the uncle with Huntington disease had 44 CAG repeats in HD gene and the other copy was normal (20 CAG repeats). This confirmed the presence of mutated HD gene in the family.

Now, the question: What is the risk of Huntington disease mutation in the offspring of the couple? This will depend on whether the consultand himself is carrying the mutation or not. As Huntington disease usually manifests after 40 years of age, many individuals who carry the mutation will be clinically normal at 32 years of age. Hence, it is essential to test the husband's DNA for HD mutation. If he is not the carrier of the mutation, he will not develop the disease in future and also there is no risk of Huntington disease in the offspring of the couple and prenatal diagnosis is not indicated. But if he is a carrier of mutation, then there is 50% chance that the offspring may inherit the mutated copy of the gene from him and develop the disease in future. The age of onset of symptoms depends on the number of CAG repeats and the number of repeats may increase when the mutation is transmitted from one generation to the next. The individuals with repeats around 80 may develop the disease in childhood. The birth of a child with HD mutation can be avoided by prenatally testing the mutation in chorionic villi at 10 to 12 weeks of gestation providing the couple an option for reproductive planning. All DNA-based tests have some error rate, usually around 1%.

This opens a lot of issues for the family. First, pre-symptomatic diagnosis in the husband may cause major psychological problems as there is no treatment for the disease. Also, if this information if not kept private and confidential it may cause problems at the job, and for medical insurance, etc. Hence, the couple should be given time before opting for DNA testing. If after adequate counselling and careful deliberation the consultand wants to go for a DNA test, then it should be ordered. After the results are available, the couple should be explained the results, and post-test counselling should be provided. Continued psychological support may be needed. If the husband is the carrier of mutation, there is 50% risk of transmitting the mutation to the offspring. Many laboratories and also families are not comfortable with the idea of termination of a affected pregnancy as the foetus will not manifest the disease until 3 to 4 decades. This is ethically debatable, especially with the present pace of developments in the field of genetics, where new treatments for many genetic diseases are expected in the future. After discussing all these issues in a non-directive manner, the family may take their reproductive decision. The whole process may take many sessions to understand difficult scientific information and various complexities of the situation.

Messages

1. DNA-based diagnosis is available for many single gene disorders and is useful for diagnosis of patient and prenatal diagnosis.
2. The confirmation of diagnosis in the proband or affected member of the family is an important first step before providing genetic counselling.
3. Mutation detection is essential for prenatal diagnosis based on DNA analysis.
4. The counselling should be non-directive and the family should make their own reproductive decisions.
5. The genetic counselling involves providing a lot of scientific information and probabilities, which may be a difficult task, for which very good communication skills are needed to be a good genetic counsellor.
6. The information provided during genetic counselling may be psychologically disturbing and adequate pre-test and post-test counselling is necessary.
7. Pre-symptomatic and prenatal diagnosis of late onset genetic disorders pose a lot of ethical, legal and social dilemmas and need to be dealt with sensitivity.
8. Pre-pregnancy counselling plays an important role in genetic disorders and is the most appropriate time for genetic counselling, as it provides time for organising investigations, understanding the situation and making appropriate decisions.

CASE-IV

Counselling for Familial Breast Cancer

A 28-year-old married woman comes for genetic counselling as her 35-year-old sister is diagnosed to have carcinoma breast and her mother died of carcinoma breast at the age of 50 years. Pedigree chart showed that one sister of her mother had carcinoma of ovary. Her maternal uncle's wife also had carcinoma breast.

Genetic counselling

Presence of three blood relatives with carcinoma breast and ovarian carcinoma suggests familial breast cancer. Note that the wife of her maternal uncle is not her blood relative and medical ailments in her do not influence the risk of genetic disorders in the consultand. Such an individual needs to be offered surveillance for carcinoma breast and ovaries as early detection may help in better treatment and improve outcome. This is the case where mutation detection in carcinoma breast related genes, namely, BRCA1 and BRCA2 is indicated. The BRCA1 and BRCA2 account for 50% and 30% of familial breast cancers, respectively. First the mutation has to be tested in one of the individuals with carcinoma breast (it can be done on the operated breast cancer tissue), and if the mutation is detected then DNA testing of the consultand and other probable carriers in the family (who are more than 18 years of age) needs to be discussed. The individuals who have the mutation need to be kept under close surveillance for carcinoma breast and ovaries as per accepted guidelines. The confirmed carriers of BRCA gene mutations can be offered even radical measures like prophylactic mastectomy or oophorectomy.

Messages

1. Three or more family members with one type of cancer or related cancers should alert the clinician for the possibility of familial cancers and refer the family for genetic counselling.

2. The pointers towards the possibility of familial cancer include cancer at young age, co-occurrence of multiple primary cancers and bilateral cancers in paired organs, associated clinical features like hyperpigmentation of lips (Peutz-Jeghers syndrome), adenomatous polyposis colon, neurofibromatosis, etc.
3. Mutation detection in the individual with the cancer is important before the mutation-based screening can be offered to the unaffected family members.
4. Mutation testing for carcinoma breast and other familial cancers is technically demanding, costly and not easily available. Even if mutation detections not done, continued surveillance for early diagnosis can be offered to individuals with familial cancer.

CASE-V

A Couple with Three Recurrent Spontaneous Abortions in the First Trimester

A non-consanguineous couple with three spontaneous abortions was referred for genetic testing. The chromosomal analysis from peripheral blood was done for both the spouses. The karyotype of the wife showed a balanced translocation between chromosomes 7 and 11 (**Figure 3**).

Genetic counselling

The balanced translocation in this case is likely to be the cause of recurrent spontaneous abortions in this case. The gametes of an individual with a balanced rearrangement may have unbalanced karyotype and the conceptus with a major chromosomal imbalance may not be compatible with life and abort spontaneously. As such individuals also have gametes with normal chromosomal complement, or balanced chromosomal complement, so they can have normal offspring as well. The risk of repeated abortions is about 30% but may vary depending on the chromosomes involved and their breakpoints. There is no treatment to prevent formation of unbalanced gametes or to prevent abortion. Some of the chromosomal imbalances may be small and such foetuses may not be aborted but may have malformations or a mental handicap. Hence, this couple should be offered prenatal karyotyping by amniocentesis if the pregnancy continues beyond the first trimester.

The other options are use of donor ova (or sperms, if husband is the carrier of a balanced chromosomal rearrangement), or preimplantation diagnosis. The latter involves *in vitro* fertilisation and single cell genetic test which in addition to being costly is also not easily available.

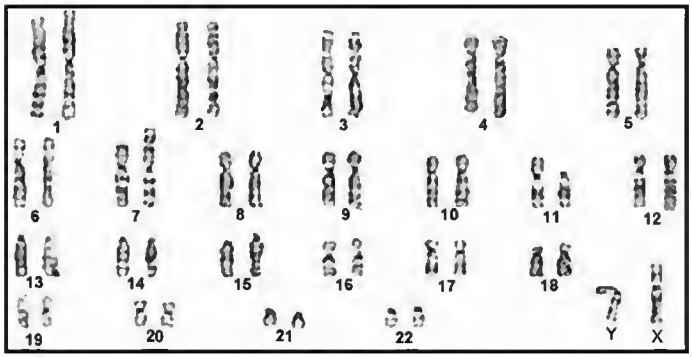

Figure 3: A karyotype showing a balanced translocation between chromosomes 7 and 11.

The other treatable causes of recurrent abortion should also be simultaneously investigated as more than one cause may coexist. Investigations for toxoplasmosis, rubella and cytomegalovirus infections are not indicated as they do not cause recurrent abortions.

Messages

1. About 5% of the couples with recurrent spontaneous abortions have one spouse with balanced chromosomal rearrangement.
2. If the karyotype is abnormal, there is no treatment but counselling, and prenatal diagnosis is needed.
3. One in 500 normal people have a balanced chromosomal translocation, and such carriers are usually phenotypically normal.
4. The individual with balanced translocation is not at any risk of medical ailment due to chromosomal abnormality.
5. All attempts should be made while counselling such a couple to protect from blame or guilt in the family.
6. Chromosomal variants, such as long 'Y' chromosome, pericentric inversion of chromosome 9, etc. are not known to be associated with recurrent spontaneous abortions.

CASE-VI

A Family with a Two-year-old Child with Metachromatic Leukodystrophy

A couple came with a 2-year-old son who was diagnosed as a case of cerebral palsy. The mother of the child was 6 weeks pregnant. The family wanted to know the risk of recurrence of a similar problem in the next child.

The pedigree chart showed that the parents were cousins and their first child had a similar problem and had died at two-and-a-half years of age. The proband (the affected child) was normally developing till about one year of age and was able to stand without support. Then he lost the milestones, and developed scissoring of lower limbs (**Figure 4**). There was hypertonia of limbs with exaggerated knee reflexes and absent ankle reflex. The deterioration continued. Magnetic resonance imaging (MRI) brain showed changes indicative of white matter involvement. The enzyme assay for metachromatic leukodystrophy showed deficiency of aryl sulphatase A which confirmed the diagnosis of metachromatic leukodystrophy.

Genetic counselling

Metachromatic leukodystrophy is an autosomal recessive disorder and the risk of recurrence to a subsequent child of these parents is 25%, i.e. 1 in 4. The prenatal diagnosis can be carried out by assaying the enzyme in chorionic villi at 11 weeks of gestation. If the foetus is found to be deficient in the enzyme, the family can take an appropriate decision according to their convictions.

If by DNA sequencing of the aryl sulphatase A gene (ARSA) mutations can be identified in the proband or his parents then prenatal diagnosis by mutation detection can be done. DNA-based prenatal diagnosis is more accurate than that by biochemical test (enzyme assay).

Figure 4: A child with metachromatic leukodystrophy. Note the scissoring of lower limbs.

Messages

1. All children with developmental neurological problems should not be labelled as cerebral palsy without evaluation, as many genetic disorders may manifest as developmental delay or mental retardation which superficially mimics cerebral palsy.
2. Presence of normal development followed by regression of milestones is characteristic of metabolic disorders.
3. Presence of consanguinity, or similarly affected 2 or more siblings, suggests the possibility of an autosomal recessive disorder.
4. Confirmation of genetic metabolic disorder by enzyme assay of involved metabolic pathway is essential for diagnosis, genetic counselling and prenatal diagnosis.

PRENATAL DIAGNOSIS

The availability of prenatal diagnosis for a number of genetic disorders has made counselling and decision-making easier. A variety of tissues can be collected from the foetus for chromosomal, DNA and biochemical analysis. These include chorionic villi (11-12 weeks of gestation) and amniotic fluid (16-20 weeks). Rarely, foetal skin, muscle, liver biopsy or blood sample may be collected for biochemical or tissue analysis. Analysis of foetal cells and foetal DNA from mother's blood has become technically possible and can be used for foetal Rh typing. Prenatal diagnosis based on free foetal DNA in mother's plasma is used not only for single gene disorders but also for aneuploidy detection. Preimplantation diagnosis is a good option for families who do not approve of termination of pregnancy.

High resolution ultrasonography can detect a number of structural malformations of the central nervous system, gut, kidneys, limbs, spine and heart. Detection of associated malformations and chromosomal analysis is useful for providing counselling in a case with prenatally detected malformation. But for counselling regarding next pregnancy, examination of baby or foetus after delivery or termination (foetal autopsy) is important, because in 30% to 40% cases associated malformations may be missed or may not be detectable on ultrasonography.

CONCLUSION

All cases in which a genetic disorder is diagnosed or suspected, a complete evaluation of the affected individual and genetic investigations are important. Genetic counselling is an integral part of management of a case with genetic disorder. It is the responsibility of the primary care physician to suspect cases with a probable genetic disorder and refer them to a clinical genetics centre. As the clinical geneticists are few in number, paediatricians, obstetricians and physicians may have to take up the responsibility of providing diagnosis and counselling for common genetic disorders.

6.9 Pharmacogenomics and Personalised Medicine

C Adithan

Optimal therapy for major illnesses is still elusive. The drug therapy of psychiatric illnesses, cancer, hypertension and many other common diseases is associated with unsatisfactory response and undesirable adverse effects. Many approaches have been adopted to improve this condition. Among them the role of genetic factors in drug response is very important.

PHARMACOGENETICS AND PHARMACOGENOMICS

The action of a drug is regulated by several factors, namely drug metabolising enzymes, transporter proteins, receptors and several other mediators. These enzymes and proteins are encoded by genes in the deoxyribonucleic acid (DNA). A number of variations have been identified in the structure of genes encoding these factors. This can result in varying drug responses in each individual depending upon their genetic make-up. A genetic variation occurring in more than 1% of the population is termed as genetic polymorphism. The study of the effect of a single gene or genetic polymorphism on drug response is called pharmacogenetics. Study of the effect of variations in multiple genes, including whole genome approach, on drug response is called pharmacogenomics. It is predicted that application of pharmacogenomics in clinical practice may lead to individualised drug therapy (personalised medicine), thus, paving the way for improved effectiveness and reduced adverse drug reactions.

PERSONALISED MEDICINE

Personalised medicine is the science concerned with providing medical care tailored to the genomic and molecular profile of an individual patient. The physician selects the drug and its dosage using detailed information about the patient including clinical data, genotype or level of gene expression, drug profile, as well as genetic details of the causative organism, if any. The important pre-requisites for success of personalised medicine are valid biomarkers and availability of reliable, simple and affordable genetic tests.

CLINICAL APPLICATIONS

The clinical practice of personalised medicine has started to receive attention with more drugs being discovered using methods of pharmacogenetics. For a drug to be used clinically based on pharmacogenetic data, identification and establishment of a valid pharmacogenetic biomarker is necessary. Some of the drugs for which a valid pharmacogenetic biomarker has been identified are warfarin, irinotecan, carbamazepine, abacavir, azathioprine, trastuzumab, imatinib, maraviroc, rituximab, omeprazole, and clopidogrel.

Oral Anticoagulant Drugs

Warfarin, an oral anticoagulant is used in patients with cardiovascular disorders. The most common complication of warfarin includes bleeding manifestations. It is metabolised by the enzyme CYP2C9 encoded by the gene CYP2C9. Further, its activity depends on the enzyme epoxide reductase complex 1 encoded by the gene *VKORC1*. Variations in the nucleotide sequences of the coding region of these enzymes result in altered metabolism and activity of warfarin. Patients with the variant genotypes, such as *CYP2C9 *1/*3* and *VKORC1 AA* have six-times lower dose requirement compared to the common genotypes of *CYP2C9 *1/*1* and *VKORC1 GG*. The United States Food and Drug Administration (US-FDA) has made label changes in warfarin and recommended genetic testing for these two genes before initiation of warfarin therapy. Based on the genotype of the patient, the dose has to be adjusted to an optimum level of international normalised ratio (INR).

Anticancer Drugs

Irinotecan, an inhibitor of the enzyme topoisomerase 1 is used as an anticancer agent. It is a pro-drug and gets converted to an active form SN 38 which inactivates topoisomerase 1, and thus, inhibits DNA replication. The SN 38 gets inactivate by the process of glucuronidation by the enzyme UGT1A1. This enzyme is encoded by the gene *UGT1A1*. It was found that the variant genotype *UGT1A1 *28/*28* was associated with impaired conjugation, and hence, results in higher plasma levels of SN38. This genotype was associated with greater haematological toxicity. This led to changes in the label of irinotecan by the US-FDA which also recommended genetic testing for patients who are to be started on treatment with irinotecan.

Anticancer agents such, as azathioprine and 6-mercaptopurine are metabolised by the enzyme thiopurine methyl transferase enzyme (TPMT) encoded by the gene *TPMT*. Individuals with variant genotype of *TPMT* have reduced or absent enzyme resulting in high drug levels and greater myelo-toxicity. It is recommended to do a genotype or phenotype test for TPMT before starting thiopurine therapy.

Other drugs where genetic testing is preferred, include trastuzumab, rituximab, imatinib and maraviroc. Trastuzumab, a monoclonal antibody targeting the HER2 protein is used in breast cancer patients who are over-expressing HER2/neu protein. It is more effective in the treatment of early stage HER2 positive breast cancer patients. Rituximab, a monoclonal antibody directed against the CD-20 protein in B-cell lymphocytes is approved for use in B-cell non-Hodgkin lymphoma and rheumatoid arthritis. The patients may be tested for expression of CD-20 protein by the B-cells for initiation of therapy with rituximab. Imatinib mesylate is used for treatment of chronic myeloid leukaemia which is associated with the chromosomal abnormality termed as 'Philadelphia chromosome' which produces mutant protein responsible for cell proliferation. Imatinib inactivates this overactive protein BCR-ABL-tyrosine kinase. Thus, testing for this genetic abnormality is necessary for treatment with imatinib mesylate.

Antiretroviral Drugs

Abacavir, the antiretroviral drug was found to have higher incidence of hypersensitivity reactions associated with patients having human leucocyte antigen (HLA)*5701. The development of high resolution HLA typing enabled identification of patients at risk for abacavir hypersensitivity and avoided adverse drug reactions. After the publication of PREDICT1 and SHAPE studies, there has been an increased demand for HLA typing tests for patients with human immunodeficiency virus (HIV) infection.

Maraviroc, an antiretroviral drug, prevents entry of HIV into the host cell by binding the CCR5 protein on cell surface. The virus requires binding to CCR5 protein for cell membrane fusion and entry into host cell. Thus, the entry of CCR5 tropic viruses is inhibited. However, the viruses which are CXCR4 tropic do not respond to maraviroc and result in dominance of CXCR4 tropic strains. It is recommended to test for tropism of the virus strain in a patient before initiation of therapy with maraviroc.

Omeprazole and Clopidogrel

The proton pump inhibitor omeprazole is metabolised by CYP2C19 enzyme. Patients with variant genotype *CYP2C19 *2/*2* have markedly reduced metabolism of omeprazole. This has been found to result in higher cure rates with anti-*Helicobacter pylori* regimen in such patients. For a patient with similar variant genotype *CYP2C19 *2/*2*, the anti-platelet drug clopidogrel can have reduced therapeutic effect due to reduced conversion to its active metabolite by the enzyme CYP2C19. In such patients, genotyping for CYP2C19 polymorphism would enable selection of a suitable alternative anti-platelet drug.

Stevens-Johnson Syndrome

Stevens-Johnson syndrome (SJS), a severe form of dermatological manifestation of hypersensitivity reaction to drugs, was found to occur with the anti-epileptic drugs, carbamazepine. Studies have shown a strong association between the HLA-B*1502 and occurrence of SJS in patients receiving this drug. This variant gene was found to occur at higher frequency in Hans Chinese, Malays and Thais. Based on strong association demonstrated, the US-FDA made label changes in carbamazepine and recommended testing for HLA-B*1502 in Asian populations before starting therapy with carbamazepine. This would help in identifying patients who are at risk of developing SJS with carbamazepine, and thus, avoid drug-induced morbidity.

BARRIERS FOR PHARMACOGENETIC TESTING

Although extensive studies are being done in the field of pharmacogenomics, the concept of personalised medicine is yet to be incorporated in clinical practice to a large extent. This can be attributed to factors, such as increase in cost of therapy due to inclusion of pharmacogenetic testing as part of drug therapy and difficulty in imparting the pharmacogenetic knowledge to clinicians on a wider scale. Further, availability of laboratory facilities to do pharmacogenetic tests is necessary for the widespread use of pharmacogenetics in clinical practice. Most clinicians prefer to rely on clinical and biochemical parameters for dose selection and empiric dose titration rather than testing for genetic make-up of the individual.

The cost of genotyping could be a major limiting factor in application of pharmacogenetics on a larger scale in clinical practice. One alternative is to do bulk testing. The cost of genotyping 1000 DNA samples is approximately 0.3 to 0.5 USD (US Dollors) per genotype compared to 130 USD for testing of a single sample. This difference is due to the fixed price of the set-up of assay marker. Hence, patient samples can be analysed only when collected in large numbers.

Several ethical issues arise with the application of pharmacogenetic methods. Categorisation of populations based on genotypes may result in exclusion of smaller groups of people from usage of drugs which are brought into the market based on pharmacogenetic tests. Further, revelation of genetic risk factors for late onset diseases and variation in drug response for such diseases may have profound psychological impact on the patient and affect the quality of life. This information can also lead to denial or increased cost of insurance policy coverage for such people.

Pharmacogenomics and personalised medicine have many promising features but there are issues in their application on a larger scale for clinical practice. They can be solved only by further refining of the process involved in it and policy decision making by the government.

6.10 Cancer Genetics

Rajiv Sarin

CANCER IS A GENETIC DISEASE

Cancer is a 'genetic disease', as gene mutation/s and chromosomal alterations are the hallmark of all cancer cells. The term 'genetic' in this context refers to molecular pathology of the disease and not to transmission from generation to generation, as is often the case for hereditary diseases. It shall be noted that while all cancers are characterised by genetic alterations, only 2% to 5% of human cancers are hereditary. It is because the genetic alterations in cancers are acquired, and remain restricted to the somatic cell. The origin of hereditary cancers is discussed separately.

The genes associated with causation of cancer are broadly classified into two types, viz. 'tumour suppressor genes' (TSGs) and 'proto-oncogenes', based on their normal cellular function and mechanism of causation of cancer. Knowledge of specific genetic alteration/s which gives rise to a particular cancer has been of immense use in improving prognostic classification, and development of targeted therapy for several cancers. In case of hereditary cancers it can be used for detection of carrier status, genetic counselling and cancer prevention.

MULTI-STEP CARCINOGENESIS AND CLONAL ORIGIN OF CANCER

The process of carcinogenesis is characterised by three steps - initiation, promotion and progression. Accumulation of 5-10 mutations in specific genes is invariably required for a normal cell to transform into a malignant phenotype as shown for the colon cancer model by Vogelstein (**Figure 1**). According to the clonal theory of cancer, cancer initiates from a single cell. It progresses through a series of mutations at successive cell divisions, with selection at each step, resulting in the establishment of an autonomous, malignant clone with selective growth advantage which leads to formation of a tumour mass. During their long natural history, most cancers develop molecular heterogeneity due to development of sub-clones, ultimately leading to development of the 'metastatic clone' which eventually kills the individual.

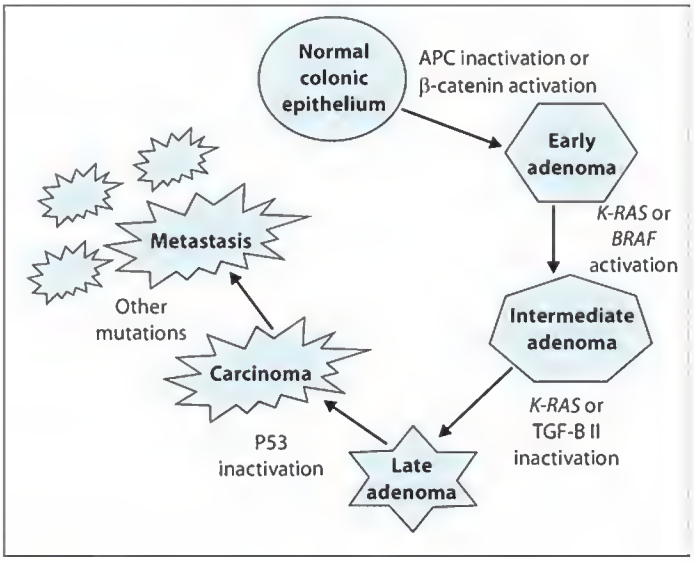

Figure 1: Multi-step carcinogenesis (Vogelstein's colon cancer model).

GENOMIC INSTABILITY

Genomic instability is a cardinal feature of cancer. In certain hereditary cancer syndromes, the underlying defect mismatch repair pathway, as seen in hereditary non-polyposis colon cancer (HNPCC), or neucleotide excision repair pathway (NERP) as seen in xeroderma pigmentosa (XP), which results in genomic instability and cancer. In sporadic cancers, the genomic instability is often the result of accumulation of several mutational events during malignant transformation and progression.

ONCOGENES AND TUMOUR SUPPRESSOR GENES

Oncogene, the activated form of proto-oncogene, is the 'accelerator switch' of cell division while tumour suppressor gene (TSG) is the 'natural brake' of cell division (**Table 1**). Mutations in specific domains of proto-oncogenes, their amplification or translocation, sometimes leading to formation of fusion genes, result in gain of function and constitutive activation of mechanisms controlling cell proliferation. Germline point mutation in the cysteine rich extracellular domain or intracellular tyrosine kinase domain of RET proto-oncogene resulting in multiple endocrine neoplasia (MEN-2) syndrome is a classical example of oncogene driven hereditary cancer. A somatic mutation, or over-expression of oncogenes, is a common mechanism of sustained growth stimulus in sporadic cancers. Some clinically relevant examples include point mutations in phosphate binding loop of K-RAS in pancreatic, colon and lung cancer; catalytic kinase domain of epidermal growth factor receptor (EGFR) in head, neck, lung and pancreatic cancers; over-expression of C-ERBB2 in breast cancer and the BCR-ABL fusion gene in chronic mylogenous leukaemia (CML). In contrast to gain-in-function mutations of oncogenes, TSGs undergo loss-of-function when certain mutations or chromosomal alterations lead to diminution in normal activity of proteins controlling apoptosis (p53 protein); cell cycle regulation (RB protein), or DNA damage repair (BRCA1 or XP proteins), etc. Somatic mutation in p53 gene is one of the most frequently occurring genetic alterations in human cancers.

TSGs are broadly classified as *Gatekeeper* or *Caretaker* genes based on their normal cellular function. As the names imply, the gatekeeper genes control critical events and check points in the cell cycle (RB, TP53, APC, etc.), while the caretaker genes maintain genomic integrity through their critical role in DNA repair (mismatch repair genes, nucleotide excision repair genes, BRCA1, etc).

Table 1: Comparison Between Oncogenes and Tumour Suppressor Genes

Oncogene (Activated Proto-oncogene)	Tumour Suppressor Gene
Encode components of a signalling pathway that regulate cell proliferation and control the machinery of cell cycle (e.g. MYC, RAS or EGFR, etc).	Regulate cell cycle progression (e.g. RB), apoptosis (e.g. p53) and DNA damage repair (e.g. BRCA1/2)
Mutation or over-expression of a single allele results in gain of function which drives cell proliferation and malignant transformation	Mutation or deletion of both alleles results in loss of tumour suppressor function thereby allowing malignant transformation
Examples	**Examples**
Point mutations (missense) KRAS in pancreatic and colon cancers RET in multiple endocrine neoplasia (MEN-2) syndrome	Point mutations (missense, nonsense, frameshift) TP53 in Li-Fraumeni syndrome RB1 gene in retinoblastoma BRCA1 and 2 in HBOC syndrome APC genes in familial adenomatous polyposis Mismatch repair genes in HNPCC
Gene amplification/over-expression NMYC in neuroblastomas C-ERBB2/HER2neu in breast cancer	Large genomic rearrangements BRCA1 and 2 in HBOC Mismatch repair genes in HNPCC
Chromosomal translocation ABL (9q34) to BCR (22q11) in CML MYC (8q24) to IgH (14q32) in Burkitt's lymphoma FLI1 (11q24) to EWS (22q12) in Ewing's sarcoma	Deletion WT1 in Wilm's tumour SMAD4 in pancreatic and colon cancers
Aneuploidy Loss of chromosome 10 (PTEN) in glioblastomas	

KNUDSON'S TWO HIT HYPOTHESIS FOR TUMOUR SUPPRESSOR GENE (RETINOBLASTOMA PARADIGM)

Knudson proposed the "two hit hypothesis" to explain genesis of retinoblastoma, a childhood malignant tumour of the eye, and clinical features distinguishing hereditary from sporadic retinoblastoma. Hereditary form of retinoblastoma occurs at a younger age, generally in the first year of life and sometimes at birth; frequently arises in both eyes; and could be multifocal within each eye. In this form, first hit is the inherited germline mutation in one of the two alleles of RB genes present in all cells of the body and second-hit is the somatic mutation in second of RB gene in one of the retinal cells, resulting in development of retinoblastoma (**Figure 2**). This hypothesis explains why both alleles of a tumour suppressor gene are to be inactivated for development of cancer and why most forms of hereditary cancer occur at a younger age, are frequently bilateral, and multiple as compared to their sporadic counterparts. It is important to note that while the mutation is recessive at cellular level (requiring both alleles to be inactivated), the inheritance pattern for cancer risk is autosomal dominant. Progeny of germline mutation carriers have 50% probability of inheriting the germline mutation (one mutated allele in each cell of the body). Subsequently a very high proportion of these carriers acquire the second inactivating mutation in one of the target organ cells (somatic mutation) resulting in 70% to 100% penetrance for cancer development in mutation carriers.

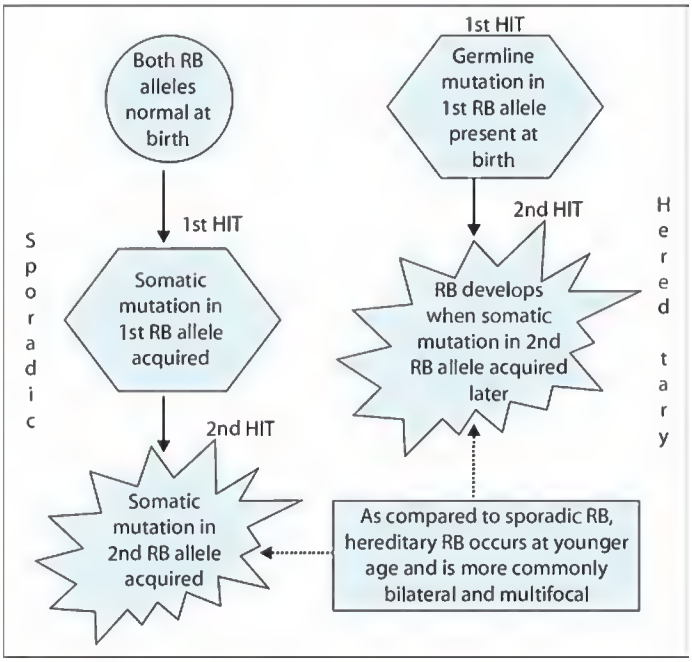

Figure 2: Kundson's two hit hypothesis in retinoblastoma.

EPIGENETIC REGULATION IN CANCER

Epigenetic alteration refers to the change in genome (or gene expression), which is inherited by the daughter cells without any alteration in the DNA sequence. Common epigenetic modifications include DNA methylation of CpG islands (cytosine precedes Guanine) in the promoter region of a gene, thereby controlling gene expression, and acetylation of histones that could silence TSGs. Global genomic hypomethylation in the CpG islands of TSGs and specific histone modifications are commonly seen in many human cancers. Being reversible, these epigenetic changes are attractive drug targets with various drugs like histone deacetylase inhibitors undergoing evaluation in clinical trials. Analysis of epigenetic silencing of the MGMT gene by promoter methylation is now in clinical use to predict response to temozolamide chemotherapy for glioblastoma.

HEREDITARY CANCER SYNDROMES AND GENETIC TESTING

It is estimated that 2% to 5% of all cancers are hereditary, occurring as a result of germline mutation in one of the several TSGs (BRCA1, BRCA2, TP53, NF1, etc), or proto-oncogene. Vast majority of hereditary cancer syndromes are autosomal dominant (**Table 2**) with few rare syndromes associated with DNA repair defects being autosomal recessive (**Table 3**).

Table 2: Autosomal Dominant Hereditary Cancer Syndromes and Their Phenotypic Features

Genetic Syndrome	Malignancy (Lifetime Risk of a Cancer)	Phenotypic/Tumour Features
Hereditary breast ovarian cancer (HBOC) syndrome Incidence: 1 in 1000 Genes: BRCA1 (17q); BRCA2 (13q)	Breast cancer (70% to 80%), Ovarian cancer (40% to 60%) Male breast cancer, prostate, pancreas, colon, etc. (especially in BRCA2 carriers)	Cancer presents at young age, frequently bilateral and same person may develop breast and ovarian primaries BRCA1 associated breast tumours are generally ER, PR and C-ERBB2 negative (Triple –ve) and poorly differentiated
Hereditary non-polyposis colon cancer (HNPCC) syndrome Incidence: 1 in 400 Genes: One of the mismatch repair genes MSH2 (2p)	All cancers (70% to 90%) Colorectal cancer (30% to 75%) Endometrial cancer (20% to 40%) Other cancers: Gastric, brain, small bowel, pelvi-ureteric, hepatobilliary	Colon polyps in 30% cases but unlike FAP polyps in HNPCC rarely exceed few dozen Compared to sporadic cases, HNPCC associated colon cancer is generally right-sided (ascending or transverse colon) and at younger age **Amsterdam -II Criteria for HNPCC**
MLH1 (3p) MSH6 (2p) PMS2 (7p) PMS1 (2q)	**Lynch-I syndrome:** HNPCC with only colorectal cancers in the family **Lynch-II syndrome:** Extracolonic cancers of HNPCC in the family **Turcot's syndrome:** Person with colon cancer and brain tumour	– At least 3 first degree relatives with colon, endometrial, small bowel or pelvi-ureteric carcinoma – At least 2 generations affected – At least one affected person <50 years age – FAP should be excluded
Familial adenomatous polyposis (FAP) Incidence: 1 in 1,000 Gene: APC (5q)	Colorectal carcinoma (100%) Upper gastrointestinal (duodenum) cancer Periampullary cancer Papillary thyroid cancer Brain tumours Hepatoblastoma Desmoid tumour	Hundreds to thousands of polyps by 2nd decade leading to cancer by 4th decade **Attenuated FAP:** Fewer polyps (10-100) **Gardners syndrome:** FAP variant with extracolonic lesions like desmoid tumours, osteoma, epidermoid cysts, dental abnormalities, fibroma, and congenital hypertrophy of retinal pigment epithelium
Peutz-Jeghers syndrome Incidence: 1 in 250,000 Gene: STK11 (19p)	All cancers (50%) Common cancers are colorectal, pancreatic, breast, ovarian, testicular, endometrial and melanomas	May present with intussuseption in childhood due to hamartomatous jejunal/gastrointestinal polyps Mucocutaneous melanocytic macules in lips and buccal mucosa (95%) Multiple and sometimes atypical naevi
Hereditary retinoblastoma Incidence: 1 in 25,000 Gene: RB1 (13q)	Bilateral retinoblastoma (90%) Rarely trilateral retinoblastoma Osteosarcoma in adolescence	Childhood tumour which presents at an average age of 1 year for bilateral and 1.5 years for unilateral cases and 90% cases by 3 years age
Li-Fraumeni syndrome (LFS) Incidence: 1 in 50,000 Gene: TP53 (17p)	All cancers (90%) Breast cancer, soft tissue sarcoma or bone sarcoma, brain tumours, leukaemia, adrenocortical tumours	**LFS:** Sarcoma before 45 years of age in proband with one 1st degree relative with cancer before 45 years of age and one 1st or 2nd degree relative with cancer before 45 years of age or sarcoma at any age.
Multiple endocrine neoplasia 2A and 2B (MEN2A and MEN2B) Incidence:1 in 30,000 Gene: RET (10q)	Medullary carcinoma thyroid (MTC) develops in (70% to 100%) parathyroid adenoma RET mutation carriers and penetrance depends on location of mutation Bilateral phaeochromocytoma (50%)	**MEN2A:** MTC, phaeochromocytoma and **MEN2B:** MTC, phaeochromocytoma, mucosal neuromas over tongue and lips (Blubbery lips), corneal nerve thickening, skeletal anomalies, gastrointestinal (GI) gangloneuromatosis but parathyroid is normal
Neurofibromatosis Type 1 (NF1) Incidence: 1 in 2500 Gene: NF1 (17q)	Cutaneous neurofibroma (100%) Plexiform neurofibroma (20%) Childhood optic glioma (15% to 20%) Malignant peripheral nerve sheath Tumour – MPNST (5% to 15%)	Cutaneous stigmata (widespread neurofibromas, *Café-au-lait* spots, axillary freckling) and Lisch nodules (hamartomas) in iris are diagnostic. Learning disabilities in 50% Hypertension is common Scoliosis and pseudoarthrosis in 10%
Neurofibromatosis Type 2 (NF2) Incidence: 1 in 25,000 Gene: NF2 (22q)	Bilateral acoustic neuroma (85%) Spinal schwannoma (65%) Skin schwannoma (65%) Meningiomas (45% to 50%) Other gliomas	Cutaneous stigmata of NF1 generally absent but few (< 6) Café-Au-lait spots in some Acoustic neuromas present with unilateral or bilateral deafness Posterior subcapsular cataract and retinal hamartomas in 1/3rd cases
Cowden syndrome Incidence: 1 in 200,000 Gene: PTEN (10q)	Early onset breast cancer (30% to 50%) Bowel cancer (20%) Follicular thyroid cancer (3% to 10%)	Mucocutaneous stigmata by 3rd decade *Diagnostic criteria:* Cobblestone-like papules of the gingiva and buccal mucosa. Facial trichilemmomas, acral keratosis Other features in 40% cases (GI polyps and macrocephaly)

Contd...

Contd...

von Hippel-lindau syndrome (VHL) Incidence: 1 in 36,000 Gene: VHL (3p)	All tumours (80% to 90% penetrance) Cerebellar and spinal haemangioblastoma (35% to 85%) Renal cell cancer (25% to 48%), phaeochromocytoma (15%)	Retinal angioma are the earliest lesions detected at a mean age of 25 years in 40% to 70% cases. Renal, liver and pancreatic cysts are common
Tuberous sclerosis (TS) (Type 1 and 2) Incidence: 1 in 10,000 Gene: TSC1 (9q) TSC2 (16p)	Sub-ependymal giant cell astrocytomas (SEGA) is a characteristic benign tumour of TS, Ependymoma Renal cell carcinoma	Characteristic facial angiofibroma (adenoma sebaceum), hypopigmented ash leaf spots and leathery Shagreen patches over neck or back Renal angiomyolipoma is very common which may bleed or cause renal failure by compression Cardiac rhabdomyoma are common Characteristic CNS hamartomas (sub-ependymal nodules and cortical tubers) which causes epilepsy, autism and common learning difficulties

Table 3: Autosomal Recessive Hereditary Cancer Syndromes and Their Phenotypic Features

Genetic Syndrome	Malignancy (Percentage Lifetime Risk)	Other Phenotypic Features
Bloom syndrome Incidence: Very rare Gene: BLM (15q26)	All cancer (penetrance 80%) Prone for all cancers (except prostate cancer) at unusually young age (mean 25 years) Multiple primary cancers are common Particularly prone for AML	Low birth weight, physical and mental growth retardation. Characteristic facial appearance (narrow skull, malar hypoplasia, small mandible); characteristic voice, photosensitive skin, telangiectasia and hypo/hyperpigmented patches Immunodeficiency and infertility are common
Ataxia telangiectasia Incidence: 1 in 100,000 Gene: ATM (11q22)	Breast cancer Lymphoma (B-CLL) Leukaemia (T-CLL)	Cerebellar ataxia, telangiectases, immune defects, gonadal dysfunction, thymic hypoplasia Increased sensitivity to X-rays Serum AFP is elevated in 95%
Xeroderma pigmentosum Incidence: 1 in 250,000 Gene: XPA-G and V (9q,2q,3p,19q,11p, 6p, 13q and 6p)	Skin cancer (basal cell carcinoma commonest followed by squamous carcinoma and melanoma) in tropical countries most patients develop skin cancer by adulthood	All forms of XP have extreme UV sensitivity which results in actinic keratosis, freckling and finally skin and conjunctival/corneal cancers Neurologic abnormalities and mental retardation are commonly seen in XP-B, XP-D, XP-A
Fanconi anaemia Incidence:1 in 350,000 14 Genes in 16p FANC 'A' to FANC 'G' FANC 'I'-'J' and FANC 'L' to FANC 'O'	Almost all patients develop bone marrow failure or haematological malignancy (commonly AML) if they live long enough If cured of the haematological condition, most patients will develop solid tumours	Commonly present with progressive bone marrow failure starting from childhood Pigmentary changes in skin, malformations of the heart, kidney and limbs (aplasia of the radius, thumb deformity) Endocrinopathy and growth retardation
Recessive hereditary colon cancer Gene: Mut YH (1p34)	Colon cancer	Adenomatous colon polyps seen in most cases which could vary from as few as 5 polyps to frank polyposis Extracolonic features of FAP/ Gardener's syndrome not seen and extra-colonic cancers not seen

While many hereditary cancer syndromes such as hereditary breast ovarian cancer (HBOC) syndrome or Li-Fraumeni syndrome do not have any specific phenotypic feature before the occurrence of cancer, some cancer predisposition syndromes have characteristic phenotypic features that predate cancer diagnosis by many years or decades. These phenotypic features include cutaneous signs in NF1, XP, tuberous sclerosis, Peutz-Jegher's syndrome or characteristic benign hamartomatous lesions or cysts in internal organs or eye as seen in FAP, NF1, tuberous sclerosis, VHL, etc. In syndromes without characteristic external or internal phenotypic features, the diagnosis of a hereditary cancer syndrome is based on detailed family history of types of cancers, age at cancer diagnosis, or bilateral, multifocal or multiple primary cancers in an individual. Based on detailed family history and clinical examination of the proband if a cancer predisposition syndrome is evident or suspected, further radiological or laboratory investigations are performed to look for other associated phenotypic features or cancers. Mutation analysis of the gene(s) likely to be implicated in the suspected syndrome helps in confirmation of the syndromic diagnosis, risk estimation and genetic counselling of the family.

The gold standard for mutation analysis is automated DNA sequencing but it is expensive, may detect sequence changes of unknown clinical significance and may fail to detect large genomic rearrangements. In addition to these technical and interpretive issues, genetic testing has several other ethical, legal and social implications (ELSI) and is, therefore, advisable only when inherited cancer predisposition is suspected and genetic testing is likely to modify or aid clinical management for patients or high risk cases in that family. Genetic testing is generally done first for the cancer affected member of the family on a gene which is most likely to be involved (e.g. BRCA1 and BRCA2 for HBOC). With the small likelihood of a false negative or false positive result due to technical errors, the four possible results

of mutation analysis are: (1) Known deleterious mutation identified; (2) Known polymorphism identified; (3) Sequence variation of unknown clinical significance identified; and (4) No mutation or sequence variation identified. A counsellor has to be well versed with the interpretation of all the alternatives to provide effective counselling.

CANCER SCREENING AND PREVENTION IN HIGH RISK INDIVIDUALS/MUTATION CARRIERS

Healthy members of families with specific hereditary cancer syndromes would be considered to be at a high-risk for developing cancer based on their relationship with the affected members and in families where a specific mutation is known all those who are found to be mutation carriers are considered at high-risk. There are well established guidelines for screening of such high-risk individuals from families with common hereditary cancer syndromes with organ specificity (HBOC, HNPCC, FAP, MEN-2). High-risk women from HBOC families are recommended to have monthly breast self examination, six-monthly clinical breast examinations by a trained oncologist, surgeon or a gynaecologist. Annual breast imaging is recommended using mammography and/or breast MRI in young women with dense breasts. Breast screening should start between 25 to 30 years of age or five years before the age of earliest cancer in the family. The sensitivity of ovarian cancer screening in detecting early stage ovarian cancer in such high-risk women is not well established but annual transvaginal ultrasound and CA-125 tumour marker starting at 35 years of age may be considered.

Preventive strategies in high-risk women from HBOC families vary from non-invasive chemoprevention with antiestrogens to prophylactic bilateral mastectomy with breast reconstruction or prophylactic oopherectomy. Prophylactic oopherectomy reduces the risk of ovarian cancer by almost 100% (rare occurrence of primary peritoneal carcinoma still exists) and reduce the risk of breast cancer by 50%. While bilateral prophylactic nipple sparing mastectomy with reconstruction can reduce breast cancer risk by almost 100%, the psychosexual issues of such surgery in healthy young women have to be discussed in detail during counselling.

MOLECULAR SIGNATURES OF CANCER FOR DIAGNOSIS, PROGNOSIS AND GUIDING TARGETED THERAPY

Classification of various tumours has evolved from conventional morphology based histopathology to immuno-histochemistry and finally to molecular pathology in which tumour specific gene mutations, over-expression, chromosomal rearrangements and global gene expression profile is characterised and used in clinical management of certain cancers. Molecular sub-classification of tumours helps in refining diagnosis, prognostification and predicting response to specific targeted therapies based on the molecular pathology. The common examples include accurate diagnosis of Ewing's sarcoma (EWS-FLI1 translocation) and lymphomas (CD markers); prognostication of neuroblastoma (N-MYC amplification) and breast cancer (gene expression profile) and guiding targeted therapy for breast cancer with HER2/Neu over-expression (Herceptin) and CD-20 positive lymphoma (rituximab). The classical t(9;22) (q34.1;q11.2) translocation of CML which results in BCR-ABL fusion gene which drives oncogenesis is targeted through tyrosine kinase inhibitors (imatinib) as shown in **Figure 3**. Imatinib is now the standard of care in patients of CML who test positive for this translocation.

MOLECULAR DIAGNOSTIC TECHNIQUES IN CANCER

A greater variety of high throughput tests are becoming available which also have greater sensitivity and specificity to study chromosomal alterations, gene over-expression, gene mutation and global gene expression profile. These technologies which were instrumental in making major discoveries of molecular and genetic basis of cancer are now being routinely used in molecular diagnosis of cancer. Some of the key diagnostic methods are outlined below.

Fluorescent *In Situ* Hybridisation (FISH)

Characterises chromosomal aberration using DNA probes, specific for a gene, chromosome segment or whole chromosome. FISH has the advantage of directly obtaining the position of the probes in relation to chromosome bands or to other previously mapped reference probes and visualise cytogenetic aberration on interphase nuclei without the need for having metaphase preparation. FISH is particularly useful for translocations in paediatric tumours and haematolymphoid malignancies and more quantitative study of over-expression of Her2Neu in breast cancer.

Microsatellite Instability Test

Microsatellites are small repetitive DNA sequences that undergo expansion or contraction of the repeat sequences during DNA replication. The mismatch repair (MMR) genes survey the newly replicated DNA for possible errors and repair the mismatched bases. Defect in MMR genes as seen in HNPCC would result in microsatellite instability (MSI) which is characterised by change of length of the microsatellite (insertion or deletion of repeats) within the colonic tumour as compared to the DNA from normal tissue. For HNPCC, a panel of five microsatellite markers recommended by National Cancer Institute (Bethesda Panel) is used for detection of MSI. If two or more microsatellite markers are unstable, it suggests HNPCC which can be confirmed through germline mutation analysis using automated DNA sequencing of hMLH1, hMSH2 and hMSH6 genes.

Gene Expression Profiling

In addition to a large number of genetic pathways involved in the multi-step carcinogenesis, there is underlying genetic instability and epigenetic modifications of gene expression. Newer techniques such as RNA microarrays are now used to study the differential expression profile of thousands of genes in the neoplastic cells as compared to the normal cells of the same tissue origin. Such studies have led to molecular classification of breast cancers, lymphomas and few other tumours and allowed better understanding of the pathways relevant to development of particular cancer type and in identifying molecular targets for cancer diagnosis and therapy.

Automated DNA Sequencing

DNA sequencing using automated capillary sequencer is the gold standard for gene mutation analysis. In the commonly used Sangers method which is frequently done by dideoxy- chain

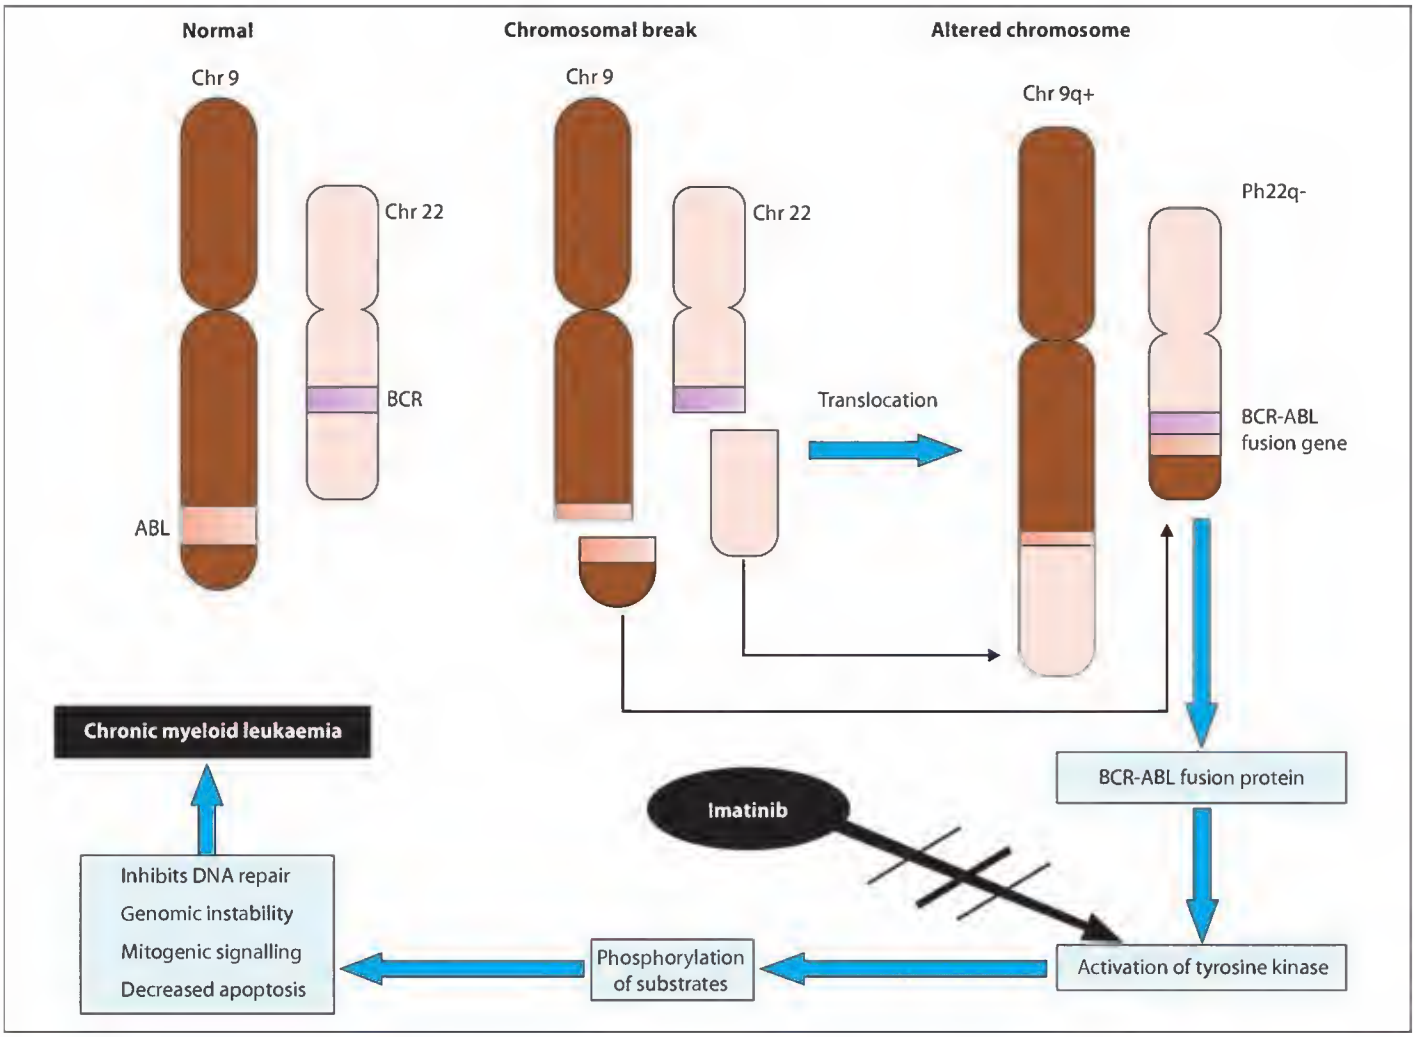

Figure 3: Chromosomal translocation: BCR-ABL fusion gene in CML has increased tyrosine kinase activity is down-regulated by imatinib.

termination, the DNA template which is to be sequenced is prepared as a PCR amplicon product. Sequencing is achieved by utilising fluorescent labelled nucleotides incorporated into the DNA copy. The DNA sequence can then be derived by the positions of the fluorescent labelled nucleotides. Laser stimulated fluorescent emissions are read directly by an optical detector as the DNA fragment passes past it. The sequencing data are stored, analysed and converted to complete DNA sequence by special software and compared with normal reference DNA sequence. A major advantage of the automated sequencing is the speed of detection and the information it gives about the nature of the change found. Capillary sequencers are also used for estimating the fragment length polymorphisms for microsatellite analysis, haplotype analysis and DNA fingerprinting. The possible results of DNA sequencing of a gene and certain caveats are described earlier in the Genetic testing section.

CONCLUSION

Cancer genetics has undergone a revolutionary change in the past two decades. This knowledge of molecular mechanisms underlying cancer initiation, promotion and progression has brought about a major change in the way we diagnose and manage certain cancers. Presently, a greater emphasis is being laid on developing specific diagnostic tests and novel therapies targeting the molecular signatures resulting in a shift in the way we practice medicine, from generalised therapy to a more tailor-made individualised therapy. For hereditary cancers, genetic testing has helped in precise risk estimation, counselling, with appropriate surveillance and cancer prevention strategies.

7.1 Basic Considerations in Critical Care

RK Mani

CRITICAL VERSUS NON-CRITICAL CARE

Critical care is not merely an extension of patient care to an acute setting. The urgency of acute illness in critical care has led to a departure from traditional approaches. The usual linear method of history, physical examination, investigations, diagnosis and treatment has given way to an iterative approach in critical care (**Figure 1**). Owing to the emergent nature of presentations the correction of life-threatening physiological derangements receives first priority that translates as the CAB (circulation, airway and breathing) after eliciting brief historical information and conducting rapid physical examination. This is followed by close monitoring to stabilise the patient (electrocardiogram, mean arterial pressure, oxymetry, central venous pressure, urine output, sensorium, intracranial pressure, etc.) that is the hallmark of critical care. The next step involves detailed history-taking and physical examination towards formulation of a working diagnosis and management strategy.

Inherent to critical care is the early recognition of organ system dysfunction and prompt institution of appropriate support. At any point in such evaluation, one may need to return to the initial steps to ensure that physiological targets are being achieved.

TIMELINESS OF INTERVENTIONS

The concept of the 'golden hour' that mandates timely and appropriately aggressive intervention is of essence in critical care. Therapeutic efficacy that translates to favourable outcome has been proven to be a function of how early the therapy was instituted from the time of presentation. Notable examples of this principle are the early goal-directed therapy for septic shock, timing of the 1st dose of antibiotic and antifungal therapy, thrombolysis and revascularisation procedures for acute myocardial infarction, surgical source control, thrombolytic therapy for acute ischaemic stroke and adjuvant therapies such as activated protein C for severe sepsis and septic shock, to

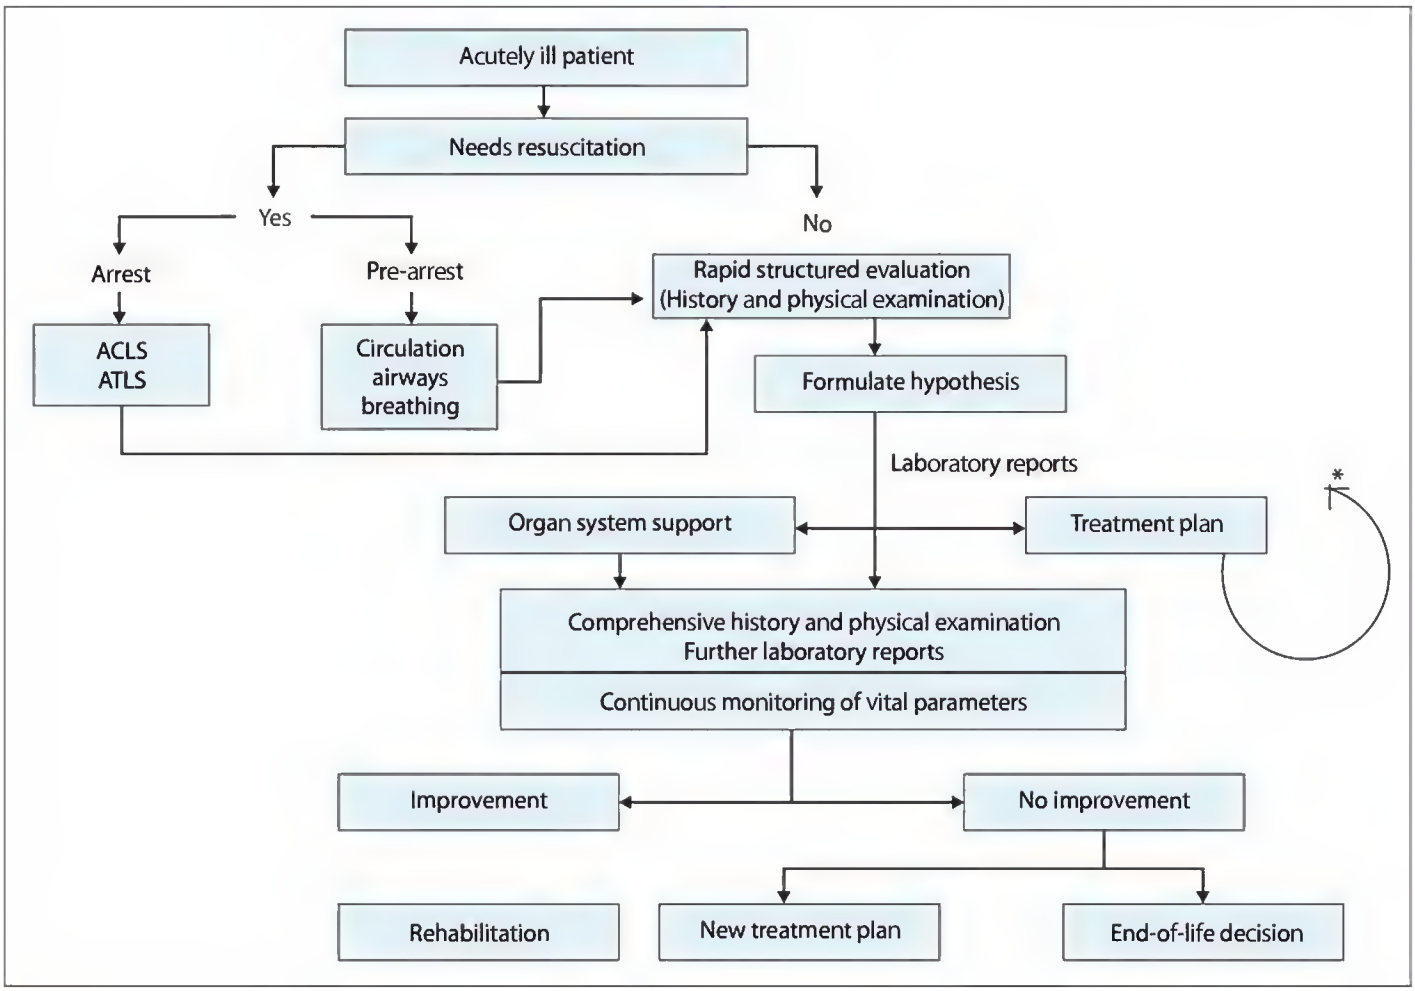

Figure 1: General approach to the management of the critically ill patient.

**The curved arrow represents the iterative approach in the management of the critically ill patient.*

ACLS = Advanced cardiac life support; ATLS = Advanced trauma life support.

name a few. Thus, it is also crucial to institute early support to organ systems in the form of oxygen supplementation, non-invasive (NIV) and invasive mechanical ventilatory support, circulatory support through fluids and vasopressors, haemodialysis and renal replacement therapy, and nutritional support. A sense of urgency is vital to minimise the eventual mortality and morbidity as well as the cost of treatment.

MINIMISING RISKS OF ORGAN SUPPORT

Mechanical ventilation (MV) is one of the primary interventions that saves lives. However, safe ventilatory strategies that minimise mechanical complications (barotrauma) as well as microstructural trauma called ventilator-associated lung injury (VALI) is an essential tenet of critical care. Non-invasive ventilation has obviated the need for more potentially injurious MV in a sizeable number of patients especially in the setting of exacerbation of chronic obstructive pulmonary disease (COPD). The concept of 'protective ventilation' is a widely accepted concept that finds practical application in the form of low tidal volume and positive end expiratory pressure (PEEP) in acute respiratory distress syndrome (ARDS), permissive hypercarbia for ARDS, bronchial asthma and COPD, and recruitment manoeuvres, such as prone positioning. The need to protect the lungs has also led to the search for supports such as extra-corporeal membrane oxygenation (ECMO) and other extra-corporeal lung-assist devices.

The risks of aggressive fluid resuscitation are minimised by improved monitoring of haemodynamic variables and the emerging awareness of the need to monitor intra-abdominal pressure.

The adverse effects of sedation and neuromuscular blocking agents have been reduced by setting specific therapeutic targets and by the practice of daily sedation interruption.

INFECTION CONTROL

The critical care unit is well recognised as the epicentre for the development of multiple drug-resistant flora. One of the key responsibilities of the intensivist is to adopt practices that minimise the incidence of nosocomial infections, prevent horizontal transmission and limit the emergence of resistant pathogens. This includes attention to hand hygiene and handling of intravenous (IV) cannulae and airways, aseptic measures for bedside procedures and imaging, head-up positioning and general housekeeping. Refining antibiotic prescribing practices are vitally important for optimising therapy, reducing the incidence of bacterial resistance and minimising costs. Protocols and policies are essential to regulate these processes.

PREVENTION OF COMPLICATIONS AND GENERAL CARE

Careful attention to detail includes pharmacological and/or mechanical measures to prevent deep venous thrombosis, eye care to protect against exposure keratitis, mouth care to reduce bacterial colonisation, skin care to prevent pressure sores and bowel care to prevent constipation.

ETHICS, END-OF-LIFE CARE AND PALLIATION

The increasing efficacy of modern critical care has raised its expectations often to unrealistic levels. The aging population, the increasing complexity of surgical interventions, the frequent use of immunosuppressive medications and implanted devices and organ transplantation all have added to the challenges of critical care. However, when critical care fails, it greatly escalates the emotional, social and financial burdens of the family. Most interventions also carry significant risks and costs requiring an informed consent from the patient or his/her family. Therefore ethical considerations weigh heavily on clinical decision-making. The physician must integrate the ethical principles of respect to patient's autonomy, beneficence, non-malefiscence and social justice in his practice.

As a corollary to ethical decision-making, it behoves the physician to disclose early and honestly poor prognosis, and offer palliative end-of-life care options to the family. Since death is a common occurrence in the intensive care unit (ICU), appropriate care of the dying is an important tenet of critical care. Ethical, social, humanitarian and legal factors impact on issues relating to voluntary foregoing of life-supporting therapies. A pathway to end-of-life care decisions has been suggested by the Indian Society of Critical Care Medicine (ISCCM) (**Figure 2**). Palliative care aimed at ensuring patient comfort starts from the time of initial care and gradually assumes centre stage as therapeutic strategies shift from the 'cure' to the 'care' mode when attempts at cure are deemed to have failed.

FAMILY NEEDS

As opposed to non-critical conditions where care is said to be patient-centric, critical care is patient- and family-centric. This is because more than 95% of critically ill patients lose the capacity to decide for themselves. It is of utmost importance that the intensivist communicates daily with the family for prognostication, emotional support, decision-making and informed consent, cost estimations and where appropriate, end-of-life decision-making. This is best done by the senior staff of the unit along with primary physicians and senior nurses.

CRITICAL CARE ORGANISATION

The ICU constitutes a team of doctors, nurses, technicians, therapists and other support staff. Most of the staff needs to work in shifts to provide uninterrupted round-the-clock cover. Adequacy of staffing is vital to ensure efficiency, infection control, patient and family satisfaction and avoidance of caregiver fatigue and attrition. Ongoing education, training and clinical research activities are integral to constant upgradation and search for excellence.

'OPEN' VERSUS 'CLOSED' INTENSIVE CARE UNITS

In the 'open model' of critical care units consultant physicians direct the care of their individual patients with the assistance of house staff that provides round-the-clock on-the-spot patient care. An intensivist, if available, is not involved directly in the care of most of the patients. Because the primary physician often does not have the time or the skills required to provide comprehensive care to the patient, he often apportions management to several single organ specialists.

A 'closed' system implies that patient care is either directed or co-managed by an intensivist. In this model, the intensivist assumes full responsibility for treatment planning and integrates the inputs from several sub specialists. He provides

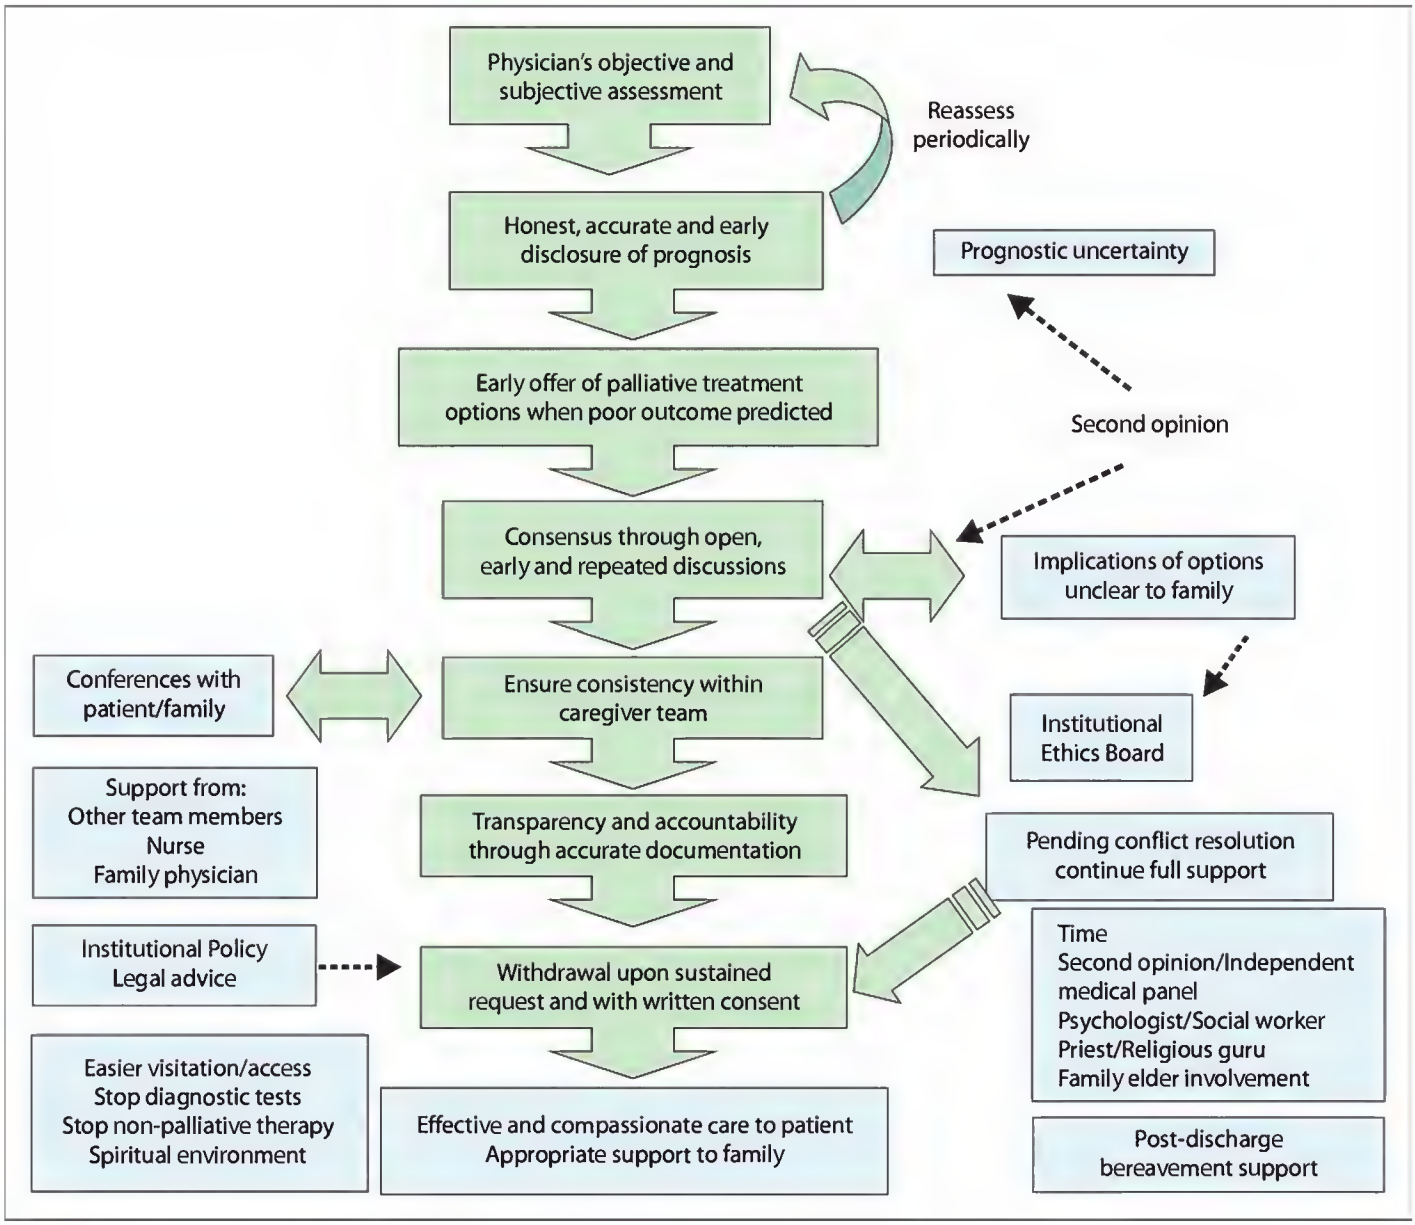

Figure 2: Pathway to end-of-life decision.

leadership in the management of individual patients, organises 'on call' cover, puts in place infection and quality control practices, staff training and clinical research. In an open structure, an 'open-door' policy may exist for admission and discharges.

Several retrospective and prospective studies showed improved outcomes in terms of mortality, morbidity and cost especially in seriously sick patients, when ICUs adopted the closed model. This model also facilitates early end-of-life decisions and appropriate reduction of futile care that minimise the escalation of costly interventions in terminally ill patients. The limitation of this model is the scarcity of trained and experienced intensivists. Currently 'open' and 'semi closed' models pre-dominate in India and true 'closed' units are a miniscule minority.

ORGAN RETRIEVAL

With expanding scope and expertise of organ transplantation the critical care specialist has a new role to play. In the foreseeable future he will be called upon to identify the potential organ donor early and notify the nearest organ procurement organisation.

QUALITY AND SAFETY

Patient safety requires that systems are in place to evaluate the quality and safety issues of the ICU. This includes data collection and monitoring to audit parameters such as mortality, length of stay, ventilator-associated pneumonia and blood stream infection rates, critical incidents and sentinel events, medication errors, etc. With training and experience, the complications of ICU procedures can be minimised. A culture that promotes safety, a team spirit that believes in constructive self-criticisms, setting protocols and standard operating procedures are essential for reducing errors and adverse events.

7.2 Monitoring of Critically Ill Patients

M Hanumantha Rao

Monitoring is one of the primary duties of an intensivist or critical care specialist. Effective vigilance is helpful in assessing the severity of organ dysfunction and suitably assist the organs by different methods. In order to ensure optimal care of these patients, it is vital to understand the technology of advanced and sophisticated monitoring equipment including the cost-benefit issues. Vigilance and anticipation of complications are the important issues in the intensive care unit (ICU). All critically ill patients need different types of monitoring, because they are likely to develop dysfunction of different organ systems during their stay in critical care unit. By proper monitoring one can assess the severity of dysfunction of each of these organs and then choose suitable therapeutic interventions and artificial support for the failing organs like heart, kidney and lung. Many physiological measurements are necessary to convey the patient's condition. To assess all the aspects of patient's condition many physiologic measurements or group of measurements are required. This chapter briefly reviews the indications, contraindications, techniques and complications of frequently used monitors in critical care units.

Many monitoring techniques are available in clinical practice (**Table 1**) and specific monitoring is required for different systemic diseases. However, many patients need monitoring of all systems. Some variables are monitored continuously and some intermittently. The variables that are monitored continuously include heart rate, arterial blood pressure, pulse oximetry (**Figure 1**). Arterial blood gases and some laboratory tests are monitored intermittently.

VITAL SIGNS

Simple, basic, economical and the most frequently used non-invasive method of monitoring the patient includes heart rate, blood pressure, respiratory rate, and temperature.

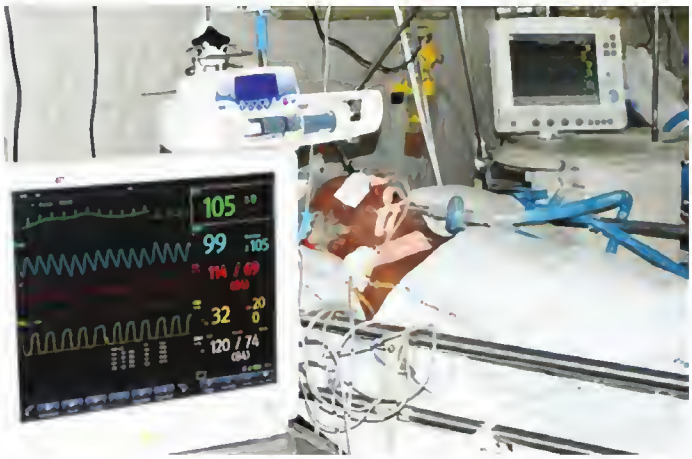

Figure 1: A 4-channel monitor connected to a critically ill patient showing ECG (green), SaO_2 (blue), IBP (red), $ETCO_2$ (yellow) and NIBP (white).

CARDIOVASCULAR MONITORING

Heart rate per minute is routinely monitored in all critically ill patients. It is clinically counted by manual palpation of the radial artery just above the wrist joint for one full minute. It can be automatically calculated by either electrocardiogram (ECG) wave or arterial pulse wave. It is a non-specific, haemodynamic variable. A slow heart rate less than 50 beats per minute is defined as bradycardia and heart rate more than 100 beats per minute is defined as tachycardia.

Electrocardiogram

It has become a routine to monitor ECG in all the critically ill patients. Most of the patients have cardiac activity monitored by a 3-lead system or a 5-lead system. Monitoring heart rate and rhythm is a standard practice. It detects dysrhythmias, myocardial ischaemia and function of pace-maker. To receive the maximum signal of ECG, electrodes need to be placed properly after de-greasing and cleaning the area with spirit. Lead II is routinely used to monitor the rhythm and lead V5 for ischaemia. ST segment analysis is crucial in suspecting ischaemia. It is a routine practice to monitor two leads simultaneously to assess both rhythm and ischaemia. Alternatively, one can use modified chest leads CM_5 or CS_5 which detect both ischaemia and dysrhythmia. The factors that may interfere with the signal is skin movement, muscle artifact,

respiration and shivering. The leads used for ECG monitoring are disposable and for single use only. Signals are usually sent to central monitoring station by a small radio transmitter.

Haemodynamic Monitoring

Arterial blood pressure

Systemic arterial blood pressure is proportional to cardiac output, when peripheral vascular resistance is constant. It is maintained by physiological compensation when there are changes in cardiac output and blood volume. It is affected by cardiac output, vasomotor tone and volume status of a patient.

Blood pressure may be normal despite grossly impaired cardiac function and so is a crude indicator of the state of the circulation. But if blood pressure is inadequate, tissue perfusion suffers. In critically ill patients auto-regulatory mechanisms in vascular beds of vital organs, like brain, kidney and liver become impaired and perfusion to these organs will be pressure dependent. Blood flow to tissues and perfusion is dependent on mean blood pressure. Mean pressure is not an arithmetic average of systolic and diastolic pressures. It is one-third the sum of systolic plus twice the diastolic pressure.

Non-invasive blood pressure

Systemic blood pressure can be monitored non-invasively (NIBP) or invasively (IBP). The use of conventional sphygmomanometer can be simple and reliable. Other indirect methods of measuring blood pressure include palpation, auscultation and oscillotonometry. The NIBP monitors have a pneumatic cuff which is programmed to inflate and deflate periodically depending on the programme. During this the phasic oscillations in the pneumatic cuff pressure produced by arterial pulsation are sensed and detects the systolic and diastolic pressures. The mean pressure is calculated by the pre-programmed computer device. This is a simple, basic and reliable monitor when the pressure is normal or high. But in hypotensive patients these are often inaccurate.

Invasive blood pressure

The most accurate and beat to beat variation of blood pressure is recorded by introducing a catheter into an artery and measuring the invasive blood pressure (IBP). This is an invasive procedure and should be used only for selected patients where it is indicated. Most frequently, radial artery of the non-dominant hand is used. Alternatively, femoral, dorsalis pedis, ulnar arteries can be used. The catheter introduced into artery is connected to a pressure monitoring line filled with heparinised saline which is connected to an electronic pressure transducer. The transducer needs to be zeroed to atmospheric pressure now and then. The fluid in the pressure monitoring line transmits pressure from the artery to pressure sensitive diaphragm of the transducer, which is connected to a monitor. The arterial pressure wave-form is displayed on the monitor and the digital values of systolic, diastolic and mean pressures. The readings are reliable and highly accurate if the transducer is zeroed and calibrated correctly. There is risk of infection and many complications are reported because of its invasive nature.

Dysrhythmia

Different types of dysrhythmias are not uncommon in critically ill patients. Therefore, it is important to monitor and record the initiation and termination of dysrhythmia in the ECG monitoring. Rhythm should be documented on admission and the change of each shift of the intensive care unit (ICU). Rhythm is better monitored in lead II or MCL_1 which is a modified chest lead.

Pulmonary Capillary Wedge Pressure

Pulmonary capillary wedge pressure (PCWP) is frequently used to assess the pre-load of the left ventricle and cardiac output by thermodilution technique. The pulmonary artery catheter, named after Swan and Ganz , is a balloon tipped, flow directed triple-lumen catheter introduced through right internal jugular vein or subclavian vein and then the balloon is inflated and passed till wedging occurs in the pulmonary capillary. After proper wedging one can record PCWP tracing and digital values of pressures.

Cardiac Output

Fick's principle is usually used to monitor cardiac output (CO) using thermodilution technique. The Swan-Ganz catheter has a temperature measuring device (thermistor). Bolus of cold saline is injected into right atrium through the proximal lumen. As the bolus reaches the thermistor, the change in temperature is used to calculate the cardiac output. The injection of cold saline can be done intermittently to calculate the cardiac output. The latest methods of monitoring the cardiac output are lithium dilution technique (LIDCO), pulse contour counter pulsation (PICCO) and ECG.

Oxygen Delivery

Tissue perfusion and delivery of oxygen is important for the survival of organs. It is deranged in different types of shocks. The delivery addresses three main issues in the supply of oxygen to the tissues, namely (i) cardiac output (CO), (ii) haemoglobin (Hb), and (iii) oxygen saturation (SaO_2). It can be calculated by using the formula.

Delivery of oxygen = Hb (g/dL) × SaO_2% × CO (L/min)
(ml/minute) × 1.34 x 10/100

Mixed Venous Oxygen Saturation

The blood from superior vena cava and inferior vena cava mixes in the right atrium and passes to pulmonary artery through the right ventricle. This sample is called mixed venous blood and it can be obtained from the distal port of pulmonary artery catheter (PAC) and some catheters have fibreoptic sensors embedded in them which directly measure SVO_2. When there is inadequate delivery of oxygen to tissues, they compensate by extracting more oxygen from arterial blood leading onto decrease in SVO_2.

RESPIRATORY SYSTEM

The monitoring of the respiratory system is very important and crucial in the management of patients who are critically ill. It is less advanced technologically compared to cardiovascular monitoring. Respiratory rate, tidal volume and minute volume can be assessed by bed-side portable hand-held spirometers. All the parameters are displayed on the monitoring screen of any latest ICU ventilator, if the patient is intubated and ventilated (**Figure 2**). Tachycardia, excessive sweating, use of accessory muscles of respiration can be monitored clinically to indicate impending respiratory failure.

Oxygen Saturation

A simple and non-invasive way of monitoring SaO_2 is by pulse oximeter (**Figure 3**). Oxyhaemoglobin and reduced haemoglobin

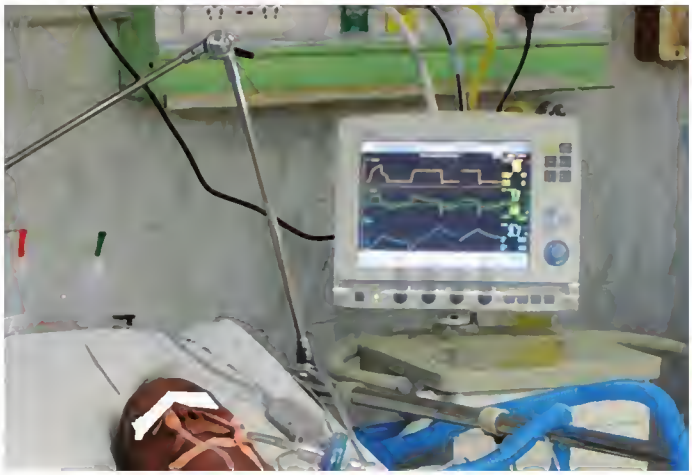

Figure 2: An intensive care unit ventilator showing the trace of airway pressure scaler (yellow), flow scaler (green) and volume scaler (blue).

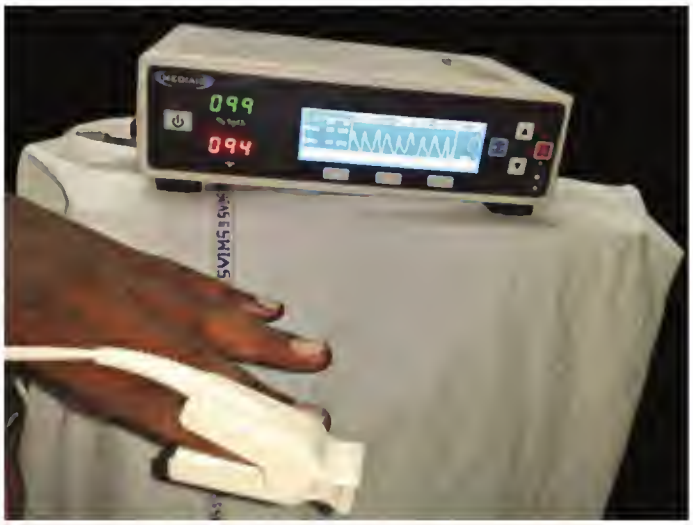

Figure 3: A pulse oximeter showing saturation wave and digital values of SaO_2 (green) and heart rate (red).

absorb light in the visible and near infrared regions at different wavelengths. In majority of patients measurement of SpO_2 by pulse oximeter reflects arterial saturation and partial pressure of oxygen (PaO_2) can be estimated by oxyhaemoglobin dissociation curve. However, in critically ill patients, peripheral perfusion is often reduced where saturation measurements are not reliable. The sensor probe can be applied to the tip of finger, toes, or lobule of ear. Oxygen saturation and heart rate can be continuously monitored. In hypothermia the SpO_2 is not accurately recorded. It is advisable to cover the probe from the ambient light, which affects the signal.

Capnography

Capnography is the technique of displaying carbon dioxide concentration changes during the respiratory cycle. Capnography provides a non-invasive means of rapidly identifying the problems, such as oesophageal intubation, inadvertent bronchial intubation and apnoea. Overall it provides a means to evaluate the integrity of the airway and the quality of patient's cardio-pulmonary functions.

Arterial Blood Gas Analysis

The analysis of arterial blood gases (ABG) helps to differentiate type I and type II respiratory failure and the severity as well. ABG analysis can be done intermittently. However, continuous monitoring can be done using a arterial catheter with fibreoptic electrode. From the analysis of ABG sample, PaO_2, partial pressure of carbon dioxide ($PaCO_2$), pH, HCO_3, absolute and standard base excess can be assessed. Proper anticoagulation of arterial blood with heparin and quick transport in ice slush to the nearest ABG analyser (**Figure 4**) is very important to get accurate values. PaO_2 should always be interpreted in relation the fraction of inspired oxygen (FiO_2). The ratio of PaO_2 to FiO_2 of inspired air (PaO_2/FiO_2) gives adequacy of gas exchange. In acute respiratory distress syndrome (ARDS) the ratio is less than 200. Serum electrolytes, lactate, blood glucose can also be measured in an ABG sample. Serial ABG analysis gives very useful information during mechanical ventilation and weaning process as well.

Figure 4: Arterial blood gas analyser.

NEUROMUSCULAR MONITORING

Central Nervous System

Clinical examination of the central nervous system is simple and non-invasive way of evaluating the brain. However, the requirement of opioids, sedation, propofol and muscle relaxants make the clinical exam extremely difficult in critically ill patients. Glasgow Coma scale score (**Table 2**) is an another simple way to assess the neurological status in the management of these patients.

Table 2: Glasgow Coma Scale Score

Eyes (E)	Open	Spontaneously	4
		To command	3
		To pain	2
		No response	1
Best verbal response (V)	–	Oriented	5
		Disoriented	4
		Inappropriate words	3

Best motor response (M)	To command	Obeys	6
	To pain	Localises to pain	5
		Flexion—withdrawal	4
		Decorticate rigidity	3
		Decerebrate rigidity	2
		No response	1
		Total	15

Intracranial Pressure

Sterile catheter can be placed in the ventricle of a patient in supine posture and by connecting it to a transducer system can give us the intracranial pressure (ICP) and trace. The normal ICP is 10 to 15 cm H_2O. The indications of ICP monitoring are head injury, subarachnoid haemorrhage and post-operative neurosurgical patients. Continuous measurement of ICP can be done by a number of devices placed within the cranium through a small burr hole made in parietal or frontal bone on non-dominant side. Subdural catheter, extradural or subdural bolt and intra-ventricular catheter can be connected to fluid filled system, which are connected to conventional pressure transducer and recording systems. Catheter block and infection are important and serious complications of these systems. Fibreoptic system can introduce a miniature pressure transducer into parenchyma to record the ICP. The transcranial Doppler is a non-invasive technique which calculates blood flow in the arteries and detects cerebral ischaemia.

Cerebral Function Monitor (CFM)

This is a compact form of electroencephalogram, where unwanted frequencies are filtered and summated. It uses only 3 electrodes and monitors electrical activity continuously. It is used in patients who develop seizures in ICU.

Jugular Venous Oxygen Saturation

Jugular venous oxygen saturation measurement and difference of cerebral arterio-venous oxygen content have been used in neuro ICU to indicate global cerebral ischaemia and to investigate hypotension. Indwelling catheters enable to record the jugular bulb oxygen saturation continuously and they reflect global changes in cerebral functions.

Peripheral Nervous System and Peripheral Neuropathy

The damage of the peripheral nerves may result in peripheral neuropathy. It is caused by diabetes mellitus, uremia, human immunodeficiency virus or nutritional deficiency. Other causes include mechanical pressure, such as compression or entrapment, direct trauma, injuries and contusion. Diagnosis of neuropathy is based on symptoms and physical examination. Examination of muscle strength, reflexes and sensitivity to position, vibration, temperature and light touch are to be assessed. Vibration perception is more sensitive than touch and pressure.

RENAL FUNCTION

A very useful guide indicating adequacy of cardiac output, splanchnic perfusion and renal function is hourly urine output monitoring. Specific gravity and osmolality of the urine are useful monitoring tools to differentiate pre-renal and renal failure.

Blood Urea and Serum Creatinine

Blood urea, serum creatinine and electrolyte trends are useful in evaluation of the progress of renal function. A rise in blood urea can occur in the absence of renal dysfunction in gastrointestinal bleeding, high protein intake and increase catabolism. Estimation of the concentration ability of the kidneys can be derived by comparing the blood and urine sodium, potassium and urea. Urine/plasma osmolality ratio of <1.2, urea ratio of <10 and a urinary sodium of >40 mmol/L indicates acute renal failure.

HEPATIC SYSTEM

Even though the damage to liver may not affect its activity because of its tremendous functional reserve, it is routine to monitor the function because it performs important functions of synthesis, storage, metabolism and excretion of toxic products. The tests of liver function alone are poor indicators of the degree of liver disease, and therefore, indicators of cell damage are frequently used instead, for instance hepatic enzymes. Albumin, because of long half-life is not a sensitive indicator of liver function. Disorders of clotting factors and prothrombin time are useful indicators of monitoring liver function.

HAEMATOLOGICAL MONITORING

Acquired coagulopathies and haemostasis abnormalities are not uncommon in critically ill patients. Clotting function assessment is monitored by platelet count, prothrombin time, activated partial thromboplastin time, fibrinogen concentration and fibrin degradation products (FDP) or D-dimer.

Oxygen delivery to the tissues is important and haemoglobin plays a crucial role and should be monitored frequently. Monitoring total leukocyte count and differential count is important to differentiate infective or non-infective causes and may give a clue of acute or chronic type of infection.

GASTROINTESTINAL SYSTEM

Bleeding from gastrointestinal system can occur in critically ill patients and simple periodic naso-gastric tube suction confirms the diagnosis. Paralytic ileus needs to be diagnosed promptly and treated. The important function of gastrointestinal system is nutrition. Naso-gastric tube feeding or enteral feeding should be considered, if there are no contraindications.

Gastric Tonometry

In critically ill patients development of acidosis in gastric mucosa may be a significant factor contributing to stress ulceration and consequent gastrointestinal bleeding. The acidosis is possibly due to mucosal ischaemia. Gastric tonometry detects ischaemia. The mucosal pH may be measured indirectly as tissues are highly permeable to CO_2, and hence, the PCO_2 of fluid within the lumen of the gut is equilibrated with that of the cells in the superficial layers of gut wall. The measurement of intra-luminal PCO_2 is made using a silicone balloon of approximately 3 ml capacity which is permeable to CO_2 and is positioned at the distal end of the nasogastric tube.

NUTRITION

Critically ill patients offer an exceptional challenge with regard to metabolism and nutrition and it is often neglected. So metabolic status needs to be monitored repeatedly. The intake of calories, lipids, proteins, fluids, electrolytes and minerals administered by enteral and parenteral routes are documented and monitored at regular intervals.

Electrolytes

Measurement of serum electrolytes is particularly important in critically ill patients. ECG helps in monitoring hypokalaemia and hyperkalaemia. Tall peaked 'T' waves are seen in hyperkalaemia. Decreased T wave amplitude and 'U' waves are seen in hypokalaemia. Syndrome of inappropriate antidiuretic

hormone (SIADH) results from inappropriate secretion of antidiuretic hormone (ADH) and result in retention of ingested or infused water. Monitoring of serum osmolarity, serum sodium, and urine sodium and urine osmolarity are to be done.

Endocrine and Metabolic Monitoring

Different endocrine abnoramalities can occur in critically ill patients. Serial blood glucose and ABG analysis are important monitoring tools for hyperglycaemia, diabetic ketoacidosis and volume depletion. An elevated ACTH levels and decreased cortisol levels occur in primary adrenal insufficiency.

Deep Venous Thrombosis

Deep venous thrombosis (DVT) is mostly asymptomatic except for mild discomfort and swelling. The incidence of venous thrombosis is high in patients with cancer, varicose veins, obesity and long period of lying down. DVT produces severe swelling of the extremity and without treatment can lead to long-term complications, like pulmonary embolism. Soleal veins of the lower leg are the most frequent sites of DVT. They are mostly asymptomatic, but may have mild calf tenderness (Homans sign). This condition is diagnosed by venography, Doppler ultrasound and impedance plethysmography.

Monitoring of Infection

Clinical and laboratory evaluation is required for monitoring of infections in critically ill patients. Patients may have the clinical signs like raised body temperature (>38°C) or hypothermia (<36°C), heart rate more than 90 beats per minute, increased respiratory rate (>20 breaths per minute). Laboratory investigations show raised total leucocyte count (>12000 cells/mm^3 or presence of 10% immature forms) or leucopaenia (<4000 cells/mm^3). Neutrophilia is seen in acute bacterial infections. Neutropaenia is seen in viral infections, brucellosis. Lymphocytosis is seen in brucellosis and tuberculosis. Monitoring of acute phase reactants like C-reactive protein is also raised in acute infections. Microbiological culture profiles of blood, sputum, urine, central venous pressure catheter tip and urinary catheter are important monitors of the infection and for institution of appropriate antibiotic.

SUMMARY

Critically ill patients have different physiological reserves and respond to insults in different ways. Monitoring is focused to examine the components of different systems including cardiac output, oxygenation of blood, etc. It may be difficult to monitor all the variables in all the patients. Different modalities of monitoring needs different monitors which are expensive. Cost benefit ratio should always be kept in mind. Invasive monitoring is used only in patients when indicated and analyse whether information obtained can modify the treatment. No amount of monitoring can cure a patient. However, successful management of critically ill patients requires the use of monitors to allow formulation of appropriate management. Monitoring is not only expensive but can also produce complications, which outweigh the benefits some times. One should strike a balance in managing the monitoring modalities of a patient who is critically ill.

7.3 Fluid and Electrolyte Balance in Health and Disease

Sanjay Jain

INTRODUCTION

A thorough understanding of the homeostatic mechanisms, that controls fluid and electrolyte balance, is essential for the accurate assessment and treatment of the wide variety of disorders. These homeostatic mechanisms function via carefully regulated mechanisms in the kidneys, lungs and the skin to maintain specific tonicity, volume and ionic composition of the body fluids.

DISTRIBUTION OF TOTAL BODY WATER

Water is the most abundant fluid in the body comprising 60% of total body weight in males and 50% in females. Two-third of this is distributed intra-cellularly and one-third is present extra-cellularly. Out of the extra-cellular compartment, three-fourth is present in the interstitium and the remaining one-fourth is distributed intra-vascularly. Another small compartment of fluid, the transcellular compartment, includes fluid in the synovial, peritoneal, pericardial and intraocular spaces, as well as the cerebrospinal fluid. The ionic composition of the extra-cellular and the intra-cellular fluids is different. The plasma and interstitial fluid are similar in composition being separated by only a thin, highly permeable capillary membrane. The only significant difference lies in the much higher protein concentration of the plasma due to the lower permeability of the capillaries to the plasma proteins. Due to a net negative charge of the proteins, they tend to hold a slightly higher concentration of sodium in the plasma. For the same reason, the concentration of anions is higher in the interstitium.

Radioactive water (tritium, $3H_2O$) and heavy water (deuterium, $2H_2O$) mix well with total body water and can be used to measure the same using the dilution principle. Extra-cellular fluid (ECF) volume can be measured using radioactive sodium, chloride, iothalamate and inulin. The presence of higher concentration of albumin in the plasma can be used to determine plasma volume (I^{125} tagged albumin). Interstitial fluid volume and intra-cellular fluid volume are indirect measurements and cannot be measured directly.

Plasma osmolality is determined by the following formula:

$$(Na^+ \times 2) + (\text{glucose}/18) + (\text{BUN}/2.8)$$

The Na^+ concentration is expressed in mEq/L while glucose and blood urea nitrogen (BUN) in mg/dL. The normal osmolality is 290 to 310 mosm/L. All fluids, with sodium and potassium concentration equal to 150 mEq/L, are considered to be isotonic.

HYPONATRAEMIA

Hyponatraemia is defined as a serum sodium less than 136 mmol/L and is the most frequent electrolyte abnormality in clinical medicine.

Pseudohyponatraemia is a rare situation in which serum Na^+ is low but the ECF osmolality and tonicity are normal. It is an artifact due to accumulation of other plasma constituents, viz. triglycerides or plasma proteins.

Causes of Hyponatraemia

Causes of hyponatraemia are discussed in **Table 1**. In hyperglycaemia, relative insulin deficiency causes myocytes to become impermeable to glucose which in turn acts as an osmole drawing water into the cell. For every 100 mg/dL rise in plasma glucose concentration, there is a 1.4 mEq/L fall in sodium.

Table 1: Causes of Hyponatraemia

Isotonic hyponatraemia
Following transuretheral resection of prostate: Isosmotic (mannitol) or hyposmotic (glycine/sorbitol) irrigation of the bladder
Hyperlipidaemia
Hyperproteinaemia
Hypertonic hyponatraemia
Hyperglycaemia
Intravenous administration of mannitol
Hypotonic hyponatraemia
Hypovolemic hyponatraemia, i.e. primary Na^+ loss (secondary water gain)
Renal loss, e.g. diuretics (almost always thiazides), post-obstructive diuresis, osmotic diuresis
Extrarenal loss, e.g. gastrointestinal loss (diarrhoea, vomiting), integumentary loss (sweating), third space loss (burns, pancreatitis, muscle trauma)
Euvolemic hyponatraemia, i.e. primary water gain (secondary Na^+ loss)
Primary polydipsia
SIADH
Hypothyroidism
Adrenal insufficiency
Chronic kidney disease
Abnormal arginine vasopressin secretion
Malignancy: Pulmonary and mediastinal tumours
CNS: Acute psychosis, stroke, haemorrhage
Miscellaneous: Beer potomania, severe nausea, HIV infection and post-operative state
Hypervolemic hyponatraemia: Primary Na^+ gain (secondary excess water gain)
Congestive heart failure
Nephrotic syndrome
Cirrhosis
Acute and chronic kidney disease
Pregnancy

SIADH = Syndrome of inappropriate antidiuretic hormone; CNS = Central nervous system; HIV = Human immunodeficiency virus

Clinical Features

The signs and symptoms depend on the degree of hyponatraemia and the rate of decline of sodium. Nausea and

malaise are the earliest findings, and may be seen when the plasma sodium concentration falls below 125 to 130 mEq/L acutely. This may be followed by headache, lethargy, muscle cramps, confusion, disorientation and obtundation, and eventually seizures, coma and respiratory arrest, if the plasma sodium concentration falls below 115 to 120 mEq/L.

The cerebral adaptation permits patients with chronic hyponatraemia to appear to be asymptomatic despite a plasma sodium concentration that is persistently as low as 115 to 120 mEq/L. Symptomatic chronic hyponatraemia is rarely, if ever, associated with cerebral oedema severe enough to cause herniation of the brain. During hyponatraemia, brain cells that have been exposed to hypotonic plasma swell, because of intracellular fluid shift. The early adaptive response of the brain cells to hyponatraemia is by loss of water into the cerebrospinal fluid (CSF) followed by extrusion of sodium and potassium from the brain cells. The late adaptive response occurs with the extrusion of organic osmolytes such as myoinositol, glycerophosphatylcholine, glutamate, glutamine, creatinine and taurine. If adaptation of the brain is incomplete, raised intracranial tension develops which may eventually lead to death.

Diagnosis

The diagnostic approach to the patient with hyponatraemia consists of a directed history and physical examination, appropriate laboratory tests, and in selected patients, assessing the response to volume expansion with isotonic saline.

Laboratory work-up includes serum osmolality, urine osmolality and urine Na^+. The plasma osmolality, which normally ranges from 275 mOsm/kg to 290 mOsm/kg, is reduced in most hyponatraemic patients, because it is primarily determined by the plasma sodium concentration and accompanying anions. In patients with hyponatraemia and a low plasma osmolality, the urine osmolality can be used to distinguish between impaired water excretion (which is present in almost all cases) and primary polydipsia, in which water excretion is normal but intake is so high that it exceeds excretory capacity. The normal response to hyponatraemia (which is maintained in primary polydipsia) is to completely suppress antidiuretic hormone (ADH) secretion, resulting in the excretion of maximally dilute urine with an osmolality below 100 mOsm/kg and a specific gravity ≤ 1.003. Values above this level indicate an inability to normally excrete free water, most commonly because of continued secretion of ADH.

In patients with hyponatraemia, hypo-osmolality and inappropriately concentrated urine, the urine sodium concentration can be used to distinguish between hyponatraemia caused by a decreased effective arterial blood volume and euvolaemic hyponatraemia. The urine sodium concentration is usually below 25 mEq/L in hypovolaemia, unless there is renal salt wasting while it is more than 40 mEq/L in syndrome of inappropriate antidiuretic hormone hyper-secretion (SIADH). Later is also associated with increased uric acid excretion.

Management

The two primary goals of therapy are: to initiate treatment of the underlying condition and to restore the normal serum osmolality without causing an iatrogenic complication. The following methods of increasing the serum sodium concentration and to restore serum osmolality can be used:

1. Restricting water intake

Water restriction to below the level of output is the primary therapy for hyponatraemia in oedematous states (such as heart failure and cirrhosis), SIADH, primary polydipsia and advanced renal failure.

2. Giving oral or intravenous sodium chloride

Sodium chloride, usually as isotonic saline or increased dietary salt, is given to patients with true volume depletion and adrenal insufficiency, and to some patients with SIADH. Administration of hypertonic saline is limited to patients with symptomatic or severe hyponatraemia or, occasionally to patients with SIADH and highly concentrated urine.

3. Giving vasopressin antagonist

Conivaptan is an intra-venous formulation that blocks V2 and V1a receptors while lixivaptan, tolvaptan and satavaptan are oral formulations that are exclusively V2 receptor antagonists.

Osmotic demyelination syndrome (ODS) is associated with rapid correction of hyponatraemia. A rapid increase in the plasma sodium concentration can lead to ODS, previously known as central pontine myelinolysis. This rapid cellular dehydration originally was identified in the pons, but has now been identified in other areas of the brain.

HYPERNATRAEMIA

Hypernatraemia is defined as elevation of serum sodium concentration to a value exceeding 145 mEq/L.

Causes of Hypernatraemia

It can be caused by either a net water loss or rarely by a gain of hypertonic sodium solution. Net water loss can occur in the absence of a sodium deficit (free water deficit) or in its presence (hypotonic fluid loss). Various causes of hypernatraemia are described in **Table 2**. Thirst is the most important protective mechanism against sustained hypernatraemia, thus the highest risk exists in those with altered mentation, intubated patients, infants and elderly patients. The other protective mechanism is ADH secretion stimulated by hyperosmolality caused by hypernatraemia.

Clinical Manifestations

The primary manifestation of hypernatraemia reflects central nervous system dysfunction, which in turn, is a consequence of cellular dehydration in the brain. Signs and symptoms vary with the degree, rapidity of onset of hypernatraemia and the age of the patient. Elderly patients generally have few symptoms until the serum sodium concentration exceeds 160 mmol/L. Intense thirst may be present initially, but it dissipates as the disorder progresses and is absent in patients with hypodipsia. Convulsions are rare except during inadvertent sodium loading, rehydration or in the presence of intracranial bleed. Values above 180 mEq/L are associated with a high mortality rate, particularly in adults.

Diagnosis

The history should include a review of recent and current medication use and questions regarding exercise, heat exposure, sweating, vomiting, diarrhoea, urine output, recent fluid intake and the presence of thirst. Physical examination should include an assessment of ECF volume and a complete

Table 2: Causes of Hypernatraemia

- Net water loss
- Pure water loss: Euvolaemic hypernatraemia
  - Insensible water losses
  - Hypothalamic lesions impairing thirst or osmoreceptor function
  - Central diabetes insipidus
  - Congenital nephrogenic diabetes insipidus
  - Acquired diabetes insipidus
- Hypotonic fluid: Hypovolaemic hypernatraemia
  - Renal causes
    - Loop diuretics
    - Osmotic diuretics
    - Post-obstructive diuresis
    - ATN-diuretic phase
    - Intrinsic renal disease
  - Gastrointestinal causes
    - Vomiting
    - Nasogastric drainage
    - Enterocutaneous fistula
    - Diarrhoea
  - Cutaneous causes
    - Burns
    - Excessive sweating
    - Pemphigus
- Hypertonic sodium gain: Hypervolaemic hypernatraemia
  - Hypertonic sodium bicarbonate infusion
  - Ingestion of sodium chloride
  - Hypertonic saline enemas
  - Hypertonic dialysis
  - Cushing's syndrome
  - Primary hyperaldosteronism

neurologic evaluation. Urine volume should be monitored, urine osmolality should be measured in several spot urine samples and 24-hour urine osmolar excretion should also be measured if polyuria is present. In the less common situation of hypervolemic hypernatraemia, there is often an antecedent history of medical intervention that includes the administration of sodium-containing solutions. The findings on physical examination are consistent with ECF volume expansion, whereas the cause of hypernatraemia is usually apparent (e.g. diarrhoea), the urine osmolality may be useful in clarifying the cause in patients without obvious gastrointestinal or insensible water losses. During hypernatraemia caused by extrarenal water losses, the renal response should be to generate hypertonic urine with an osmolality of 700 to 800 mOsm/kg.

If the urine osmolality (U_{osm}) is less than 300 mOsm/kg, then water loss is occurring via the kidneys, secondary to decreased hypothalamic release of ADH (central diabetes insipidus) or impaired sensation in the cortical collecting tubule (nephrogenic diabetes insipidus). In central diabetes insipidus, provision of ADH results in an increase in U_{osm}, whereas in nephrogenic diabetes insipidus, it results in little to no increase in U_{osm}.

If U_{osm} is between 300 mOsm/kg and 800 mOsm/kg, patients might have partial forms of nephrogenic or central diabetes insipidus or an osmotic diuresis from urea or glucose. In patients believed to have diabetes insipidus, a water deprivation test can be performed to assess the integrity of pituitary release and renal response to ADH.

Management

For treating acute hypernatraemia, normal saline solutions are initially given intravenously. In the highly volume-contracted patient with severe hypernatraemia, administering isotonic saline solutions has two advantages. It provides fluid resuscitation in impending cardiovascular collapse. Moreover, the isotonic salt solution, which is hypotonic with respect to the hypertonic patient, avoids an unnecessary rapid fall in the serum sodium level.

Amount of the water deficit and ideal rate of correction must be considered while correcting the water deficit in the hypernatraemic patient. The maximum safe rate at which the plasma sodium concentration should be lowered, is by ≤ 0.5 mEq/L per hour and no more than by 12 mEq/L per day. The preferred route for administering fluids is the oral route or a feeding tube. If neither is feasible, fluids should be given intravenously. Only hypotonic fluids are appropriate including pure water, 5% dextrose, 0.2% sodium chloride (referred to as one-quarter isotonic saline) and 0.45% sodium chloride (one-half isotonic saline).

HYPOKALAEMIA

It is one of the most common electrolyte abnormalities in clinical practice. Hypokalaemia is defined as serum potassium (K^+) less than 3.6 mEq/L.

Spurious hypokalaemia is an entity when serum K^+ levels are low but total body K^+ stores are normal. It may be seen in marked leucocytosis (TLC >1,00,000) where white blood cells take-up K^+, if the serum sample is stored at room temperature. It may be seen in the setting of an insulin dose being given just prior to taking a serum sample due to intracellular shift of K^+.

Causes of Hypokalaemia

The causes of hypokalaemia may be classified into reduced K^+ intake and increased K^+ losses **(Table 3)**. Decreased intake of K^+ rarely causes hypokalaemia. The daily requirement is 40 to 120 mEq/L; however, the normal kidney is able to decrease the daily excretion of K^+ in the presence of low intake.

Clinical Manifestations

The clinical manifestations tend to be proportionate to the degree of hypokalaemia. Patients are asymptomatic above the K^+ level of 3.0 mEq/L. However, rapidly falling K^+ levels or other conditions predisposing to arrhythmias can give rise to symptoms at a much higher level. The usual manifestations are described below:

1. Muscle weakness

Hypokalaemia is one of the causes of acute flaccid paralysis starting in the lower limbs and progressing upwards. It can also lead to respiratory muscle involvement to cause respiratory failure or affect gastrointestinal muscles resulting in ileus. Other muscular manifestations include cramps, paresthesias and tetany.

2. Cardiac arrhythmias

Various types of cardiac arrhythmias can be induced by hypokalaemia including atrial pre-mature complexes, ventricular pre-mature complexes, sinus bradycardia, paroxysmal atrial tachycardia, atrioventricular block and

ventricular tachycardia (VT)/ventricular fibrillation (VF). Presence of concomitant coronary ischaemia, digitalis, increased beta adrenergic activity and hypomagnesemia increases the risk of arrhythmias.

3. Renal abnormalities

Hypokalaemia can induce impaired urinary concentrating ability, increased ammonia production, increased renal bicarbonate production and hypokalaemic nephropathy.

4. Rhabdomyolysis

Severe hypokalaemia (< 2.5 mEq/L) may induce rhabdomyolysis and myoglobinuria.

Table 3: Causes of Hypokalaemia

- Decreased potassium intake
- Increased transcellular shift
  - Metabolic alkalosis
  - Insulin administration
  - Beta-2 adrenergic agonists
- Increased potassium loss
  - Renal
    - Diuretics, especially loop diuretics
    - Primary mineralocorticoid excess
    - Metabolic acidosis
    - Hypomagnesemia
    - Amphotericin B
    - Salt wasting nephropathy
    - Polyuria
    - Non-reabsorbable ions
  - Extra-renal loss
  - Excessive sweating: Generally insignificant, may be seen after heavy exercise when sweating is > 10 L per day
  - Gastrointestinal losses, e.g. diarrhoea, nasogastric aspiration, vomiting
  - Dialysis or plasmapheresis

Diagnosis

Total body K^+ depletion may result from renal or extrarenal causes. Most of the times, a good history and examination reveals the source of K^+ loss (renal *versus* extrarenal). If the source is unclear, a 24-hour urinary K^+ excretion may be of benefit. A 24-hour urinary K^+ >20 mEq/L implies that renal potassium loss is the cause of hypokalaemia. The presence of metabolic acidosis is most often due to diabetic ketoacidosis or renal tubular acidosis type 1 or type 2. The transtubular potassium concentration gradient (TTKG) is used to evaluate the force for K^+ secretion in the cortical collecting duct in the kidney.

The electrocardiographic changes of hypokalaemia include flattening or inversion of T waves (early), prominent U waves, ST-segment depression, prolonged PR interval and widening of QRS complex. These changes do not correlate well with plasma K^+ levels.

Treatment

In the absence of an independent factor, causing transcellular K^+ shifts, the magnitude of the deficit in body stores of K^+ correlates with the degree of hypokalaemia. On an average, serum K^+ decreases by 0.3 mmol/L for each 100 mmol reduction in total body stores, but the response is extremely variable.

Oral correction is recommended in all non-urgent settings where patient does not have any arrhythmias or paralysis and does not have any contraindication to oral supplementation. Intravenous K^+ supplementation is used for profound, life-threatening hypokalaemia and in patients who do not tolerate oral solution. Electrocardiogram (ECG) monitoring should be done with supplementation rates >20 mEq/hr. The concentration of administered potassium should be no more than 40 mEq/L in a peripheral vein or 60 mEq/L in a central vein. Infusion rates should be limited to <20 mEq/hr with peripheral cannula and >40 mEq/hr via central line. In all cases, serum K^+ should be checked after 2 to 4 hours of ongoing replacement. Serum Mg^{2+} levels should be checked if hypokalaemia is refractory to correction.

HYPERKALAEMIA

Hyperkalaemia is a common and life-threatening electrolyte imbalance. Early recognition of this condition can allow for the initiation of corrective measures. Hyperkalaemia is defined as a serum K^+ concentration of larger than 5.0 mEq/L. The normal concentration of K^+ depends on the K^+ intake, its excretion by the kidney, and by the balance between extra-cellular and intra-cellular spaces.

Causes of Hyperkalaemia

The causes of hyperkalaemia may be divided into two major groups as described in **Table 4**.

In normal individuals, a phenomenon referred to as K^+ adaptation ensures a proportionate rise in K^+ secretion by the kidney in response to an increase in ingested K^+. Hence, in the presence of normal renal function, hyperkalaemia due to excess intake is rare. Of these metabolic acidosis is a frequently seen cause. In response to every 0.1 unit reduction in extra-cellular pH, the plasma K^+ concentration will rise by 0.6 mEq/L (range 0.2-1.7 mEq/L).

Table 4: Classification of Causes of Hyperkalaemia

- **Hyperkalaemia due to excess release of intracellular potassium**
- Metabolic acidosis
- Insulin deficiency and hypertonicity
- Tissue catabolism
- Exercise
- Beta-adrenergic blockade
- Drugs, e.g. succinylcholine, digitalis overdose
- Hyperkalaemic periodic paralysis
- Pseudohyperkalaemia
- **Hyperkalaemia due to reduced renal clearance**
- Renal failure
- Decreased effective circulating volume
- Impaired sodium reabsorption, e.g. primary hypoaldosteronism, adrenal insufficiency, secondary hypoaldosteronism, renal tubular acidosis, drugs (angiotensin converting enzyme inhibitors, non-steroidal anti-inflammatory drugs, potassium sparing diuretics)
- Increased chloride reabsorption, e.g. Gordon's syndrome, cyclosporine
- Ureterojejunostomy

Clinical Manifestations

Hyperkalaemia is associated with very few overt symptoms and signs, and these manifests only at very high levels or when the rise is rapid. Severe muscle weakness and paralysis may be seen in some cases. The primary cause of mortality in hyperkalaemia

is cardiac rhythm disturbances. As a result, hyperkalaemia can be recognised by some typical ECG abnormalities.

A tall and symmetrical T-wave is the first sign of hyperkalaemia. T-waves are usually taller than half of the preceding QRS complexes when considered significant and may appear tented in severe cases. Due to slowing of cardiac conduction, other subsequent changes ensue, including progressive lengthening of the PR interval and QRS duration, atrioventricular conduction delay and loss of P-waves, progressive widening of the QRS complex and merging of the T- and U-waves resulting in a 'sine wave' pattern. The terminal event is ventricular fibrillation or asystole. The level of K^+ does not correlate with the degree and progression of ECG changes.

Diagnosis

The most common causes of hyperkalaemia, such as renal failure, drugs and transcellular K^+ shift, are relatively simple to identify. Chronic hyperkalaemia not related to these aetiologies is usually due to impaired secretion of K^+. Assessment of the TTKG is helpful to differentiate between decreased effective circulating volume (TTKG >10) and other causes (TTKG <5). In cases where TTKG is < 5, the presence of kaliuresis in response to administration of mineralocorticoid indicates hypo-aldosteronism.

Management

Hyperkalaemia requires emergent treatment. Severe arrhythmias can occur at K^+ levels >7.5 mEq/L but may also occur at lower levels. The goals of therapy are to decrease membrane excitability; thereby preventing arrhythmias, shifting K^+ to the intra-cellular space and promoting K^+ loss and removal of exogenous source of K^+.

1. Membrane excitability is controlled by the infusion of 1000 mg (10 ml of a 10% solution) of calcium gluconate over 2 to 3 minutes. The effect begins within minutes but is short lived (only 30 to 60 minutes). The dose can be repeated if no change in ECG is noted within the next 5 to 10 minutes. This does not affect the levels of K^+.
2. Insulin causes a shift of extra-cellular K^+ into the cells by enhancing the effect of the Na^+-K^+ ATPase pump. An infusion of 10 to 20 units of regular insulin in 20 to 50 g of dextrose can result in the fall of K^+ by 0.5 to 1.5 mEq/L in 15 to 30 minutes. This effect peaks at 30 minutes and lasts several hours. Diabetic patients with hyperglycaemia may be given insulin alone.
3. Sodium bicarbonate is effective in shifting K^+ into the intra-cellular space when given in hyperkalaemia associated with metabolic acidosis. The action begins within 30 to 60 minutes and persists for several hours.
4. Beta-2-adrenergic agonists promote the cellular uptake of K^+. The onset of action is within 30 minutes and lasts for 2 to 4 hours. These drugs can be effectively used in the treatment of acute hyperkalaemia, lowering the plasma K^+ concentration by 0.5 to 1.5 mEq/L.
5. Removal of potassium can be achieved using loop or thiazide diuretics if renal function is adequate. Potassium binding resins, like sodium polystyrene sulfonates, are useful in binding dietary potassium in the gut and preventing its absorption. One gram of resin binds 1 mEq of K^+ and releases 2 to 3 mEq of sodium. The usual dose is 25 to 50 g mixed in 20% sorbitol to prevent constipation. It lowers plasma K^+ concentration by 0.5 to 1.5 mEq/L. A retention enema may also be used.
6. The most effective way of lowering K^+ is by haemodialysis. Severe hyperkalaemia, not responding to conservative management, is an indication for haemodialysis. Peritoneal dialysis may be done in hypotensive patients but is only 15% to 20% effective.

CALCIUM METABOLISM

Calcium plays a vital role in body homeostasis. Diverse physiologic processes in body like muscle contraction, neuromuscular signaling, blood coagulation and hormone secretion take place because of calcium. Total body calcium is around 1 to 2 kg of which 99% is in the bones. The normal total levels of calcium in body are 8.5 to 10.5 mg/dL of which 50% is ionised. The remainder is ionically bound to negatively charged proteins (albumin and immunoglobulins) or loosely complexed with phosphate, citrate, sulphate or other anions. Intra-cellular calcium concentrations are 10,000 folds lower than extra-cellular levels. The levels are maintained by feedback mechanism involving parathyroid hormone and active vitamin D. Liver, kidneys, intestines and bones are the principle sites of metabolism.

Causes of Hypocalcaemia

The causes of hypocalcaemia can be classified according to the activity of parathyroid hormone (PTH) **(Table 5)**.

Table 5: Causes of Hypocalcaemia

Low or absent parathyroid hormone (PTH)	
Parathyroid agenesis:	Isolated/DiGeorge syndrome
Parathyroid destruction:	Radiation/surgical/infiltration by metastases/autoimmune process
Decreased PTH release:	Hypomagnesemia, activating calcium sensing receptor (CaSR) mutations
High or ineffective PTH	
Chronic renal failure	
Vitamin D deficiency/resistance	
Pseudohypoparathyroidism	
Drugs: Calcium chelators, bisphosphonates, phenytoin, ketoconazole	
Severe acute hyperphosphataemia: Tumour lysis, rhabdomyolysis	
Miscellaneous	
Acute pancreatitis	
Hungry bone disease (after parathyroidectomy)	
Severe burns, sepsis, acute renal failure, extensive transfusions with citrated blood (transient)	

Clinical Manifestations

Hypocalcaemia may be asymptomatic if the decrease in serum calcium are relatively mild and chronic. Moderate-to-severe hypocalcaemia is associated with paresthesias, usually of the fingers and toes, and circumoral region. Tapping the inferior portion of zygoma produces twitching of perioral muscles (Chvostek's sign). Carpal spasm can be induced by inflation of blood pressure cuff to 20 mmHg above the patient's systolic blood pressure for 3 minutes (Trousseau's sign). Life-threatening complications, like cardiac arrhythmias, bronchospasm, laryngospasm and seizures, may occur due to severe hypo-calcaemia.

Diagnosis

Besides measuring serum calcium, it is useful to determine albumin, phosphorus and magnesium levels. Each 1 g/dL reduction in the serum albumin concentration lowers the total calcium concentration by approximately 0.8 mg/dL (0.2 mmol/L) without affecting the ionised calcium concentration. Serum intact PTH measurements provide critical information in patients with hypocalcaemia, but can be interpreted correctly only when serum calcium is measured simultaneously. Suppressed PTH levels along with hypocalcaemia suggests absent or reduced PTH secretion as the cause of hypocalcaemia. Elevated PTH levels should direct to search for secondary hyperparathyroidism. Levels of 25-hydroxy vitamin D should be done if nutritional cause of hypocalcaemia is suspected. 1, 25 dihydroxy vitamin D levels are useful in patients with renal dysfunction and hypocalcaemia.

Management

The treatment depends on the severity of hypocalcaemia, the rapidity with which it develops and accompanying complications. Acute symptomatic hypocalcaemia is treated with intravenous calcium gluconate 10 ml 10% wt/vol (90 mg) diluted in 50 ml of 5% dextrose or 0.9%; normal saline is given over 5 minutes. It may be followed by a continuous infusion of 5 ampules of calcium gluconate (450 mg) in dextrose 5% or normal saline 500 ml over 12 hours. Intra-muscular or subcutaneous route should be avoided due to chances of necrosis. Associated magnesium deficiency should also be corrected.

Asymptomatic chronic hypocalcaemia can be treated with oral formulations containing calcium (1 to 2 g/day) and vitamin D2 or D3 (25,000 to 1,00,000 U daily) or calcitriol (1,25 dihydroxy vitamin D) 0.25 to 2 µg/day. Vitamin D deficiency is treated with oral supplementation of vitamin D (50,000 U 2 to 3 times per week for several months).

HYPERCALCAEMIA

It is a very common problem in day-to-day practice. It could be an incidental finding on laboratory testing or reflection of some serious underlying disease.

Causes of Hypercalcaemia

Broadly, the aetiology can be classified on the basis of either related to or unrelated to PTH **(Table 6)**.

Table 6: Classification of Aetiology of Hypercalcaemia

Parathyroid hormone (PTH) related
Primary hyperparathyroidism: Solitary adenomas/multiple endocrine neoplasia (MEN)
Tertiary hyperparathyroidism (CKD with long-term stimulation of PTH)
Lithium therapy
Familial hypercalciuric hypercalcaemia
PTH unrelated
Malignancy associated: Solid tumours (breast, lung, kidney), blood disorders (myeloma)
Vitamin D associated: Vitamin D intoxication, granulomatous disease like sarcoidosis, lymphomas
High bone turnover: Hyperthyroidism, immobilisation, thiazides, vitamin A intoxication
Excessive calcium intake: Milk alkali syndrome, total parenteral nutrition

Clinical Manifestations

Hypercalcaemia is largely asymptomatic in half of the patients. Mild hypercalcaemia (upto 11 to 11.5 mg/dL) may present with vague symptoms like difficulty in concentration, personality changes or depression. Groans (constipation), moans (psychotic noise), bones (bone pain, especially if PTH is elevated), stones (kidney stones) and psychiatric overtones (including depression and confusion) are a common mnemonic for hypercalcaemic symptoms. Symptoms are common at calcium levels of 12 to 13 mg/dL, especially if they develop acutely and may include lethargy, stupor or coma, as well as gastrointestinal tract symptoms like anorexia, nausea, constipation or pancreatitis. Bone pains, pathologic fractures, polyuria or polydipsia may also occur. ECG changes in the form of short QT interval, widened T-waves and atrioventricular conduction disturbances may also occur. Severe hypercalcaemia (> 15 mg/dL) is life-threatening and coma or cardiac arrest could occur. Immediate measures should be taken to decrease the levels.

Management

The treatment of hypercalcaemia depends on the serum calcium levels, symptom presentation or rapidity with which it develops. Mild asymptomatic hypercalcaemia does not require immediate treatment. The steps in the treatment include hydration, diuretics like furosemide, bisphosphonates, calcitonin and glucocorticoids. Use of oral or parenteral phosphate is not recommended due to systemic toxicity of calcium-phosphate complex. Dialysis can be used as a useful therapy in emergency conditions where severe hypercalcaemia is associated with renal failure and is difficult to manage medically.

MAGNESIUM

Magnesium is a critical co-factor in more than 300 enzymatic reactions in the human body and is essential to the normal functioning of the human body. The average daily intake of magnesium is 360 mg, out of which approximately one-third is absorbed through the small bowel. It is mainly excreted through the kidneys; with 15% to 25% ultrafiltrate magnesium reabsorption through the proximal tubule and 5% to 10% in the distal tubule. Approximately 1% of total body magnesium is present in the serum and interstitial space with the normal plasma magnesium concentration of 1.4 to 2.2 mEq/L. Magnesium is found in various dietary sources, best being green leafy vegetables. It is also found in nuts, soybean and whole grain foods.

Hypermagnesemia

Under normal physiological conditions, magnesium is excreted in the urine. Hypermagnesemia is seen when either the renal function is impaired or there is excess of magnesium load.

Causes of hypermagnesemia

Causes of hypermagnesemia are listed in **Table 7**.

Clinical manifestations

Depends on the serum magnesium concentration, symptoms can range from asymptomatic (<3 mEq/L) to life-threatening cardiac and neuromuscular effects (>4 mEq/L). Magnesium concentration of 4 to 6 mEq/L leads to nausea, headache, lethargy and sluggish deep tendon reflexes. Concentration of 6 to 10 mEq/L leads to somnolence, hypocalcaemia, hypotension and absent reflexes. Levels more than 10 mEq/L

Table 7: Causes of Hypermagnesemia

Renal failure: Hypermagnesemia up to 2 to 3 mEq/L is seen in end-stage kidney disease. Severe hypermagnesemia is seen only if excess exogeneous magnesium load is given.
Magnesium infusion: Parenteral infusion like treatment for pre-eclampsia, eclampsia
Magnesium enemas and oral ingestion which exceeds the renal excretory capacity
Hormonal: Primary hyperparathyroidism, diabetic ketoacidosis, adrenal insufficiency
Tumour lysis syndrome
Milk alkali syndrome

causes muscle paralysis, complete heart block, respiratory and cardiac arrest.

Management

Prevention is by avoiding magnesium loading in patients with impaired renal functions. Cessation of magnesium supplements in patients with normal renal function will allow restoration to normal levels. Intravenous calcium gluconate can be given as a magnesium antagonist. Haemodialysis may be required in patients with renal failure or with severe life-threatening hypermagnesemia.

Hypomagnesemia

Hypomagnesemia is especially common in intensive care unit settings with nutrition, diuretics, etc. In the presence of hypomagnesemia, kidney can decrease the renal excretion. Hypomagnesemia can occur in the setting of gastrointestinal or renal losses. However, it is often associated with other metabolic abnormalities like hypokalaemia, hypocalcaemia and metabolic acidosis.

Causes of hypomagnesemia

Causes of hypomagnesemia are listed in **Table 8**.

Table 8: Causes of Hypomagnesemia

Gastrointestinal losses: Chronic diarrhoea especially if associated with dietary deficiency, malabsorption, steatorrhoea and small bowel resection
Acute pancreatitis, alcoholic patients
Renal losses: Loop and thiazide type diuretics, primary defect in renal tubular magnesium handling, Bartter's and Gitelman's syndrome
Hormonal: Primary aldosteronism
Hypercalcaemia: Resulting from increased reabsorption of calcium in the loop of Henle leading to hypomagnesemia
Drugs: Aminoglycosides, amphotericin B, cisplatin, cyclosporine, pentamidine, proton pump inhibitors
Hungry bone syndrome following parathyroidectomy

Clinical manifestations

The clinical features of hypomagnesemia include tetany, positive Chvostek's and Trousseau's signs and generalised convulsion. ECG changes include widening of QRS complex, peaking of the T-waves, prolongation of PR interval and diminution of T-wave and ventricular arrhythmias, especially during myocardial ischaemia. hypomagnesemia can also present along with hypocalcaemia. Mild hypomagnesemia can lower the plasma concentration of calcium. Vitamin D deficiency is also noted in hypocalcaemic and hypomagnesemic patients.

Management

It is important to correct the underlying cause of hypomagnesemia, e.g. stopping the offending drug. Magnesium is replaced by oral route in asymptomatic patients or those with mild deficiency by sustained release formulations, dose being 2 to 4 tablets per day. Intravenous magnesium replacement is required in conditions like ventricular arrhythmias and tetany.

7.4 Acid Base Disorders

Alladi Mohan, Surendra K Sharma

INTRODUCTION

In critical care practice, a wide range of disorders affecting the acid-base balance are encountered. In addition to diseases that cause primary acid-base disorders, a number of disease states either predispose patients to develop these conditions or require the use of medications that alter renal, gastrointestinal, or pulmonary function and secondarily alter acid-base balance. The history and physical examination and measurement of blood and urinary indices allow identification of the underlying cause of these disorders in most cases. Arterial blood gas (ABG) analysis, considered to be one of the most precise measurements in medicine, is a crucial investigation that is frequently employed in the critical care setting. It provides valuable precise information regarding the acid-base, ventilation and oxygenation status of the patient.

BASIC PHYSIOLOGICAL AND CHEMICAL CONCEPTS

Interpretation of the ABG report requires a clear understanding of the basic concepts and physiological principles underlying the disorders of acid-base homeostasis, oxygenation and ventilation. A brief overview regarding the essential fundamental physiological concepts is provided and a practical approach for the bed-side interpretation of ABG results is described.

Acid-Base Chemistry

pH

The concept of pH was put forward by the Danish chemist, Soren Peter Sorensen in 1909 to refer to the negative logarithm of hydrogen ion (H^+) concentration.

$$pH = -\log [H^+]$$

The pH is a 'dimensionless representation' of the H^+ concentration, it has no units and is just a number. There are several advantages of the expression pH compared to H^+. Measured by the pH electrode, pH is related to the logarithm of H^+ 'activity' rather than 'concentration' of H^+ and this seems physiologically more appropriate. The relationship between pH and H^+ is shown in **Table 1**. For each 0.1 pH unit increment, H^+ falls by 20%; by remembering this relationship, the intermediate values can be derived accurately.

Overview of Acid-Base Balance in the Human Body

The normal extracellular fluid (ECF) H^+ concentration is 40 nmol/L. Under normal physiological conditions, the H^+ concentration varies little from its normal value due to the processes of acid-base regulation as maintenance of H^+ concentration at this level is considered to be essential for normal cellular processes. In order to achieve this, close interaction between three physiological systems of the body, namely, the chemical buffers of the body namely kidneys and the lungs is considered essential.

Table 1: Relationship between pH and $[H^+]$

pH	$[H^+]$ (nmol/L)
6.8	158
6.9	125
7.0	100
7.1	79
7.2	63
7.3	50
7.4	40
7.5	31
7.6	25
7.7	20
7.8	15

Dissolved carbon dioxide (CO_2) is in equilibrium with carbonic acid

$$CO_2 + H_2O \underset{\longleftarrow}{\xrightarrow{\text{Carbonic anhydrase}}} H_2CO_3^-$$

Carbonic acid ionizes according to the equation

$$H_2CO_3 \xrightarrow{\text{Carbonic anhydrase}} H^+ + HCO_3^-$$

By the law of mass action

$$\frac{[H^+]\,[HCO_3^-]}{[H_2CO_3]} = K'$$

Taking logarithm on both sides, we have

$$\log \frac{[H^+]\,[HCO_3^-]}{[H_2CO_3]} = \log K'$$

Therefore,

$$\log [H^+] + \log \frac{[HCO_3^-]}{[H_2CO_3]} = \log K'$$

and

$$\log [H^+] = \log K' - \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

By changing signs on both sides of the equation, we have

$$-\log [H^+] = -\log K' + \log \frac{[H_2CO_3^-]}{[H_2CO_3]}$$

Since $-\log [H^+]$ is called pH and $-\log K'$ is called pK, the equation can be re-written as

$$pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

This has been called the 'Henderson-Hasselbalch' equation.

The pK represents the pH at which maximum buffering capacity can be achieved for that reaction. Since the carbonic acid concentration is dependent on the amount of dissolved CO_2 which in turn is dependent on its solubility and the partial pressure of carbon dioxide ($PaCO_2$) in the arterial blood. Therefore, in this equation, H_2CO_3 can be substituted by s x $PaCO_2$, where, s = solubility coefficient. In the clinical setting, pK = 6.1; s = 0.0301.

Therefore,

$$pH = 6.1 + \log \frac{[HCO_3^-]}{0.0301 \times PaCO_2}$$

The body responds to the perturbations in the acid-base balance by buffering, which is the immediate response followed by respiratory (alteration in ventilation) and renal (alteration in bicarbonate excretion) responses.

The major buffer system in the ECF is the CO_2-bicarbonate buffer system. Other buffer systems that play a role in buffering are protein and phosphate buffer systems. In the blood, concentration of phosphate is very low and it is quantitatively unimportant. Protein buffers in blood include haemoglobin and plasma proteins. Haemoglobin is an important blood buffer particularly for buffering CO_2. According to the 'isohydric principle', at a given moment, all buffer systems which participate in defense of acid-base changes are in equilibrium with each other. It is important to remember that the carbonate and phosphate salts in bone act as a long-term supply of buffer, especially during prolonged metabolic acidosis.

NOMENCLATURE FOR CLINICAL INTERPRETATION OF ARTERIAL BLOOD GAS MEASUREMENTS

The nomenclature for clinical interpretation of ABG measurements are listed in **Table 2**. Normal laboratory values and acceptable therapeutic ranges for pH and $PaCO_2$ are shown in **Table 3**. The typical alterations in the ABG results and the expected compensatory mechanisms in simple acid-base disorders are listed in **Tables 4A and B**.

Table 2: Nomenclature for Clinical Interpretation of ABG Measurements: Acid-Base Status

Acidosis is an abnormal process or condition which would lower arterial pH if there were no secondary changes in response to the primary aetiological factor

Alkalosis is an abnormal process or condition which would raise arterial pH if there were no secondary changes in response to the primary aetiological factor

Acidaemia = Arterial pH < 7.36

Alkalaemia = Arterial pH > 7.44

Simple acid-base disorders are those in which there is a single primary aetiological acid-base disorder

Mixed acid-base disorders are those in which two or more primary aetiological disorders are present simultaneously

Respiratory disorders are caused by abnormal processes which tend to alter pH because of a primary change in $PaCO_2$ levels

Metabolic disorders are caused by abnormal processes which tend to alter pH because of a primary change in HCO_3^-

ABG = Arterial blood gas; $PaCO_2$ = Partial pressure of carbon dioxide; HCO_3^- = Bicarbonate

Table 3: Normal Laboratory Values and Acceptable Therapeutic Ranges for pH and $PaCO_2$

Variable	Mean	1SD	2SD	Acceptable Therapeutic Range
pH	7.40	7.38-7.42	7.35-7.45	7.30-7.50
$PaCO_2$ (mmHg)	40	38-42	35-45	30-50

SD = Standard deviation; $PaCO_2$ = Partial pressure of carbon dioxide

Table 4A: Expected Compensatory Mechanisms in Respiratory Acid-Base Disorders

Acid-base Disorder	Initial Change	Compensatory Response	Equations for Expected Range of Compensation
Respiratory acidosis	↑$PaCO_2$	↑HCO_3^-	
Acute			For every 10 mmHg↑ in $PaCO_2$, pH decreases by 0.08 units Expected pH = 7.4 – [0.008 × ($PaCO_2$ – 40)]
Chronic			For every 10 mmHg↑ in $PaCO_2$, pH decreases by 0.03 units Expected pH = 7.4 – [0.003 × ($PaCO_2$ – 40)]
Respiratory alkalosis	↓$PaCO_2$	↓HCO_3^-	
Acute			For every 10 mmHg↓ in $PaCO_2$, pH increases by 0.08 units Expected pH = 7.4 + [0.008 × (40 – $PaCO_2$)]
Chronic			For every 10 mmHg↓ in $PaCO_2$, pH increases by 0.03 units Expected pH = 7.4 + [0.003 × (40 – $PaCO_2$)]

Table 4B: Expected Compensatory Mechanisms in Metabolic Acid-Base Disorders

Acid-base Disorder	Initial Change	Compensatory Response	Equations for Expected Range of Compensation
Metabolic acidosis	↓HCO_3^-	↓$PaCO_2$	↓$PaCO_2$ = 1.2 × △ (HCO_3^-) Expected $PaCO_2$ = [1.5 × (HCO_3^-) + 8] ± 2 (Winter's formula)
Metabolic alkalosis	↑HCO_3^-	↑$PaCO_2$	↑$PaCO_2$ = 0.7 × △ (HCO_3^-) Expected $PaCO_2$ = [0.7 × (HCO_3^-) + 21] ± 2

Indices for Acid-Base Balance

Indices for acid-base balance include $PaCO_2$, actual bicarbonate, standard bicarbonate and buffer base. *Standard bicarbonate* is the measurement made in the clinical laboratory after the blood has been equilibrated at 37°C with a $PaCO_2$ of 40 mmHg. *Actual bicarbonate* is calculated from $PaCO_2$ and pH using Henderson-Hasselbalch equation. Base excess is defined as the number of mEq of acid or base needed to titrate 1 L of blood to a pH of 7.40 at 37°C while $PaCO_2$ is held constant. For quick bed-side calculation, it can be assumed that at $PaCO_2$ held constant at 40 mmHg, 7 mEq of acid or base are required to change pH by 1 unit (0.10). *Base excess (or deficit),* which is a true reflection of non-respiratory component of acid-base balance, is an estimate and not an actual measurement. Therefore, it will be reliable only if the measurements used to derive it, the pH and $PaCO_2$ are estimated accurately. Base excess is determined as follows:

Calculating $PaCO_2$ Variance

First, the $PaCO_2$ variance is determined by calculating the difference between the measured $PaCO_2$ and 40; then, the decimal point is shifted two places to the left.

Example:

pH 7.06, $PaCO_2$ = 74
74 – 40 = 34
$PaCO_2$ variance = 0.34
pH 7.48, $PaCO_2$ = 20
40 – 20 = 20
$PaCO_2$ variance = 0.20

Calculating Predicted pH

Predicted respiratory pH is calculated as follows. If the $PaCO_2$ is greater than 40, half the $PaCO_2$ variance is subtracted from 7.40. If $PaCO_2$ is less than 40, the $PaCO_2$ variance is added to 7.40.

Examples:

1. pH 7.06, $PaCO_2$ = 74
   74 – 40 = 34
   $PaCO_2$ variance = 0.34
   0.34 × ½ = 0.17
   Predicted respiratory pH = 7.40 – 0.17 = 7.23
2. pH 7.48, $PaCO_2$ = 20
   40 – 20 = 20
   $PaCO_2$ variance = 0.20
   Predicted respiratory pH = 7.40 + 0.20 = 7.60

Estimate of Base Excess/Deficit

The difference between the predicted respiratory pH and the measured pH reflects the metabolic pH change. Normally, a 10 mEq/L variance from normal buffer baseline represents a pH change of 0.15. If the pH decimal point is moved two places to the right, a 10 (10 mEq/L) to 15 (0.15) relationship will be evident and this has been expressed as "⅔ relationship". By determining the difference between the measured pH and the predicted respiratory pH, moving the decimal point two places to the right and multiplying by ⅔, base excess/deficit can be calculated.

When the measured pH is greater than the predicted pH, it is termed as *base excess*. When the measured pH is less than the predicted pH, it is termed as *base deficit*.

Examples:

1. pH 7.06, $PaCO_2$ = 74, predicted pH = 7.23
   Difference between predicted and measured pH = 7.23 – 7.06 = 0.17
   Applying ⅔ rule, 0.17 × ⅔ = 0.11
   Base deficit = 11 mEq/L
2. pH 7.48, $PaCO_2$ = 20, predicted pH = 7.60
   Difference between predicted and measured pH = 7.6 – 7.48 = 0.12
   Applying ⅔ rule, 0.12 × ⅔ = 0.08
   Base deficit = 8 mEq/L
3. pH 7.20, $PaCO_2$ = 90
   90 – 40 = 50
   $PaCO_2$ variance = 0.50
   0.50 × ½ = 0.25
   Predicted respiratory pH = 7.40 – 0.25 = 7.15
   Difference between predicted and measured pH = 7.20 – 7.15 = 0.05
   Applying ⅔ rule, 0.05 × ⅔ = 0.033
   Base excess = 3 mEq/L
   Base excess/deficit calculation serves as a useful guide for bicarbonate administration.

Anion Gap

Anion gap (AG) represents the concentration of all the unmeasured anions in the plasma (**Table 5**) and is calculated by the following formula:

$$AG = [Na^+] - [Cl^-] + [HCO_3^-]$$

Normal AG is 12 ± 4 mEq/L. Conditions resulting in metabolic acidosis other than hydrochloric acidosis usually lead to a decrease in the serum bicarbonate concentration without a concomitant rise in serum chloride thereby increasing the AG.

Table 5: Unmeasured Anions and Cations Contributing to the Anion Gap

Unmeasured Anions	Unmeasured Cations
Serum proteins, mostly serum albumin (15 mEq/L)	Calcium (5 mEq/L)
Organic acids (5 mEq/L)	Potassium (4.5 mEq/L)
Phosphates (2 mEq/L)	Magnesium (1.5 mEq/L)
Sulphates (1 mEq/L)	
Total = 23 mEq/L	**Total = 11 mEq/L**

Delta Ratio

Delta ratio is related to the AG and buffering, and is defined as:

Delta ratio = increase in AG/decrease in bicarbonate

A high delta ratio can occur when the bicarbonate levels are already elevated at the onset of the metabolic acidosis either due to a pre-existing metabolic alkalosis, or as a compensation for pre-existing respiratory acidosis. A low delta ratio occurs with hyperchloraemic normal AG acidosis (**Table 6**).

DIAGNOSIS OF ACID-BASE DISORDERS

Clinical Assessment

Patients with acid-base disturbances (**Tables 7A and B**) may present with symptoms due to the aetiological causes that

Table 6: Utility of Delta Ratio when Assessing Metabolic Acid-Base Disorders

Delta Ratio	Interpretation
<0.4	Hyperchloraemic normal AG acidosis
<1	High AG and normal AG acidosis
1 to 2	Usual for uncomplicated high AG acidosis Lactic acidosis: average value 1.6 DKA more likely to have a ratio closer to 1 due to urine ketone loss
>2	High AG acidosis and a concurrent metabolic alkalosis or a pre-existing compensated respiratory acidosis

AG = Anion gap; DKA = Diabetic ketoacidosis

resulted in the disturbance. They may also present with manifestations that develop as a consequence of the disturbance as well as with symptoms that have nothing to do with the acid-base disturbance. Therefore, a carefully obtained history and a thorough physical examination are essential for the interpretation of ABG report. The following sequence may be followed to interpret the ABG report to diagnose acid-base disturbances (**Figure 1**).

Step 1: Validity of the ABG report

First, whether pH, $PaCO_2$ and HCO_3^- are compatible should be confirmed using the Henderson-Hasselbach equation which can also be expressed as:

$$H^+ = 24 \times \frac{PaCO_2}{[HCO_3^-]}$$

Step 2: Acidosis or alkalosis?

Net deviation in the arterial pH will indicate whether an acidosis or an alkalosis is present (**Table 2**). If pH is normal, either no acid-base disorder is present or compensating disorders are present.

Step 3: Identifying the primary disturbance: respiratory or metabolic?

Simple acid-base disorders result in a predictable change in the $PaCO_2$ and HCO_3^- (**Tables 4A and B**). Low $PaCO_2$ and HCO_3^- indicate respiratory alkalosis or metabolic acidosis; but a mixed disorder cannot be excluded. Elevated $PaCO_2$ and HCO_3^- indicate respiratory acidosis or metabolic alkalosis; but a mixed disorder cannot be excluded. If $PaCO_2$ and HCO_3^- show a change in opposite directions, it is indicative of a mixed disorder.

Table 7A: Causes of Metabolic Acid-Base Disorders

Metabolic Acidosis	Metabolic Alkalosis
Elevated AG	**Alkali load**
Endogenous	Milk-alkali syndrome
Ketoacidosis	Bicarbonate administration
Diabetes mellitus	Excess bicarbonate-precursor administration
Starvation	**Contraction alkalosis**
Alcohol-induced	Gastric causes
L-Lactic acidosis	Vomiting
Hypoxic (e.g., shock, hypoxaemia, severe anaemia, cyanide poisoning,carbon monoxide poisoning)	Gastric aspiration
Non-hypoxic (e.g., diabetes mellitus, liver failure, kidney failure, sepsis, drugs [ethanol, ethylene glycol, methanol, salicylates, phenformin], neoplasms)	Renal alkalosis
D-Lactic acid acidosis (associated with jejuno-ileal bypass, short bowel syndrome or intestinal obstruction; due to formation of D-lactate by gut bacteria) Uraemic acidosis	Diuretics
Exogeneous	Post-hypercapnoeic metabolic alkalosis
Methanol	Diarrhoea states
Ethylene glycol	Villous adenoma
Salicylates	Hereditary chloride-losing diarrhoea of infancy
Paraldehyde	**Metabolic alkalosis without volume contraction**
Normal AG	Steroid excess (primary)
Non-renal	Primary mineralocorticoid excess [e.g. adrenal adenoma (Conn's syndrome); bilateral adrenal hyperplasia (pseudo-Conn's syndrome); adrenal carcinoma]
Diarrhoea	Cushing's syndrome
Pancreatic fistula	Indeterminate hyperaldosteronism
Urinary diversion	Dexamethasone-suppressible hyperaldosteronism
Acid ingestion	Secondary aldosterone excess
Renal	Renovascular disease
Uraemia	Renin-secreting tumours
Proximal RTA	Errors of steroid metabolism
Hypokalaemic distal RTA (e.g. classic, amphotericin-induced)	11-hydroxylase deficiency
Hyperkalaemic distal RTA (e.g. short-circuit distal RTA, such as, urinary tract obstruction; sickle cell disease; drug-induced)	11- dehydrogenase deficiency
Mineralocorticoid deficiency (e.g. Addison's disease; selective aldosterone deficiency; hyporeninemic hypoaldosteronism)	17- hydroxylase deficiency
	Terminal steroid metabolism defect
Others	Liddle's syndrome
Pyroglutamic acidaemia (acetaminophen induced)	Bartter's syndrome (loss of function mutations in TALH)
	Gittleman's syndrome (loss of function mutation in Na^+-Cl^- cotransporter in DCT)
	Iatrogenic hypermineralocorticoidism
	Exogenous corticosteroids
	Glycyrrhizic acid
	Carbenoxolone fludrocortisone

AG = Anion gap; RTA = Renal tubular acidosis; TALH = Thick ascending limb of Henle's loop; DCT = Distal convoluted tubule.

Table 7B: Causes of Respiratory Acid-Base Disorders

Respiratory Acidosis	Respiratory Alkalosis
Neurological causes	**Pregnancy**
Poliomyelitis	**Pulmonary receptor stimulation**
Excessive sedative, hypnotic drug use	Pneumonia
Spinal cord injury with quadriparesis	Pulmonary embolism
Phrenic nerve palsy	Bronchial asthma
Guillain-Barré syndrome	**Hypoxia**
Myasthenia gravis	High altitude
Eaton-Lambert syndrome	Left to right shunts
Paralytic agents	Congestive heart failure
Botulism	**Pulmonary oedema**
Myopathies, muscular dystrophies, myositis	**Psychogenic Drugs**
Motor neuron disease	Theophylline
Electrolyte abnormalities	Catecholamines
Hypokalaemia	Salicylates
Hypocalcaemia, Hypophosphataemia	Progesterone
Chest-wall disease	Doxapram
Scoliosis	**Central nervous system**
Flail chest	Subarachnoid haemorrhage
Pleural disease	Respiratory centre disease
Pneumothorax	Cheyne-Stokes respiration
Massive pleural effusion	**Cirrhosis of liver**
Obstructive airway disease	**Fever**
Acute tracheal, laryngeal, bronchial obstruction	**Sepsis**
Obstructive sleep apnoea	**Errors of ventilator management**
Diffuse (small-airway) obstruction	Excessive tidal volume
Errors of ventilator management	Excessive ventilation rate
Excessive dead space	
Insufficient tidal volume	
Insufficient ventilation rate	
Others	
Myxoedema (idiopathic alveolar hypoventilation)	
Oxygen therapy in chronic hypoxia	

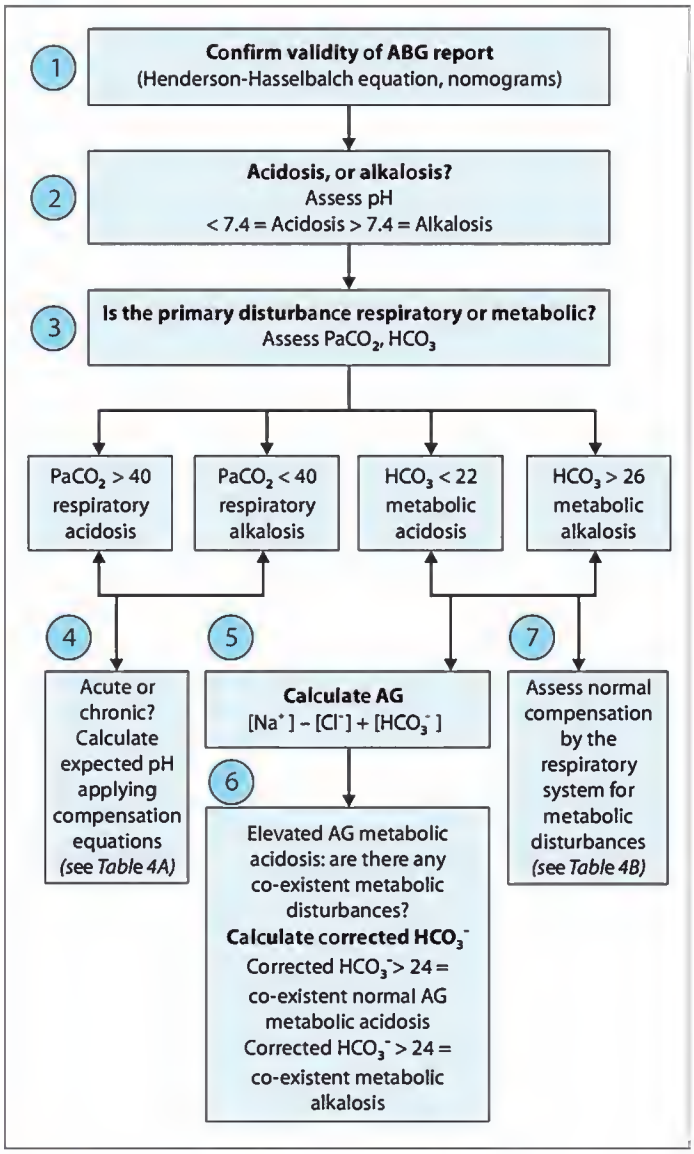

Figure 1: Stepwise approach for interpretation of an arterial blood gas (ABG) analysis report and assessment of acid-base status.

AG = Anion gap; $PaCO_2$ (mmHg); HCO_3^- (mEq/L)

Step 4: For respiratory disturbance: acute or chronic?

In acute respiratory disturbances, a $PaCO_2$ variation from normal by 10 mmHg is accompanied by a pH shift of approximately 0.08 units. In chronic respiratory disturbances, renal compensation and bicarbonate shift requires several hours to develop and is likely to be maximal after 4 days. Thus, during chronic respiratory disturbances, a $PaCO_2$ variation from normal by 10 mmHg is accompanied by a pH shift of only 0.03 (**Table 4A**). If the expected values and the actual values match, a mixed disorder is unlikely. If the expected values and the actual values differ, a mixed disorder is present.

Step 5: For metabolic acidosis, calculating the anion gap

The AG should be measure in all patients with metabolic acidosis. For the purposes of routine clinical use, AG greater than 12 is considered to be elevated AG. Causes of *elevated AG* metabolic acidosis can be remembered with the mnemonic **MULEPAKIR** [**M** = methanol poisoning; **U** = uraemia; **L** = lactic acidosis; **E** = ethylene glycol poisoning; **P** = paraldehyde ingestion; **A** = aspirin overdosage; **K** = ketoacidosis (diabetic keotacidosis; alcoholic ketoacidosis and starvation); **I** = isoniazid overdosage; and **R** = rhabdomyolysis].

Serum albumin level has important bearing while calculating the AG. Albumin has a negative charge on its surface and accounts for a significant proportion of the unmeasured anions (**Table 5**). A 50% reduction in the serum albumin concentration will result in a 75% reduction in the AG. In patients with severe hypoalbuminaemia, eventhough elevated AG metabolic acidosis is actually present, the measured AG may be less than or equal to 12. So, in a patient with severe hypoalbuminaemia if the AG increases and approaches 12, an additional metabolic cause for the increased AG must be suspected and looked for.

Two methods are used to correct the AG for the influence of albumin in patients with hypoalbuminaemia. The expected AG is calculated using the serum albumin and phosphate concentrations, as follows:

$$\text{Expected AG (mEq/L)} = (2 \times \text{albumin [g/dL]}) + (0.5 \times PO_4 \text{ [mg/dL]})$$

The expected AG is then compared with the AG calculated using the formula ($Na^+ - [Cl^- + HCO_3^-]$). If the calculated AG is found to be more than the expected AG, the difference is attributed to unmeasured anions from non-volatile acids.

Alternatively, adjusted AG can be calculated using the formula:

$$\text{Adjusted AG} = \text{Calculated AG} + 2.5 \times [4.5 - \text{measured albumin (g/dL)}]$$

Conditions causing normal AG acidosis (≤12) can be remembered by the acronym **ACCRUED** (**A** = acid infusion; **C** = compensation for respiratory alkalosis; **C** = carbonic anhydrase inhibitors; **R** = renal tubular acidosis; **U** = ureteral diversion; **E** = extra-alimentation or hyper-alimentation; **D** = diarrhoea). Normal AG metabolic acidosis can also be grouped as per the serum potassium levels. Causes of normal AG acidosis with a normal to high potassium include hyperaldosteronism, type IV renal tubular acidosis (RTA), moderate degree of renal failure, administration of hydrochloric acid and post-hypocapnia. Normal AG acidosis with a low potassium level can be seen in proximal type II RTA and distal type I RTA.

When urine electrolytes are available, assuming a urine pH of less than 6.1 and euvolaemia, urinary AG, [calculated as urinary $(Na^+ + K^+) - Cl^-$] can help in distinguishing renal from non-renal causes. A negative urinary anion gap indicates a non-renal cause of acidosis (e.g. diarrhoea).

Others

Delta ratio is also useful in the assessment of elevated anion gap metabolic acidosis to determine if a mixed acid-base disorder is present. *Osmolar gap* is also useful in differentiating the causes of elevated AG metabolic acidosis. Osmolar gap is calculated by subtracting the calculated serum osmolality from measured osmolality using the formula shown below:

$$\text{Calculated osmolality} = 2[Na^+ \text{ (mEq/L)}] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{Blood urea nitrogen (mg/dL)}}{2.8}$$

$$\text{Osmolar gap} = \text{Measured osmolality} - \text{Calculated osmolality}$$

Osmolar gap > 10 mOsm/L is considered abnormal when calculated using this formula. Conditions causing increased osmolar gap metabolic acidosis include ethanol, ethylene glycol, methanol, acetone and propylene glycol poisoning. While a high AG, high osmolar gap metabolic acidosis is seen in methanol and ethylene glycol poisoning, normal AG, high osmolar gap metabolic acidosis is seen in isopropyl alcohol poisoning.

Step 6: Determining whether other metabolic disturbances co-exist with an elevated anion gap acidosis

A normal AG acidosis or a metabolic alkalosis may exist concurrently with an elevated AG acidosis. In this situation, corrected bicarbonate should be calculated as follows:

$$\text{Corrected } HCO_3^- = \text{measured } HCO_3^- + (AG - 12)$$

where, AG = anion gap

If the corrected HCO_3^- is greater than 24, a metabolic alkalosis co-exists; if it is less than 24, then a normal AG metabolic acidosis co-exists.

Step 7: Assessing the normal compensation by the respiratory system for a metabolic disturbance

In simple metabolic acidosis, the measured $PaCO_2$ will fall within the range predicted by Winter's formula (**Table 4B**). If a concurrent respiratory disturbance is also concurrently present, it would be defined by the direction the $PaCO_2$ varies beyond the range predicted by Winter's formula rather than the $PaCO_2$ variation from the normal value of 40.

In metabolic alkalosis, the magnitude of respiratory compensatory response is not easily predictable because degree of $PaCO_2$ increase does not exhibit an exactly linear relationship with the HCO_3^-. However, for practical purposes, the following equation has been found to be useful to calculate the expected:

$$PaCO_2 = [0.7 \times (HCO_3^-) + 21] \pm 2$$

In compensated metabolic alkalosis, the measured $PaCO_2$ is equivalent to the expected $PaCO_2$. If the measured $PaCO_2$ is higher than the expected $PaCO_2$, the respiratory compensation is not adequate, and the condition is termed as a primary metabolic alkalosis with a superimposed respiratory acidosis. In primary metabolic alkalosis with a superimposed respiratory alkalosis, the $PaCO_2$ is lower than the expected.

TREATMENT

The aetiological causes responsible for acid-base disturbances largely determine the status and prognosis in patients with acid-base disorders. Therefore, it is essential to recognise the underlying cause responsible for the disturbance so that specific treatment can be instituted.

Metabolic Acidosis

Metabolic acidosis may induce a wide range of adverse clinical effects, some of which may be life-threatening. In life-threatening metabolic acidosis, exogeneous alkali therapy aims to prevent or reverse the detrimental consequences of severe acidaemia affecting the cerebral, respiratory, metabolic and cardiovascular systems. Intravenous sodium bicarbonate is the mainstay of alkali therapy and should be given judiciously in amounts that will return blood pH to a safer level of about 7.20. The distribution of HCO_3^- being 40% of the body weight, the amount of HCO_3^- required to return the serum concentration to normal can be calculated as follows:

$$HCO_3^- \text{ deficit} = \text{Body weight (kg)} \times 0.4 \times (\text{desired } HCO_3^- - \text{measured } HCO_3^-)$$

Except in situations of extreme acidaemia, sodium bicarbonate should be administered as an infusion rather than a bolus; about 30 minutes must elapse following the completion of the infusion before its clinical effect can be judged. One-half of the calculated deficit can be replaced in 3 to 4 hours, if severe heart failure is not present. Subsequently, monitoring of the patient's acid-base status will determine additional alkali requirements. Alterations in respiratory function, dyselectrolytaemia (especially hypokalaemia) and hypo-tension must be recognised and treated. Specific therapy is required in the setting of poisoning and overdosage. Chronic metabolic acidosis (e.g. chronic kidney disease) is treated with oral sodium bicarbonate.

Metabolic Alkalosis

Metabolic alkalosis is usually mild; when severe (pH >7.6) or rapidly developing it may be life-threatening. The chloride-responsive metabolic alkalosis can be treated with intravenous

saline administration. When alkalosis is severe, or there is a risk of volume overload, 1N hydrochloric acid administration may be required. Chloride-unresponsive alkaloses are more difficult to treat and treatment is directed at the underlying cause.

Respiratory Acidosis

Treatment of respiratory acidosis is directed at improving ventilation using non-invasive or invasive ventilatory strategies; administration of bicarbonate can be harmful and should be avoided.

Respiratory Alkalosis

Treatment of respiratory alkalosis should be directed towards the underlying cause, identification and correction of electrolyte abnormalities that usually co-exist. Usually, re-assurance, re-breathing from a bag or treating the underlying psychological stress is enough to alleviate respiratory alkalosis. Controlling fever, seizure activity and sepsis will also help.

7.5 Enteral and Parenteral Nutrition in Critically Ill Patients

Shilpa S Joshi

Feeding is not considered medical therapy under ordinary circumstances. But when patients are critically ill and cannot eat themselves food takes the form of medical therapy.

The incidence of hospitalised malnutrition is well documented, especially in critically ill patients. Despite the advances in medicine, definitive indications for the use of nutritional support are unclear. Use of enteral and parenteral therapies should be widespread for various reasons:

1. Protein calorie malnutrition is common in a variety of hospitalised patients.
2. Documented association between malnutrition and increased morbidity and mortality.
3. It seems intuitive that well-nourished patients would respond more favourably to therapeutic interventions than malnourished patients.
4. Nutritional support can be provided safely to a wide variety of patients.
5. Several randomised prospective clinical trials showed that nutritional support benefits the patients.

Therefore, there is a clear-cut evidence base for the role of enteral and parenteral therapies in hospitalised as well as critically ill patients.

Nutritional support is a delivery of formulated enteral or parenteral nutrients to appropriate patients for the purpose of maintaining/restoring nutritional status.

ENTERAL NUTRITION

By definition, enteral nutrition means 'within or by the way of gastrointestinal (GI) tract'. In practice, enteral nutrition is generally considered tube feeding. The consensus of nutritional experts is that the GI tract is more physiologically and metabolically effective than the intravenous route for nutrient utilisation. Any disease process that adversely affects oral intake may ultimately lead to significant nutritional deprivation and depletion. Patients who cannot eat, will not eat, or should not eat, yet who have adequate function of the GI tract, are candidates for enteral tube feeding.

Once the patient has been assessed and found to be a good candidate for enteral nutrition, the clinician selects the appropriate tube and route of access for tube placement. Enteral access selection depends on several factors as given below:

1. Anticipated length of time for which enteral feeding will be required
2. Degree of risk for aspiration or tube displacement
3. Presence or absence of normal digestion and absorption
4. Whether or not there is a planned surgical intervention
5. Administration issues such as formula viscosity and volume.

Advantages of Enteral Feeding

Various advantages of enteral feeding are: (i) it is a preferred route of nutrition support as it is more physiologic, (ii) cost-effective, (iii) safe, (iv) fewer side-effects as compared to parenteral nutrition, (v) maintenance of GI immune barrier, (vi) avoidance of central catheter related complications. The indications for enteral feeding are listed in **Table 1**.

Table 1: Indications of Enteral Feeding

Oral intake inadequate or contraindicated	Mechanical: stroke, central nervous system Disorders, coma, oropharyngeal and oesophageal disorders, partial or complete oesophageal or gastric obstruction Poor appetite: chemotherapy, radiation therapy, drug effect, nausea Transitional feeding: advance from parenteral to oral intake Psychological: anorexia nervosa, depression, Alzheimer's disease
Increased nutritional requirements	Burns, trauma, sepsis, surgical or medical stress
Digestive and absorptive disorders	Inflammatory bowel disease, short bowel syndrome, pancreatitis, irradiated bowel, proximal and distal intestinal fistulae, immunocompromised syndromes
Metabolic and excretory disorders	Glycogen storage disease, hepatic encephalopathy, renal disease

Contraindications of Enteral Feeding

Enteral feeding is contraindicated in patients with peritonitis, distal intestinal obstruction, intractable vomiting or severe diarrhoea.

ASSESSMENT OF NUTRITIONAL NEEDS OF A PATIENT

Before initiation of feedings, assessment of nutritional status of every patient is fundamental and includes some key components: nutritional history, anthropometric procedure, clinical examination, biochemical data, evaluation of weight loss and previous nutrient intake before admission, level of disease severity, co-morbid conditions, and function of the GI tract.

Assessment of these parameters will help to document presence of malnutrition and will help clinician to select best method for providing nutrients and allows objective monitoring of nutritional efforts. These assessment are also needed to estimate caloric protein, micronutrient requirement and also help to select/make right kind of formula.

FORMULA COMPOSITION

Energy

The target goal of enteral nutrition (defined by energy requirements) should be determined and clearly identified at

the time of initiation of nutritional support therapy. Energy requirements may be calculated by Harris Benedict equation, which is as follows:

Males (kJ/day): REE = 278 + 58 (Wt) + 21 (H) -28.5 (Af) x SF

Females (kJ/day): REE = 2734 + 40 (Wt) + 7.7 (H) -19.7 (Af) x SF

where, kJ = Kilo Joules; REE = Required energy requirement; Wt = Weight in kilograms; H = Height in meters, Af = Activity factor, and SF = Stress factor

Values for activity factor and stress factor for various diseases to be considered as standard are given below:

Activity factor (AF)	**Stress factor (SF)**
Bed rest = 1.0	*Post-operative with complication = 1.24*
Ambulatory = 1.1	*Skeletal trauma = 1.1-1.3*
Active = 1.2-1.3	*Sepsis = 1.3-1.6*
	Cancer = 1.2

where, 1 calorie is about 4.185 kJ.

Efforts to provide more than 50% to 65% of goal calories should be made to achieve the clinical benefit of enteral nutrition over the first week of hospitalisation. Studies suggest that more than 50% to 65% of goal calories may be required to prevent increases in intestinal permeability in burn and bone-marrow transplant patients, to promote faster return of cognitive function in head injury patients and to improve outcome from immune modulating enteral formulations in critically ill patients.

If unable to meet energy requirements (100% of target goal calories) after 7 to 10 days by the enteral route alone, consider initiating supplemental parenteral nutrition. Initiating supplemental parenteral nutrition before this 7 to 10 days period in the patients already on enteral nutrition does not improve outcome and may be detrimental to the patient.

Proteins

Proteins in the diet serve as a source of amino acids that body cannot make (essential amino acids) and provide nitrogen for the synthesis of other amino acid (non-essential amino acids). Insufficient protein intake can potentially affect all aspects of a patient's care, for example, it can lead to muscle atrophy and can make it difficult to wean off the patient from ventilator. In addition to the importance of adequate amounts of protein is the quality of protein.

Proteins can be modified in various ways in enteral formulation, for example intact protein, hydrolysed protein, amino acids. Intact proteins and protein isolates requires normal pancreatic enzymes to catabolise them into small polypeptides and free amino acids.

Hydrolysed protein formulas can be directly absorbed into the blood stream. These feeds can be administered when the feeds are administered via jejunum and where only absorption of proteins takes place.

IMMUNOMODULATORY AGENTS

Glutamine and Branched Chain Amino Acids

Glutamine and branched chain amino acids are amino acids found in skeletal muscles. These have been identified as key amino acids in preserving nitrogen balance during stress and injury. Numerous studies have indicated that glutamine is necessary to maintain integrity of intestinal mucosa, immune function of lymphocytes to preserve muscle glutamine pool and to improve overall nitrogen balance.

Arginine

Arginine is a conditionally essential amino acid, i.e. it can be conditionally essential after injury. Human and animal studies have shown that increased intake of arginine after trauma decreases nitrogen losses and accelerate wound healing.

Standard formulas contain arginine in the amount of 1 g and 2 g/L. Arginine enriched formulas contain 14 to 15 g/L.

Nucleotides

Nucleotides are added to some formulas as immunity enhancers. In animals, dietary supplementation of nucleotides has shown to facilitate growth and maturation of developing gut.

Agents such as ribonucleic acid (RNA) nucleotides increase total lymphocyte count, lymphocyte proliferation and thymus function.

Taurine

Taurine is conditionally essential nutrient since it can be synthesised by dietary cysteine or methionine.

EPA-DHA

Omega-3 fatty acids eicosapentaenoic acid and docosohexaenoic acid displace omega-6 fatty acids from the cell membranes of immune cells. This effect reduces systemic inflammation through the production of alternative biologically less active prostaglandins and leukotrienes.

Patients with acute respiratory distress syndrome and severe acute lung injury should be placed on an enteral formulation characterised by an anti-inflammatory lipid profile (i.e. omega-3 fish oils, borage oil) and antioxidants.

High Nitrogen Products

These have increased proportions of branched chain amino acids. These products are used for patients with catabolic stress.

Most of formulas contain a non-protein kcal: nitrogen ratio of 150:1 (with ranges between 100:1–200:1) which is thought to be optimal for patients.

Most of the enteral formulations offer high nitrogen products. Patients who do not need high nitrogen formulas are likely to use amino acids for energy and increase urea production. As a result this formula should be given carefully to renal patients.

Carbohydrates

Carbohydrates (CHO) provide 30% to 90% of total calories of enteral formulas and in most of the formulas these are the principle source of energy. The main difference among the formulas is the form and composition of CHO. In general, the longer carbohydrate molecule are less osmotic, taste less sweet are require more digestion than the shorter ones.

Lactase deficiency is most prevalent disaccharide deficiency and hence, most of the enteral formulas are lactose free.

Fibre

Enteral formulas containing fibre may have potentially clinical applications including ameliorating constipation and tube feeding-associated diarrhoea, improving mucosal healing in inflammatory bowel disease, supporting gut barrier of critical ill patient and increasing intestinal adaptation in short bowel

syndrome. Predominant source of fibre of enteral formula is soya derived polysaccharides.

Soluble fibre may be beneficial for the fully resuscitated, haemodynamically stable critically ill patient receiving enteral nutrition who develops diarrhoea. Insoluble fibre should be avoided in all critically ill patients. Both soluble and insoluble fibre should be avoided in patients at high-risk for bowel ischaemia or severe dysmotility.

Lipids

Fat is a dense source of energy and also serves as a vehicle for fat soluble vitamins and essential fatty acids. Most of the enteral formulas contain vegetable oil as primary source of fat. Vegetable oil is also a good source of essential fatty acids. Fat does not contribute to osmolality of enteral formula.

Long Chain Triglycerides

Vegetable oils are predominant source of fat in enteral formulas. Long chain triglycerides are slowly cleared from blood stream and require carnitine for its absorption.

Medium Chain Triglycerides (MCTs)

MCTs are 6 to 12 carbon long and are usually prepared from palm kernel or coconut oil. They offer many advantages over long chain triglycerides, as they are absorbed intact without appreciable pancreatic or biliary function and are subjected to more rapid clearance from blood stream. They are transported to the liver principally via portal venous system where they cross mitochondrial membrane and can be oxidised independent of carnitine. These should not be used in patients who are prone to high ketone levels as they produce ketone.

Vitamins, Minerals and Trace Elements

A combination of antioxidant vitamins and trace minerals should be provided to all critically ill patients receiving specialised nutritional therapy.

Supplemental vitamins and minerals should be given when quantity of formula does not fulfil the requirement.

Water

Fluid balance in patients receiving enteral nutrition should be monitored. The daily water requirement for a healthy adult is 1 mL/kcal taken for approximately 30 to 32 mL/kg. Minimum of 30 mL of water every 6 hours is recommended as a flush for tube patency alone.

Probiotics

Administration of probiotic agents has been shown to improve outcome (most consistently by decreasing infection) in specific critically ill patient populations involving transplantation, major abdominal surgery, and severe trauma. No recommendations can currently be made for use of probiotics in the general intensive care unit population because of a lack of consistent outcome effect.

PHYSICAL CHARACTERISTICS OF A FORMULA

Osmolality

Osmolality is a physical phenomenon of net permeability resulting in equilibrium across the cell membrane. It is a measure of concentration of free particles, molecule or ions in a given solution in water. These particles include electrolytes, minerals, carbohydrates, proteins or amino acids and are expressed in milli osmoles per kilogram of water. All nutrients and dietary components except water contribute to osmolality solution. It has been widely thought that isotonic formulas (osmolality ranging from 280 to 320 milli osmoles/kg) are tolerated well than hyper or hypotonic formulas.

Renal Solute Load

Renal solute load refers to the constituents in the formula that must be excreted by the kidneys. Protein, sodium, potassium, and chloride are the major constituents of enteral formulas that contribute to the renal solute load. It is important, as there is obligatory water loss with each unit of solute.

Nutritional Formulations

A wide variety of commercially prepared formulas with variable sources and concentrations of protein, carbohydrate and fat are currently available.

Polymeric Formulas

Polymeric formulas are composed of intact proteins, disaccharides and polysaccharides and variable amount of fat. The osmolality of polymeric formula is usually lower than that of elemental formulas. These formulas require a functioning GI tract for digestion and absorption of nutrients. Polymeric formulas can be further subdivided into hypercaloric formulas, normocaloric formulas, etc.

Pre-Digested Formulas

Pre-digested formulas are composed of low molecular nutrients, have minimal residue and are thought to lead less stimulations of pancreatic and GI secretion and are less allergic than other formulas. These formulas have greater osmolalities than the polymeric formulas because of the small molecule weight of nutrients.

Modular Products

Individual macro-nutrients modules, such as glucose polymers, proteins, and lipids, are available as additives to foods and enteral formulas to change overall fuel composition.

Disease Specific Formulas

These products are designed for patients who have specific medical conditions that may require nutrient modifications.

Formula Selections

Selection of appropriate formulas is based on patient's medical and nutritional status, digestive and absorptive capabilities indicate whether pre-digested or polymeric formulas can be used.

Administration of Tube Feeding

Proper administration of enteral formulas ensures safe delivery of desired nutrients, enhanced patient tolerance and optimal nutritional support. There are various methods of feeding the patients. Choice of technique depends upon GI function, feeding site, and ultimately patient's response.

1. ***Bolus feeding***

   Bolus feeding is rapid administration of large volumes of formula over a short period of time usually by syringe. This form of feeding is least cumbersome but is associated with

increased possibility of aspiration, regurgitation and GI side-effect. A rate of 30 mL/min or a volume of 500 to 750 mL per feed appears to mark physical tolerance limit.

2. ***Continuous feeding***

   Continuous infusion is controlled delivery of prescribed volume of formula at a constant rate over a continuous period of time using infusion pumps or gravity assisted sets. This method is considered advantageous since gastric cooling is minimised and few GI tract side effects are experienced. Continuous infusion into jejunum is more analogous to normal gastric emptying.

3. ***Intermediate infusions***

   In intermediate feeding, total quantity of formula needed for 24 hours is divided into equal portions and required fractions are administered in 3 to 6 feedings. Each feeding is administered over 30 to 90 minutes period.

Techniques of Feeding

1. Selection of appropriate formulas.
2. Elevate the head of the patient's bed to at least 30 degree to horizontal levels before feeding begins.
3. Aspirate through nasogastric or gastrostomy tube before initiating feeding to determine whether retained gastric secretions are present.
4. Begin feeding schedule of 100 to 150 mL of isotonic or slightly hypertonic formulas every 4 hours.
5. Increase formula amount by 50 mL every 1 or 2 feeding up to 450 mL every 4 hours.
6. Flush the tube at least with 30 mL of water after feeding and every 4 hours to maintain patency.

Complications of enteral feeding are shown in **Table 2**.

Table 2: Complications of Enteral Feeding

Mechanical complications	Blockage of tube Dislocation of tube Aspiration pneumonia
Gastrointestinal complications	Delayed gastric emptying Constipation Malabsorption

PARENTERAL NUTRITION

Parenteral nutrition is a form of intravenous therapy that provides opportunity to replenish or maintain nutritional status. Parenteral nutritional was originally developed to nourish those whose GI tract was not capable of digesting and absorbing nutrients.

Central parenteral nutrition is delivery of nutrients through the large diameter vein usually subclavian or superior vena cava. Peripheral parenteral nutrition is usually delivered through small veins usually in the forearm. Central parenteral nutrition is indicated when volume and concentration of solution preclude peripheral administration and when anticipated duration of therapy is greater than 7 days to 2 weeks and when substantial depletion of body fat and protein has occurred. Peripheral parenteral nutrition is preferred when solution concentration is less than 1000 mOsm/L and duration of therapy is less than 10 days.

RATIONAL OF PARENTERAL NUTRITION

1. The patient is well nourished before admission but after 7 days of hospitalisation enteral nutrition has not been feasible or target goal calories have not been met consistently by enteral alone.
2. On admission, the patient is malnourished and enteral nutrition is not feasible.

   A major surgical procedure is planned, the pre-operative assessment indicates that enteral nutrition is not feasible through the peri-operative period and the patient is malnourished.
3. Indications: The basic indications for the use of parenteral nutrition are required for nutrition when the GI tract is either not working or not available or not appropriate (**Table 3**).

Table 3: Indications for Parenteral Nutrition

Non functioning gut, e.g. paralytic ileus
Malnourished patients after major abdominal surgery
Severe mucositis systemic chemotherapy, upper gastrointestinal strictures or fistulae and acute pancreatitis
Patients with major resections of the small intestine (short bowel syndrome) before compensatory adaptation occurs
Patients in the intensive care unit with systemic inflammatory response syndrome or multiple organ dysfunction syndromes.

PARENTERAL MACRONUTRIENTS

Proteins/Amino Acids

The primary function of protein in parenteral nutrition is to maintain nitrogen balance, thus, preventing skeletal muscle from being degraded from gluconeogenesis. Protein requirement can be very high during intensely catabolic state. A positive nitrogen balance may not be feasible during the first few days of the catabolic stress. A positive caloric balance is necessary to establish a positive nitrogen balance. For delivered amino acids to be incorporated into new protein rather than catabolise the ratio of non-protein calories to gram of nitrogen should approach 150:1. This ratio is based on the fact that 10% to 15% or more of required calories during catabolism are derived from protein breakdown.

Commercial amino acids are available. Dilute solutions are most often used for peripheral administration. Amino acid profiles of parenteral solutions are based on Food and Agriculture Organisation – World Health Organisation (FAO-WHO) recommendations for optimal proportion of essential amino acids.

Carbohydrates

Primary function of parenteral carbohydrate is to serve as energy source. Optimum carbohydrate is an amount adequate to spare protein without exacerbating hyperglycaemia. Commercial carbohydrates consist of N-hydrate, dextrose monohydrate in sterile water.

Fats

Parenteral lipids provide as a source of essential fatty acids and calories. These can be substituted for dextrose calories for patients with glucose intolerance or used as concentrated caloric source for patients who require volume restriction. Fats

have lower respiratory quotient than carbohydrates, which is a rational for use of lipids to provide large proportion of non-protein calories in patients with respiratory failure. Because fat emulsions are isotonic, these can be administered through peripheral vein. Alternatively these may be directly added to parenteral nutritional solution.

Electrolytes

Electrolytes requirement for patients receiving total parenteral nutrition may vary depending on body weight, presence of malnutrition or catabolism, the degree of electrolyte depletion, change in organ function, ongoing electrolyte losses and disease process.

Vitamins

Vitamin requirements during parenteral nutrition therapy are uncertain because these are not based on balanced studies. Recommendations for parenteral nutritional therapy have been made by American Medical Association—Nutrition Advisory Group.

Water

Water requirements vary depending on the capacity of patient to excrete an osmotic load. Usually requirements are 30 ml/kg in normal adult or approximately 1 ml/kcal delivered. An additional 360 ml per day is recommended for each centigrade of temperature elevation. Also 300 to 400 ml of water per day may be necessary for new intra-celluloid fluid, if anabolism is being induced.

Restriction of water is necessary during volume overload and presence of hyponatraemia. Patients who become hyperosmotic may need additional free water on daily basis.

Trace Elements

Trace elements are those nutrients that make-up less than 4 g or 0.01% of total body content. Individual trace elements may be supplemented in appropriate dose as specific patients deficiency dictates.

Osmolality and Osmolarity

While osmolality is most often used in reference to enteral feeding, osmolarity is preferred term for parenteral solutions. Body maintains serum osmolality between 280-300 mOsm/kL. To avoid the irritation to veins, solutions with osmolarity greater than 900 mOsm/L are not usually administered peripherally.

Initiation of Parenteral Nutrition

Prior to initiation of parenteral nutrition, a baseline biochemistry profile should be checked and fluid and electrolyte abnormalities should be corrected.

Monitoring

During the first week of parenteral nutrition (and subsequently if patient is unstable with respect to fluid and electrolyte or metabolic issues) the patient should be monitored intensively.

Reintroduction of Diet

Diet should be reintroduced in a graded fashion.

COMPLICATIONS

The complications of parenteral therapy can be divided into three categories: (i) *technical*—pneumothorax, malposition, subclavian artery puncture, air embolism etc; (ii) *septic*—catheter related sepsis, septic thrombosis; and (iii) *metabolic* – hyperglycaemia, hypoglycaemia, hyperkalaemia, hypophosphataemia, etc. With proper patient monitoring, most of these complications can be minimised.

7.6 Acute Respiratory Failure

Ashit M Bhagwati

INTRODUCTION

Respiratory system is responsible for gas exchange in the human body. Inability to maintain a normal state of gas exchange leads to respiratory failure. Disorders involving the respiratory centre in the brain, peripheral nerves, respiratory muscles, airways, pleura, lung parenchyma and the chest wall can lead to compromise of gas exchange; thereby leading to a clinical scenario of acute respiratory failure (ARF). ARF is one of the most common life-threatening disorders encountered in the intensive care unit (ICU) and is associated with poor prognosis.

DEFINITION

Clinically, respiratory failure occurs when hypoxaemia (PaO_2 is less than 60 mmHg), i.e. inadequate oxygenation of the blood or hypercarbia (arterial PCO_2 is >50 mmHg), i.e. excess content of circulating carbon dioxide; or frequently, a combination of both types of gas exchange abnormalities occur.

CLASSIFICATION

ARF is classified as hypoxaemic respiratory failure (type 1), hypercapnic respiratory failure (type 2), post-operative/peri-operative respiratory failure (type 3) and shock-related respiratory failure (type 4).

Respiratory failure is also classified as per its onset; acute or chronic respiratory failure. ARF refers to disorders of recent onset (hours to days). It suggests that respiratory failure has developed too rapidly for physiologic compensation to occur; therefore, pH is less than 7.3. Chronic respiratory failure develops overmonths to years, allowing compensatory mechanisms to improve oxygen transport and to buffer respiratory acidaemia; therefore the pH is slightly decreased. Sometimes, ARF may be superimposed on chronic respiratory failure.

HYPOXAEMIC (TYPE 1) RESPIRATORY FAILURE

Hypoxaemic respiratory failure (type 1) is defined as a condition in which the respiratory system exhibits a failure in its gas exchange function of oxygenation, PaO_2/FiO_2 <200, respiratory rate >35 breaths/min and with active use of accessory muscles of respiration. It is also associated with a normal or low $PaCO_2$. The underlying physiologic aberration results from a disease process that involves the lung itself such as a ventilation-perfusion (V/Q) mismatch, shunting or diffusion impairment. The classic example of acute hypoxaemic respiratory failure is acute lung injury (ALI) or acute respiratory distress syndrome (ARDS).

Aetiology

Type 1 ARF is usually seen in diseases of the lung parenchyma, cardiovascular system and lower airways. The causes are due to low inspired concentration of oxygen (alveolar hypoventilation), impairment of diffusion, VA/Q mismatch, intrapulmonary shunting and low mixed venous oxygen content (**Table 1**).

Table 1: Aetiology of Type 1 Respiratory Failure

Respiratory System

Airway disease: Asthma, COPD

Parenchymal:

Airspace: Pneumonia (bacterial, viral, mycoplasmal, fungal), atelectasis, bronchiectasis, and tumours

Vascular: Pulmonary embolism, fat embolism, pulmonary arterial hypertension

Pleura: Pneumothorax

Chest Wall: Flail chest

Cardiovascular System

Pulmonary oedema (cardiac failure), cyanotic congenital heart disease

Miscellaneous: Obesity

Physiology

The process of gas exchange has two components: the flow of gas between the atmosphere and the terminal airways; and the diffusion of gases between the terminal lung regions and the pulmonary capillary blood. The efficiency of gas exchange can be evaluated clinically by measuring the PA_{O_2}, $PaCO_2$ and the alveolar-arterial (A-a) PO_2 gradient. Thus, patients with hypoxaemia may be divided into those with a normal gradient and those with an increased gradient (**Table 2**). The alveolar PO_2 can be calculated from the alveolar air equation:

$$PA_{O_2} = (PB - PH_2O)\, FiO_2 - (PaCO_2/R)$$

here, PA_{O_2} is alveolar PO_2; FiO_2 is fraction of inspired oxygen;

PB is barometric pressure (760 mmHg at sea level), PH_2O is water vapour pressure (47 mmHg at sea level), and R is respiratory exchange ratio (assumed to be 0.8).

Ventilation-perfusion mismatch and intrapulmonary shunting are the clinically important causes of hypoxaemia in ARF.

Ventilation-Perfusion Mismatch

In the presence of disease, the V/Q units vary. The low V/Q units contribute to hypoxaemia and hypercapnia as compared to high units where wastage of ventilation may occur without affecting the blood gases unless quite severe. If the patient is given 100% oxygen to breathe, there is a dramatic increase in the PaO_2 as it eliminates low V/Q units, thereby correcting the hypoxaemia.

Intrapulmonary Shunts

Normally in health some degree of intrapulmonary shunting does occur, i.e. referred to as anatomical shunt accounting for 2% of the shunt. In addition, cyanotic congenital heart diseases or A-V malformations in the lungs cause right-to-left shunt.

When the deoxygenated blood bypasses the ventilated alveoli and mixes with the oxygenated blood that has perfused the ventilated alveoli, reduction in the arterial content of oxygen occurs, i.e. hypoxaemia (PaO_2 level decreases). Such situation

occurs in conditions such as pneumonia, atelectasis and severe pulmonary oedema of either cardiac or non-cardiac origin. Hypercapnia occurs when the shunt exceeds > 60%.

In low V/Q mismatch and intrapulmonary shunting, the decreased PaO_2 is always associated with an elevated P (A-a) oxygen gradient. In patients with low V/Q mismatch, the PaO_2 has a dramatic rise in response to 100% oxygen, whereas in patients with intrapulmonary shunting, it shows a much smaller response. Differentiating between these causes of hypoxaemia is important clinically (**Table 2**).

Table 2: Physiological Conditions Causing Type 1 Respiratory Failure

Pathophysiology of Hypoxaemia	P (A-a) O_2 Gradient	$PaCO_2$
Low partial pressure of inspired oxygen	Normal	Normal or decreased
Low ventilation-perfusion mismatch	Increased	Normal or decreased
Right-to-left shunt	Increased	Normal or decreased
Diffusion impairment	Increased	Normal or decreased

ARDS is the classic example of severe hypoxaemic respiratory failure. The European American Consensus Conference on ARDS defined ALI and ARDS. ALI is a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiologic and physiologic abnormalities that cannot be explained by, but may co-exist with, left atrial or pulmonary capillary hypertension. The clinical criteria for ALI include: (i) acute onset of pulmonary failure, (ii) hypoxia with a PaO_2/FiO_2 ratio ≤300 mmHg, (iii) bilateral chest infiltrates visible on chest radiograph, and (iv) a pulmonary artery occlusion pressure ≤18 mmHg or no clinical evidence of increased left atrial pressure on the basis of chest radiograph and other clinical data.

On the other hand, ARDS is defined as a more severe form of ALI with a PaO_2/FiO_2 ≤200, regardless of the level of positive end-expiratory pressure (PEEP) used on the ventilator.

Clinical Manifestations

Manifestations of hypoxaemic respiratory failure are due to a combination of features of arterial hypoxaemia and tissue hypoxia. Arterial hypoxaemia causes hyperventilation due to stimulation of carotid body chemoreceptors, leading to dyspnoea, tachypnoea and hyperpnoea. There may be cyanosis; degree of cyanosis depends on the concentration of the haemoglobin and the patient's perfusion. Other features include generation of lactic acid due to anaerobic metabolism. Increased blood lactate levels may further stimulate ventilation. Mild hypoxia may also lead to impaired mental performance. With the progression of hypoxia alteration in the sensorium, somnolence, coma, seizures can occur leading to permanent brain damage.

Patient develops tachycardia, diaphoresis, and systemic vasoconstriction leading to hypertension. Severe hypoxia can lead to bradycardia, vasodilation, hypotension, myocardial ischaemia, infarction, arrhythmias and cardiac failure. The manifestations of hypoxia are further amplified in the presence of tissue hypoxia. Symptoms and signs also reflect not just acute hypoxaemia, but also the underlying cause of respiratory failure.

Chest radiograph may be normal initially but later on (in established cases) may show bilateral infiltration (interstitial, airspace or both). Arterial blood gas analysis is central to diagnosis and reveals hypoxaemia with normal, but usually a low PCO_2.

Criteria for Diagnosis of Acute Respiratory Distress Syndrome (ARDS)

1. Predisposing factors for ARDS, viz. sepsis, burns, pancreatitis, aspiration, malaria, leptospira, etc.
2. Tachypnoea, breathlessness, tachycardia, crackles on auscultation.
3. Progressive infiltrates in both the lung fields.
4. Normal pulmonary capillary wedge pressure.
5. Refractory hypoxaemia with PaO_2/FiO_2 ≤200.
6. Decreased lung compliance ≤40 mL/cm water.

HYPERCAPNIC (TYPE 2) RESPIRATORY FAILURE

Aetiology

Type 2 respiratory failure can result from abnormalities in any one component of the respiratory system including the brain, spinal cord, neuromuscular system, thorax, pleura and upper airways. Diseases of the lower airways (alveoli) or circulatory system are rare causes of type 2 respiratory failure (**Table 3**).

Table 3: Aetiology of Type 2 Respiratory Failure

Brain

Drugs: narcotics, barbiturates, sedatives, poisons, general anaesthetics

Metabolic: hyponatraemia, hypocalcaemia, hypercapnia, severe alkalosis, myxoedema

Infections: meningitis, encephalitis, bulbar polio, cerebral abscess

Neoplasms

Trauma

Central alveolar hypoventilation, obstructive sleep apnoea

Occult status epilepticus

Spinal Cord

Traumatic transection, compressive tumours, poliomyelitis

Neuromuscular

Drugs: neuromuscular blockers, aminoglycosides

Metabolic: hypokalaemia, hypophosphataemia, hypomagnesemia

Infections: tetanus, Guillain-Barré syndrome, sepsis

Trauma

Neoplasm

Myasthenia gravis

Others: critical illness neuropathy, muscular dystrophies, respiratory muscle fatigue

Upper Airways

Upper airway mass: adenoid hyperplasia, goiter, polyps, malignant tumours

Infections: epiglottitis, laryngotracheitis

Trauma

Others: bilateral vocal cord palsy, tracheomalacia, laryngeal oedema

Chest Wall

Trauma: Flail chest

Others: kyphoscoliosis, scleroderma and massive pneumothorax or pleural effusion

Physiology

The hallmark of acute hypercapnic respiratory failure is an elevated $PaCO_2$. Three processes, alone or in combination, can produce acute hypercapnic respiratory failure: a reduction in minute ventilation, an increase in CO_2 production and alveolar hypoventilation.

Reduction in minute ventilation can be affected by processes affecting the central nervous system, peripheral nervous system, neuromuscular junction, respiratory muscles, chest wall abnormalities, metabolic and electrolyte abnormalities, and upper airway obstruction. In these disorders alveolar-arterial oxygen pressure difference ($A\text{-}aDO_2$) is usually normal unless lung disease is present.

Excessive CO_2 production is usually due to fever, burns, sepsis, high carbohydrate diet, burns and hyperthyroidism. Agitation, myoclonus, or other causes of muscle activity can increase VCO_2 and contribute to type 2 respiratory failure. Increase in the respiratory quotient, which is normally 0.8-2.0 doubles VCO_2. Reduced CO_2 elimination also occurs due to decreased alveolar ventilation.

Alveolar hypoventilation may result from VA/Q mismatch (high VA/Q, increased physiological dead-space and wasted ventilation) as in pulmonary embolic diseases, intrinsic lung diseases (e.g. emphysema, asthma, cystic fibrosis or pulmonary fibrosis) and in chest wall disorders (e.g., scoliosis). Hypoventilation is characterised by hypercapnia and hypoxaemia. As minute ventilation reduces to less than 4 L/min, the $PaCO_2$ rises dramatically. Usually these patients have normal $A\text{-}aDO_2$ gradients.

Patients at risk of hypercapnic respiratory failure may also be divided into two major categories: those with normal lungs (e.g., sedative overdose, neuromuscular disorders or chest wall abnormalities) and those with intrinsic lung disease (e.g., emphysema, chronic bronchitis or asthma) where maldistribution of ventilation and perfusion results in an increase in dead space. The final result is inadequate CO_2 clearance despite normal or increased minute ventilation.

Clinical Manifestations

Patients with acute hypercapnic respiratory failure largely present with central nervous system (CNS) disturbances. Hypercapnia is a CNS depressant leading to lethargy, somnolence, coma, asterixis, restlessness, tremors, slurred speech, headache and papilloedema.

Symptoms of hypercapnia may overlap those of hypoxaemia. Basically, hypercapnic patients may have either decreased or increased minute ventilation depending on the primary disorder. As a result these patients have dyspnoea, tachypnoea, hyperpnoea with tachycardia and uncompensated respiratory acidosis.

Diagnosis

History is most important in diagnosis of ARF. It should aim at eliciting relevant information about possible predisposing factors, co-morbid conditions and identifying processes that affect prognosis. The clinical signs and symptoms of ARF reflect the underlying disease process and the associated hypoxaemia and hypercapnia. Diagnosis of respiratory failure requires arterial blood gas study, not only to determine the presence and severity of respiratory failure but also to differentiate between type 1 and type 2 respiratory failure.

POST-OPERATIVE/PERI-OPERATIVE (TYPE 3) RESPIRATORY FAILURE

Post-operative/peri-operative respiratory failure can be defined as the need for intubation and mechanical ventilation (MV) within the 48 hours after surgery. In the post-operative/peri-operative period, surgical patients following general anaesthesia often develop reduction in functional residual capacity leading to atelectasis in the dependent lung units. This leads to respiratory failure referred to as post-operative/peri-operative respiratory failure (**Table 4**). To avoid this situation, a proper pre-operative assessment is mandatory to identify the patients who are at increased risk after non-thoracic and thoracic surgery. These subgroup of patients are best managed with frequent change of posture, chest physiotherapy, adequate analgesia for post-operative pain relief. Non-invasive ventilation (NIV) also may be used to tide over the crises. However, evidence-based studies on the usefulness of respiratory physiotherapy, incentive spirometry and NIV to prevent respiratory complications are lacking.

Table 4: Aetiology of Type 3 Respiratory Failure

Intra-pulmonary Causes
Atelectasis, aspiration, pneumonia
Acute lung injury/acute respiratory distress syndrome
Volume overload/congestive heart failure
Pulmonary embolism
Asthma/Chronic obstructive pulmonary disease
Pneumothorax
Extra-pulmonary Causes
Upper airway obstruction
Obstructive sleep apnoea syndrome
Diaphragmatic dysfunction/phrenic nerve injury

SHOCK-RELATED (TYPE 4) RESPIRATORY FAILURE

Respiratory muscles consume less than 5% of the total cardiac output and oxygen delivery. Shock leads to increase in dead-space ventilation and pulmonary inflammation. The increase in dead-space ventilation is an early accompaniment of shock. It leads to hypoperfusion of the respiratory muscles, leading to respiratory muscle fatigue, causing a combined metabolic (lactic acidosis) and respiratory acidosis. Under this situation, more than 40% of the cardiac output is distributed to the respiratory muscles.

Intubation and MV help redistribution of the cardiac output to the vital organs while shock is being treated.

MANAGEMENT

The general principles of support are similar regardless of the type of respiratory failure. The priorities in the management of ARF vary according to the aetiology. However, the primary aim in all the cases are the same: (i) to maintain a patent airway and ensure adequate ventilation and oxygenation; and (ii) to treat, if possible, the primary condition. This includes removal of excessive secretions to maintain clear airway, use of aerosolised bronchodilators, antibiotics, viz. aminoglycoside (tobramycin),

colistin according to sensitivity pattern and effective systemic antimicrobials for the treatment of infections.

Hypoxaemic Respiratory Failure (Type 1)

Patients with acute hypoxaemic respiratory failure are best managed in the ICU. The management of these patients involves both supportive and specific strategies that are generally performed simultaneously. Supportive therapy is aimed at stabilising the clinical condition of the patient by improving gas exchange and includes airway management and correction of hypoxaemia. Hypoxaemia is corrected by oxygen administration and use of ventilatory support (non-invasive and invasive mechanical ventilatory support). Measures are also directed towards specific therapy for identifying and reversing the underlying pathophysiologic mechanisms. Specific therapy varies depending on the underlying disease (e.g. use of antibiotics to treat patients with pneumonia and diuretics for pulmonary oedema).

Oxygen therapy

Oxygen supplementation is the most important therapy for hypoxaemic respiratory failure. After the airway is secured, attention is directed to the management of hypoxaemia. The treatment goal is to provide adequate oxygen delivery to the tissues (SaO_2 >90% and PaO_2 ≥60 mmHg). Oxygen can be delivered by different means (nasal cannula for flow rates ≤ 5 L/min, face mask for flow rates ≥6 L/min or use of air entrainment devices, (i.e. venturi masks for higher flow rates). If the patient's condition does not improve with high-flow oxygen: MV, either invasive or non-invasive, should be considered.

Non-invasive ventilation

In last few years, substantial data has emerged on the use of NIV in patients with acute hypoxaemic respiratory failure to avoid endotracheal intubation and ventilator-associated pneumonia, thereby reducing mortality. However, despite emerging studies regarding NIV as an adjunct in the management of hypoxaemic respiratory failure, its safety and efficiency remains unanswered. This is mainly due to varied aetiologies in subgroups of patients causing respiratory failure. Recently, a few studies have focused on some of the individual diagnoses within the large category. It has been found to be very effective in cardiogenic pulmonary oedema. NIV may also be useful when some components or degree of cardiac decompensation participates in the clinical feature, even if it is not the main or only cause of episode of respiratory failure.

It should be noted that patients with hypoxaemic respiratory failure should preferably be ventilated with a full face mask during acute phase and may be shifted to nasal mask, once the condition stabilises.

Mechanical ventilation

The two major goals of therapy are to maintain alveolar ventilation and correct hypoxaemia. In cases where NIV fails to correct hypoxaemia, invasive MV is used. Patients with severe ARF and a large intrapulmonary shunting may require high FiO_2 while on the ventilator. MV increases alveolar ventilation, eliminates CO_2 and corrects acidaemia. Due to the danger of oxygen toxicity, patients should be treated with the lowest concentration of oxygen that provides adequate oxygenation.

Hypercapnic Respiratory Failure (Type 2)

Oxygen therapy

Hypoxaemia secondary to hypoventilation can be easily treated with by supplemental oxygen (increasing FiO_2). Failure of PaO_2 to improve should alert to the possibility of an unsuspected concomitant lung disease producing a shunt effect (e.g. pneumonia, atelectasis). In many patients with chronic ventilatory failure, especially chronic obstructive pulmonary disease (COPD), oxygen therapy can cause acute worsening of hypercapnia. Three mechanisms have been proposed to explain this phenomenon. These patients may have a 'blunted' CO_2 drive to breathe and the hypoxaemic drive is suppressed by supplemental oxygen. Oxygen may increase V/Q inequality by inhibition of hypoxic pulmonary vasoconstriction or by changing bronchomotor tone. Finally, haemoglobin affinity for CO_2 decreases with increasing oxygen saturation (Haldane effect), which may further contribute to hypercapnia. Therefore, supplemental oxygen therapy for ventilatory failure aims at maintenance of PaO_2 in a 'safe' range that does not compromise systemic oxygen delivery but minimises the possibility of worsening hypercapnia (SaO_2 of 90% to 92%).

Air entrainment oxygen masks (venturi masks) can be used to deliver precise doses of oxygen. If venturi masks are unavailable or are not feasible, a nasal cannula at flow rates of 0.5-2.0 L/min may be used to treat hypoxaemia (low-flow oxygen therapy). However, despite therapy, progressive hypercapnia and acidosis may develop in some patients and lead to confusion, stupor or coma, even when the FiO_2 is increased only moderately. Such patients may require tracheal intubation and MV.

Therapy in patients with asthma or COPD consists of oxygenation, hydration and aggressive treatment of the underlying aggravating factor with bronchodilators (theophyllin, anticholinergics and beta-agonists) and corticosteroids. Infection needs to be treated with appropriate antibiotics and any electrolyte abnormality must be corrected. In patients who progress to respiratory muscle fatigue, elective intubation and MV may be necessary to prevent respiratory arrest.

Non-invasive ventilation (NIV)

NIV is most commonly applied in acute hypercapnic respiratory failure commonly associated with COPD, where the ventilatory response to raised $PaCO_2$ is decreased.

Administration of NIV in patients with COPD with respiratory failure helps to increase the neural output to the diaphragm and other respiratory muscles, and thus, resets the respiratory control centre making it more responsive to an increased $PaCO_2$. These patients are then able to maintain a normal $PaCO_2$ throughout the daylight hours without the need for MV.

The use of NIV in patients with acute exacerbations of COPD is considered the ventilatory mode of choice. It helps by reducing the rate of endotracheal intubation. It also improves the vital signs, gas exchange, thereby reducing dyspnoea.

There is also reduction in the in-hospital mortality, with reduction in the complications like nosocomial pneumonia.

NIV may also be used in patients with acute exacerbations of bronchial asthma. Uncontrolled studies have reported improvements in gas exchange and low rates of intubation after

the initiation of NIV in patients with severe asthma. In another randomised trial, no benefit of NIV in asthma was demonstrated.

Although the use of NIV in asthma is inconclusive, a trial of NIV in selected patients is justified, particularly in patients who fail to respond promptly to medical treatment and have no contraindications.

It has also been suggested that aerosolised medicines may be delivered more effectively by NIV. However, NIV is not recommended for routine use in patient with asthma exacerbation.

Mechanical ventilation

Some patients with ventilatory failure may respond to early and aggressive management of the primary disorder. Others, with progressive pathology or whose loads are not rapidly reduced may require MV. Although no $PaCO_2$ absolutely mandates MV, if the pH is < 7.20 and if rapid reversal with therapy is not expected, or failure of NIV occurs or NIV is contraindicated, then prompt MV is initiated. Delayed MV in these patients increases the risk of circulatory collapse and other complications.

A common error in MV of a patient with acute on chronic respiratory failure is to reduce the $PaCO_2$ to normal (40 mmHg), which leads to a compensatory reduction in bicarbonate. On resumption of spontaneous breathing, patients who are chronically hypercapnic will retain CO_2 rapidly (to their previous pre-morbid level). As the kidneys require more time (24 to 48 hours) to compensate, an acute respiratory acidosis may ensue and impede liberation from MV. Accordingly, the ventilatory goal in patients with acute on chronic respiratory failure is not a normal $PaCO_2$ but rather a $PaCO_2$ approximating their baseline value when they are not acutely decompensated, at which the pH is normal range.

7.7 Sepsis and Acute Respiratory Distress Syndrome

Alladi Mohan, Surendra K Sharma

SEPSIS

Sepsis (derived from the Greek word *sepo* meaning "decay or putrefaction"), severe sepsis (acute organ dysfunction secondary to infection) and septic shock (derived from the French word *choquer* meaning 'to collide with'), are major health care problems world over. The incidence of sepsis and related syndromes is increasing and the conditions affect millions of individuals around each year.

DEFINITION OF SEPSIS AND RELATED SYNDROMES

Though the existence of sepsis and related disorders were known since time immemorial, formal definitions for the same were laid by the American College of Chest Physicians (ACCP) and Society of Critical Care Medicine (SCCM) Consensus Conference in 1991. With advances in the understanding of the pathophysiological aspects of septic shock and the dissatisfaction in several quarters regarding these definitions, a Consensus Sepsis Definitions Conference was convened in 2001 under the auspices of ACCP, SCCM, the European Society of Intensive Care Medicine, and the Surgical Infection Societies to re-visit the definitions of sepsis and related conditions. The key change was regarding the definition of systemic inflammatory response syndrome (SIRS) [manifested by (but not limited to) 2 or more of the following conditions: temperature > 38 °C or, < 36 °C; heart rate > 90 beats/min; respiratory rate > 20/min or ($PaCO_2$) < 32 mmHg; white blood cell count >12.0 × 10^9/L, < 4:0 × 10^9/L, or > 10% immature (band) forms] which was expanded to include longer list of possible signs of sepsis (**Table 1**).

As per the new guidelines, sepsis is defined as infection plus systemic manifestations of infection (**Table 1**). *Severe sepsis* is defined as sepsis plus sepsis-induced organ dysfunction or tissue hypoperfusion (**Table 1**). *Septic shock* is defined as sepsis-induced hypotension persisting despite adequate fluid resuscitation.

Staging System for Sepsis

Since the definitions of sepsis and related syndromes does not allow for precise characterisation and staging of patients with this condition, staging systems have been proposed to stratify these patients by both their baseline risk of an adverse outcome and their potential to respond to therapy. In line with the tumour, node, metastasis in vogue for cancer, a classification scheme for sepsis that will stratify patients basing on their *predisposing* conditions, the nature and extent of the *infection*, the nature and magnitude of the host *response*, and the degree of concomitant *organ dysfunction*, termed PIRO staging system has been described (**Table 2**). Several attempts are underway to apply the PIRO system clinically with promising results.

Aetiology

Gram-negative bacterial infection is the most common cause of sepsis and related syndromes. However, septic shock can be caused by Gram-positive bacteria and fungi also. Polymicrobial aetiology of sepsis has also been described. In India, septic shock can occur due to falciparum malaria, enteric fever, dengue fever and other infections.

Pathogenesis

The pathophysiological hallmark of sepsis and related syndromes is the mismatch of the host response to the intensity of the pathogenic stimuli, ultimately leading to organ injury or

Table 1: Diagnostic Criteria for Sepsis in Patients with Documented or Suspected Infection

General variables
Fever (core temperature >38.3°C)
Hypothermia (core temperature <36°C)
Heart rate >90/min or >2 SD above the normal value for age
Tachypnoea
Altered mental status
Significant oedema or positive fluid balance (>20 mL/kg over 24 hours)
Hyperglycaemia (plasma glucose >120 mg/dL) in the absence of diabetes
Inflammatory variables
Leukocytosis (WBC count >12,000 /mL)
Leukopaenia (WBC count <4000/mL)
Normal WBC count with >10% immature forms
Plasma C-reactive protein >2 SD above the normal value
Plasma procalcitonin >2 SD above the normal value
Haemodynamic variables
Arterial hypotension (SBP <90 mmHg, MAP <70, or an SBP decrease >40 mmHg) or <2 SD below normal for age)
SvO_2 >70%
Cardiac index >3.5 L/min/m^2
Organ dysfunction variables
Arterial hypoxaemia (PaO_2/FiO_2 <300)
Acute oliguria (urine output <0.5 mL/kg/h for at least 2 hours)
Creatinine increase >0.5 mg/dL
Coagulation abnormalities (INR >1.5 or aPTT >60 sec)
Ileus (absent bowel sounds)
Thrombocytopaenia (platelet count <100,000/µL)
Hyperbilirubinaemia (plasma total bilirubin >4 mg/dL)
Tissue perfusion variables
Hyperlactatemia (>1 mmol/L)
Decreased capillary refill or mottling

dysfunction with or without hypotension. This results in a predominantly proinflammatory (SIRS), mixed [mixed antagonistic response syndrome (MARS)], or predominantly anti-inflammatory compensatory anti-inflammatory syndrome. The current concepts underlying the molecular pathogenesis of sepsis are shown in **Figure 1**. The major complications of septic shock are listed in **Table 3**.

Table 3: Major Complications of Sepsis

- Cardiopulmonary
  - Acute lung injury, acute respiratory distress syndrome
  - Depression of myocardial function
- Renal
  - Acute kidney injury
  - Drug-induced renal damage
- Disseminated intravascular coagulation
- Neurological
  - Critical illness polyneuropathy
- Multiorgan dysfunction syndrome

Clinical Manifestations

The clinical manifestations of sepsis result as a consequence of the complex interplay among the immune, coagulation, and neuroendocrine systems in response to severe infection. These manifestations overlap the signs and symptoms due to the underlying medical conditions and primary site of infection. Septic shock should be suspected whenever, a patient with fever or hypothermia, tachycardia and tachypnoea and evidence of decreased organ perfusion develops hypotension. It is not strictly necessary that tachycardia, tachypnoea or fever be present to make the diagnosis. Generally, there is predisposition to infections such as a patient on cytotoxic or immuno-suppressive drugs, chronic debilitating disease such as diabetes mellitus, cirrhosis of liver, etc. Haemtogenous seeding of the skin or underlying soft tissue can manifest as cellulitis, pustules, bullae, or haemorrhagic lesions. Other features that help in pointing towards a diagnosis of septic shock include evidence of impaired organ perfusion, altered mental status, jaundice, gastrointestinal bleed due to stress ulceration, disseminated intravascular coagulation (DIC) and acute respiratory distress syndrome (ARDS). Acrocyanosis and ischaemic necrosis of

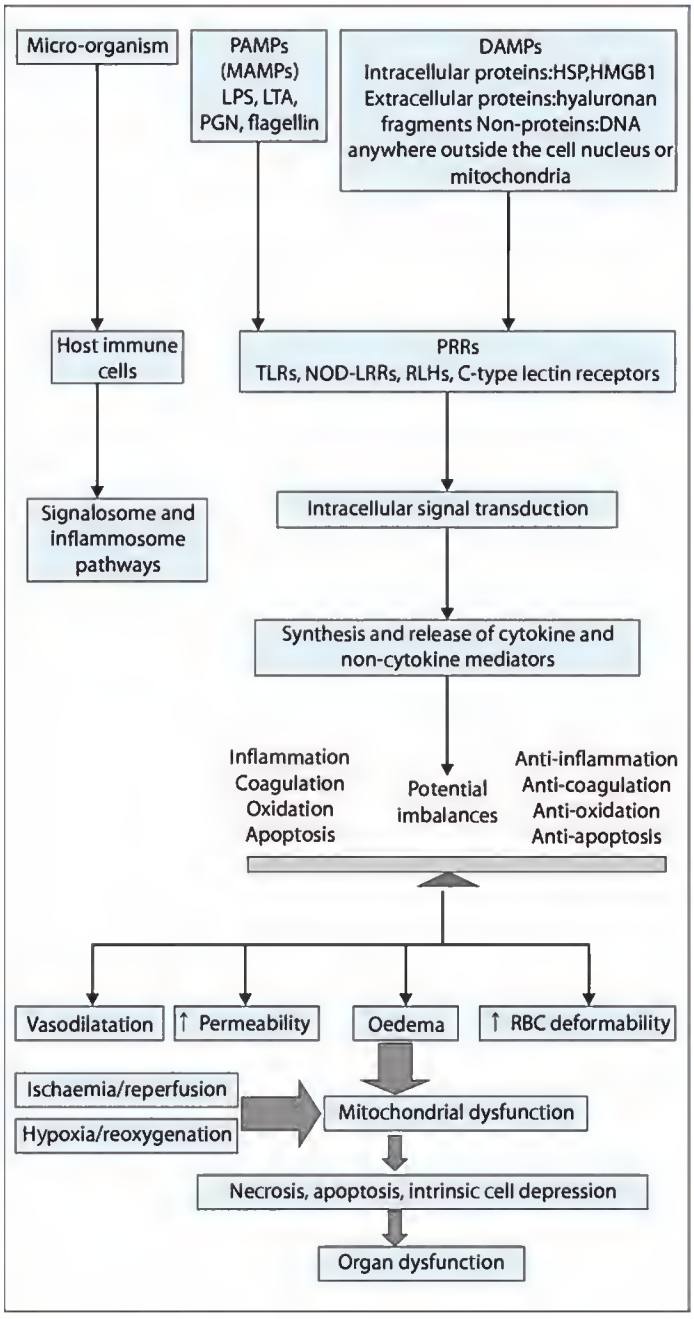

Figure 1: *Overview of the molecular pathogenesis of sepsis.*

peripheral tissues, usually digits, may be evident due to hypotension and DIC.

Principles of Management

The basic principles of initial resuscitation (fluid therapy, vasopressors, inotropic support, infection issues (source identification and control, appropriate antibiotic therapy), blood product administration and haemodynamic support described in the updated Surviving Sepsis Campaign guidelines for the management of severe sepsis and septic shock 2008 must be followed meticulously (**Figure 2**).

Broad-spectrum, site-specific appropriate intravenous antibiotics (monotherapy or combination therapy as appropriate) should be started as early as possible, and always within the first hour of recognising severe sepsis and septic shock. The antimicrobial regimen must be assessed daily to optimise efficacy, prevent resistance, avoid toxicity and minimise costs. The antibiotic therapy must be administered for 7 to 10 days. The duration may be longer if the response is slow, the foci of infection are undrainable, or if immunodeficiency is present. Low doses of corticosteroids and recombinant human activated protein C may be considered as useful adjunctive therapies in selected sub-groups of patients. The optimal timing for initiating these modalities of treatments appears to be 6 to 24 hours from onset of shock. Patients receiving these treatments should systematically be monitored for superinfection and serious bleeding complications. Principles of mechanical ventilation (MV) are described under ARDS. Factors indicating poor prognosis in septic shock are shown in **Table 4**.

Table 4: Factors Indicating Poor Prognosis in Septic Shock

Pre-existing factors
Old age
Nature of co-existing illness (e.g. leukaemia)
Number of failed organs
Cardiovascular
Lack of ventricular dilatation
Persistence of tachycardia and raised cardiac output
Others
Delay in institution of treatment
Acute respiratory distress syndrome
Disseminated intravascular coagulation
Hypothermia
Leucopaenia
Hyperglycaemia
Metabolic acidosis
Renal failure
Polymicrobial infection

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is defined as an acute lung injury (ALI) resulting in extensive bilateral pulmonary infiltrates, severe refractory arterial hypoxaemia and stiff lungs. It is a common cause of ICU admission world over.

Aetiology

Bacterial sepsis is the single most important cause of ARDS in hospitalised patients. Other common causes of ARDS are listed in **Table 5**.

Definition

The American-European Consensus Conference definitions of ALI and ARDS are simple to apply in the clinical setting and also recognise that the severity of clinical lung injury varies according to the severity of arterial hypoxaemia. Recently, pulse oximetric saturation (SpO_2) to fraction of inspired oxygen (FiO_2) ratio (S/F ratio) has been found to correspond to the arterial oxygen tension (PaO_2) to FiO_2 ratio (P/F) (**Table 6**). These non-invasive substitutes for assessing oxygenation can

Table 5: Causes of Acute Respiratory Distress Syndrome

Common Causes

Infections

- Gram-negative and Gram-positive bacterial sepsis
- Pneumonia (bacterial, viral, mycoplasma, pneumocystis)
- Pancreatitis
- Burns
- Gastric aspiration
- Bilateral lung contusion
- Cardiopulmonary bypass

Uncommon Causes

- Multiple blood transfusions
- Inhalational injuries (ammonia, chlorine, nitrogen dioxide, phosgene, smoke, sulphur dioxide)
- Fat embolism
- Raised intracranial pressure
- Infections (pulmonary and miliary tuberculosis, falciparum malaria, enteric fever, leptospirosis)
- Drugs (e.g. thiazides, methadone, barbiturates, narcotics, lidocaine, cytosine arabinoside, phenytoin, salicylates)
- Heat stroke
- High altitude pulmonary oedema

Table 6: Definitions of Acute Lung Injury and Acute Respiratory Distress Syndrome

Acute lung injury	Acute respiratory distress syndrome

be useful in the settings where arterial blood gas (ABG) analysis is not available and facilitate the monitoring of the course of the disease.

Clinicopathological Stages of ARDS

Irrespective of the precipitating factors ARDS usually evolves along a stereotypic common pathway with characteristic clinical, pathological and radiological changes as exudative phase, proliferative phase, fibrotic phase and phase of healing and repair. These changes are usually described by the term *diffuse alveolar damage*.

Clinical Features

ARDS is acute and rapid onset of respiratory failure, dyspnoea, dry cough, disorientation and agitation that usually develops 24 to 72 hours after the precipitating event marking the exudative phase. Tachypnoea, tachycardia, cyanosis, crepitations and rhonchi may also be present. Arterial hypoxaemia that is refractory to treatment with supplemental oxygen which may eventually warrant tracheal intubation and assisted MV is a characteristic feature of ARDS.

Diagnostic Work-up

The patient should be carefully evaluated for an underlying cause keeping in mind the possibility of treatable infections, such as sepsis, pneumonia, tuberculosis (TB), malaria among others. Other useful investigations include:

Arterial blood gas analysis

The ABG analysis usually reveals severe refractory hypoxaemia, hypocapnia and alkalosis if the patient is breathing spontaneously. Hypercapnia usually does not occur unless chronic lung disease co-exists.

Chest radiograph

In patients with ARDS, the radiographic changes become evident by about 12 hours after the clinical onset of respiratory failure. Initially, patchy, ill-defined opacities may become apparent through out the lungs. They rapidly coalesce and diffuse massive air-space consolidation becomes evident. In contrast to cardiogenic pulmonary oedema of cardiogenic origin, air-bronchogram is frequently visible. After about a week, the lungs remain diffusely abnormal, but the pattern gradually becomes 'reticular' or 'bubbly' suggestive of a diffuse interstitial and air-space fibrosis.

Computed tomography

Computed tomography (CT) of the chest also facilitates the identification of some causes of ARDS, such as, pneumonia and lung abscess. The CT of the chest reveals diffusely distributed, non-uniform, ground-glass opacification or consolidation which may not conform to the gravity distribution early in the exudative phase. Susbequently in the exudative phase, the consolidation becomes more homogeneous and gravity dependent. As the proliferative and fibrotic stages evolve, there is a decrease in the overall lung density and the appearance of an interstitial reticular pattern. Complications of ARDS, such as pneumothorax, pneumomediastinum and interstitial emphysema may also be evident on CT of the chest.

Echocardiography

Echocardiography is useful in differentiating ARDS from cardiogenic pulmonary oedema.

Swan-Ganz catheterisation

Swan-Ganz catheterisation facilitates measurement of pulmonary capillary wedge pressure (PCWP). A PCWP less than 18 mmHg and cardiac index more than 2.1 L/min/m^2 is altered in ARDS.

Fibreoptic bronchoscopy and bronchoalveolar lavage

Fibreoptic bronchoscopy and bronchoalveolar lavage (BAL) are employed to exclude infectious causes of ARDS. Most prominent finding on BAL in patients with ARDS (though non-specific) include increased number of polymorphonuclear leukocytes (making up to nearly 80% of the total cell population; normal value <5%). Eosinophilia in the BAL fluid, when it occurs, has therapeutic implications.

Differential Diagnosis

Several conditions mimic ARDS clinically, but, alveolar inflammatory changes are characteristic of ARDS. These conditions include:

Haemodynamic pulmonary oedema

In haemodynamic pulmonary oedema, PCWP is elevated (> 18 mmHg), and echocardiographic abnormalities may be evident. Once PCWP is brought to normal, infiltrates on the chest radiograph may clear.

Diffuse alveolar haemorrhage

The initial clinical presentation of diffuse alveolar haemorrhage may resemble ARDS and is accompanied by a dramatic fall in the haematocrit, occurrence of haemoptysis, and the presence of frothy red fluid on bronchoscopy. Haemosiderin-laden macrophages may be demonstrable in the BAL fluid.

Idiopathic acute eosinophilic pneumonia

Patients with idiopathic acute eosinophilic pneumoia may be previously healthy and present with cough, dyspnoea, fever, and occasionally chest pain. Peripheral blood and BAL fluid eosinophilia is present. This condition rapidly responds to corticosteroid treatment, usually within 48 hours.

Metastatic malignancy

When malignancy presents as ARDS it is uniformly fatal. Cytologic examination of blood drawn from pulmonary circulation through the Swan-Ganz catheter keeping the balloon inflated, or BAL fluid is usually helpful in confirming the diagnosis. More invasive procedures such as transbronchial lung biopsy, open lung biopsy may have to be undertaken at times to ascertain the diagnosis. These procedures are, however, associated with increased risk of complications.

Management

In the appropriate clinical setting, a high index of clinical suspicion is necessary to diagnose ARDS early. Efforts directed at establishing the cause of ARDS must be actively pursued to facilitate institution of specific treatment.

General therapeutic measures

Patients with ARDS should be admitted in an ICU equipped with facilities for invasive monitoring and providing assisted MV. Ideally, pulmonary and systemic arterial lines should be inserted for haemodynamic monitoring and rational fluid replacement therapy. SpO_2 monitoring by pulse oximetry, periodic ABG analysis must also be done. Adequate nutrition should be ensured; enteral route is preferred to the parenteral route as it does not cause the serious risk of catheter induced sepsis. If sepsis is presumed to be the cause of ARDS, empirical antibiotic treatment may be started in the early phase of the disease as detailed above.

Haemodynamic stabilisation

The fundamental principles remain same as in **Figure 2**.

Ventilatory support

While some patients with ARDS can be managed with conservative measures and non-invasive ventilation, tracheal intubation and assisted MV are required in a majority of the patients. Aim of MV is to maintain gas exchange with minimal complications. Initially, spontaneous ventilation using a face mask with a high flow gas delivery system can be used to deliver a FiO_2 of up to 0.5 to 0.6. Continuous positive airway pressure (CPAP) may be added to improve PaO_2 without increasing FiO_2. If a FiO_2 of more than 0.6 and CPAP of more than 10 cm H_2O are needed to achieve a PaO_2 of more than 60 mmHg, tracheal intubation and MV must be considered. The maximal clinical benefit is likely to occur if MV is initiated early, i.e. within 96 hours of the onset of ARDS, a time when alveolar recruitment potential is the greatest.

Recent evidence suggests that, whatever mode of ventilation is used, tidal volume should be set in the region of 6 mL/kg ('lung protective ventilation') and the peak pressure should be limited to 30 to 35 cm H_2O to prevent lung overdistension. Presently, in the absence of routine static pressure-volume curve measurement, positive end expiratory pressure (PEEP) is set at a relatively high level such as 15 cm H_2O in patients with ARDS. It is also a common practice to increase the I:E ratio to 1:1 or 2:1 (inverse ratio ventilation) with close monitoring of intrinsic PEEP and haemodynamics during pressure control ventilation (**Table 7**). The usefulness of recruitment manoeuvres such as the high function where intermittent breaths of larger tidal volume are administered either via the mechanical ventilators or by hand, sustained inflation or CPAP aimed at increasing alveolar recruitment are also being studied.

Other ventilatory strategies

Other alternative approaches to conventional MV include prone positioning of the patient, high frequency ventilation (HFV, rate

> 60/min) techniques such as high frequency jet ventilation (HFJV) and high frequency oscillatory ventilation (HFOV), and liquid ventilation, among others. The relative merits of these alternative methods of MV must be critically weighed against the potential side-effects in every setting.

Extracorporeal respiratory support

In extracorporeal membrane oxygenation (ECMO), venous blood is removed via a cannula in the inferior vena cava or right atrium, passed through a heart/lung machine, and is returned to either the right atrium (veno-venous bypass) or aorta (veno-arterial bypass). Extracorporeal carbon dioxide (CO_2) removal (ECCOR) involves use of an extracorporeal veno-venous circuit with lower blood flow and oxygenation still occurring via the patient's lungs. These modalities may be useful in selected patients and, studies with a large sample size are required to clarify their role in the management of ARDS.

Pharmacological therapies

Though various pharmacological therapies are directed at the pathophysiologic mechanisms of ARDS. These include neuromuscular blockade, inhaled nitric oxide, vasoactive agents (intravenous phenylephrine, inhaled prostacyclins, almitrine, among others. The therapeutic potential of these strategies needs further study.

Corticosteroids

The role of corticosteroid treatment in the management of ARDS is controversial. The studies published in the 1980s had employed high-dose corticosteroids (1 to 8 doses of 30 mg/kg methylprednisolone) for short durations (< 48 hours). Compared with placebo, corticosteroid treatment resulted in either no difference or increased the incidence of ARDS. In more recent studies, low-to-moderate doses of corticosteroids (methylprednisolone 1 to 2 mg/kg per day to start) for longer duration (mean 25 to 32 days), with gradual tapering has been evaluated. Presently, corticosteroid therapy is not considered to be beneficial before the onset of ARDS or early in its course. A difference of opinion exists among experts regarding the efficacy of corticosteroids for late-stage ARDS. Even though low-dose corticosteroid therapy improves lung function and shortens the duration of MV in persistent ARDS, the impact on long-term mortality is unclear. More data are required from clinical trials before they can be recommended for routine use in patients with unresolved ARDS.

Nutritional supplementation

Enteral feeding with omega-3 fatty acids, such as, eicosapentanoic acid, γ-linolenic acid, and antioxidants was shown to facilitate improvement in oxygenation and reduction in mortality in earlier trials. However, this benefit has not been replicated in more recent clinical trials.

Figure 3 outline algorithm for the management of ARDS.

ARDS in the Tropics

Infectious causes such as pulmonary and miliary tuberculosis TB, falciparum malaria, enteric fever, and leptospirosis are rare but treatable causes of ARDS. When the cause of ARDS is not clear, especially in endemic areas, these aetiological causes should be kept in mind and active efforts directed at establishing this diagnosis must be pursued to facilitate early institution of specific therapy.

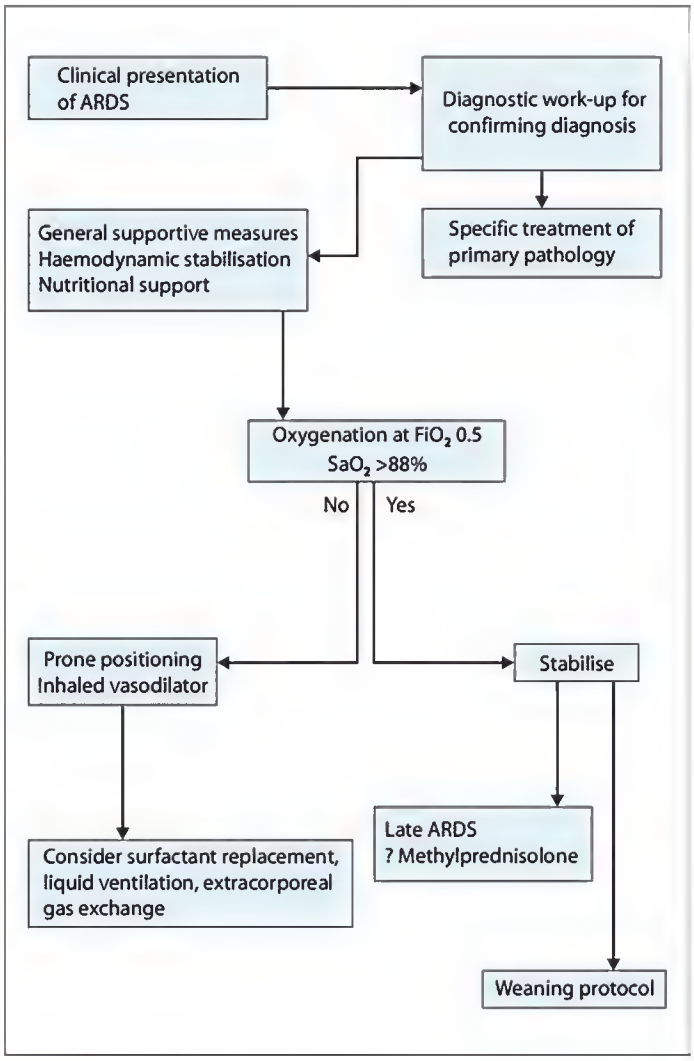

Figure 3: Treatment algorithm for the management of ARDS.

FiO_2 = Fraction of inspired oxygen; SaO_2 = Arterial oxygen saturation

Outcome

Interestingly, initial indices of oxygenation and ventilation have not been found to be useful in predicting the outcome in ARDS. Majority of deaths in patients with ARDS are attributable to sepsis or multi-organ dysfunction rather than primary respiratory disease. Certain prognostic factors have been identified to predict risk of death at the time of diagnosis of ARDS (**Table 8**).

Table 8: Predictors of Mortality in Patients with ARDS

Advanced age
Chronic liver disease
Non-pulmonary organ dysfunction
Sepsis
Organ transplantation
Human immunodeficiency virus infection
Active malignancy
Failure of pulmonary function to improve during the first week of treatment

Prevention

No form of therapy is known to prevent the occurrence of ARDS. Corticosteroid therapy, routine administration of antibiotics in the absence of evidence of infection, and use of prophylactic PEEP have not been shown to prevent ARDS in patients at risk.

7.8 Mechanical Ventilation

Surender Kashyap, Surinder Singh

Mechanical ventilation (MV) of the lungs is defined as assisting or substituting spontaneous respiration of the patient with artificial respiration with a lung ventilator or manual resuscitator bag. Application of positive airway pressure overcomes the increased airway resistance (asthma, chronic obstructive pulmonary disease [COPD]) and inflates less compliant alveoli (acute respiratory distress syndrome [ARDS], pneumonias), improves functional residual capacity (FRC) and improves oxygenation by recruitment of atelactic lung units. Positive pressure counteracts the hydrostatic pressure in capillaries and redistributes (decreases) extracellular lung water. However, MV is associated with a number of complications which are discussed briefly in the following sections.

COMMONLY USED TERMS

It is important to know the jargon of terms used in context to ventilation for better understanding of this subject. The commonly used terms are as under:

Cycling

The mechanism used to terminate inspiration and switch over to exhalation is called cycling. It is also used to classify ventilators.

Pressure Cycling

Inspiration is terminated after desired airway pressure (P_{AW}) is achieved. The tidal volume (V_T) is directly proportional to P_{AW} and inversely proportional to airway resistance, e.g. in bronchospasm.

Volume Cycling

Inspiration stops after delivering the set V_T. Airway pressure increases with airway resistance (bronchospasm) or low compliance (pulmonary oedema).

Flow Cycling

Inspiration is terminated after the flow rate falls to a particular level e.g. 25% of peak flow rate.

Time Cycling

Inspiration is terminated after the set inspiratory time. Modern ventilators use a combination of these cycling mechanisms.

Trigger

Trigger is the signal used to start ventilator breaths. Ventilator itself triggers breaths at a set respiratory rate (RR). Alternatively, ventilator senses patient's inspiratory pressure (pressure trigger) or inspiratory flow (Flow trigger) for triggering breaths. Recently, electrophysiological activity of diaphragm is being used as trigger (*see* NAVA).

Breathing Circuit

The arrangement of corrugated tubings designed to deliver gas to the patient is called breathing circuit. It requires periodical and between-patients cleaning and sterilisation. Most components are re-usable, expensive and include corrugated tubings, humidifier or (HME), flow sensor, Y-piece, water traps and exhalation valve.

Gas Flow

Flow of the air (enriched with oxygen) in the breathing circuit is called gas flow. A number of ventilators use a continuous basal flow of 5 to 10 L which is used for sensing patient's effort and is called basal flow or bias flow.

Diagnostic Functions

Newer ventilators can measure changes in compliance, resistance, positive end-expiratory pressure (PEEP) and air trapping, etc. Auto-PEEP is measured by 'end-exipratory hold' or occlusion for 5 to 10 seconds whereas similar manoeuvre after end-inspiration 'inspiratory hold' depicts plateau/alveolar pressure ($P_{PLAT/ALV}$). These diagnostic functions are helpful in making rational ventilator adjustments.

Nebulisation

Some of the ventilators have programmable nebulisers to allow aerosol therapy without interruption, or modification of ventilation.

MODES OF VENTILATION

Mode of ventilation specifies the method and type of ventilatory assistance being provided by the ventilator. Commonly used modes for ventilating the lungs are as under:

Manual Ventilation

It refers to the hand delivered ventilation using ambu bag-mask or bag-tracheal tube technique with or without oxygen supplementation. Manual ventilation is quite effective, and controlled or assisted ventilation can be given until a ventilator becomes available.

Spontaneous Mode

Ventilator does not give breaths, but delivers the set fraction of inspired oxygen (FIO_2), continous positive airway pressure (CPAP) and pressure support.

Controlled Mechanical Ventilation (CMV)

The ventilator is set to deliver fixed breath rate and V_T (CMV-V) or inspiratory pressure (CMV-P). Spontaneous respiration is abolished with deep sedation or neuromuscular blocking drugs. CMV is used in initial phase of ventilation.

Assist-Control

Respiratory rate, V_T and trigger sensitivity level are set in this mode and the patient triggered breaths are assisted by the ventilator, otherwise it works CMV mode. Common assisted modes are as follows:

Synchronised Intermittent Mandatory Ventilation (SIMV)

Ventilator delivers the set breath rate and V_T (SIMV-V) or inspiratory pressure (SIMV-P) using patient trigger. SIMV

improves patient comfort and allows spontaneous breathing between synchronised ventilator breaths.

Pressure Support Ventilation (PSV)

Inspiratory efforts of the patient trigger the ventilator to augment gas flow to achieve the desired airway pressure. PSV helps the patient to overcome increased airway resistance and decreased compliance and thus it "off loads" the inspiratory muscles.

Proportionate Assisted Ventilation (PAV)

Proportion of assisted ventilation is directly proportional to the effort of the patient. The proportion to be assisted is set as percentage, but the assistance decreases with decreasing patient's effort (exhaustion) and hypoventilation can occur.

Adaptive Support Ventilation (ASV)

The clinician determines minute ventilation and ventilator algorithm manages the RR/V_T relationship with changing lung dynamics. If the patient fails to trigger, controlled breaths are delivered automatically to avoid hypoventilation.

Neurally Adjusted Ventilatory Assistance (NAVA)

This under-investigation mode senses the electrical activity of diaphragm (through oesophageal electrode) to trigger ventilator-assisted breaths and aims at enhanced patient comfort by neuro-ventilatory coupling. The mode is not yet available in most of the available ventilators.

Positive End-Expiratory Pressure (PEEP)

PEEP is achieved by adding resistance to the exhalation. It prevents complete emptying of alveoli, airway closure and increases the duration for gas exchange. Application of PEEP in ARDS protects the alveoli from shearing stress due to repeated collapse and expansion. However, inap-propriately high PEEP increases the risk of barotrauma and hypotension.

Continuous Positive Airway Pressure

PEEP during spontaneous respiration is called CPAP. In addition to the effects of PEEP, it decreases the inspiratory work required for opening up of closed airways.

Biphasic Positive Airway Pressure (BiPAP)

Two distinct phases of positive pressure are applied during inspiration and expiration. Inspiratory PAP (iPAP) resembles PSV whereas expiratory PAP (ePAP) resembles CPAP. Apart from intensive care unit (ICU) ventilators, separate BiPAP machines are also available. S-PAP and DuoPAP are equivalents of BiPAP.

Volume Assured Pressure Support; Volume Support; Variable Pressure Support; and Pressure Augmentation

In addition to ventilator support, e.g. PSV, these modes ensure delivery of the desired V_T in spontaneously breathing patient. Ventilator monitors the inspiratory flow and if the patient is unlikely to inhale desired V_T, the ventilator augments the gas flow and delivers the set V_T.

Inverse Ratio Ventilation (IRV)

IRV is sometimes used in severe cases of ARDS by setting an inspiration longer than exhalation during CMV. It can improve oxygenation with increased risk of cardiopulmonary complications.

Airway Pressure Release Ventilation (APRV)

APRV has been tried in place of IRV with mixed results. The lungs are kept continuously inflated with brief periods of relief for exhalation without formal breath cycles. Spontaneous breathing is possible with considerable effort. Airway pressures and circulatory effects are less pronounced than IRV.

Apnoea Back-up Ventilation

It is a safeguard CMV mode and starts automatically in case patient stops breathing or triggering breaths. Parameters for back-up ventilation should be adjusted for individual patient while starting the ventilation.

TYPES OF VENTILATORS

Different types of mechanical ventilators are available for use in the hospitals (ICU ventilators), for transport of the patient (transport ventilators), for use at home (domiciliary ventilators) and (anaesthesia ventilators) for anaesthetic applications. A simple but effective form of multi-purpose ventilator is manual resuscitator bag (Ambu bag).

INDICATIONS FOR MECHANICAL VENTILATION

Main indications for MV include respiratory failure associated with hypoxia, hypercapnoea or both, compromised circulatory status and pulmonary oedema.

Clinical Indications

Clinical indications include ARDS, acute severe asthma, COPD with acute exacerbation, Landre Guillain Barré syndrome, poliomyelitis, head injury with diffuse brain oedema, pulmonary oedema and after major surgical operations. Severe tetanus (opisthotonus) and recently bird flu and swine flu have become indications for mechanical ventilation. Only those patients who are likely to recover completely from underlying disease are selected for ventilation. Brain dead patients may require ventilation until organ harvesting. Objective indications for mechanical ventilation are given in **Table 1**.

Table 1: Objective Indications for Mechanical Ventilation

Blood gas values	PaO_2 <60 mmHg despite FiO_2 0.6 $PaCO_2$ >50 mmHg HCO_3 is also raised and pH <7.3 Alveolar-arterial O_2 gradient >400 mmHg on 100% oxygen
Bedside measurements	Respiration rate >35 breaths/min; Rapid shallow breathing index, i.e. RR/ V_T (L) >100
Spirometric values	Tidal volume <5 mL/kg Minute ventilation >10 L/min Vital capacity <15 mL/kg Peak inspiratory pressure (> –25 cm H_2O or 0 to 24 cm H_2O

PaO_2 = Arterial oxygen tension; $PaCO_2$ = Arterial CO_2 tension; HCO_3 = Plasma bicarbonate

Note: All these parameters may not be available in every patient; hence, clinical judgement is important.

PROCESS OF MECHANICAL VENTILATION

Initiation of Mechanical Ventilation

Initiating MV has inherent risks and requires meticulous preparation, which should be based on **ABCDE. A = Airway:**

Maintenance of patient airway and tracheal intubation is necessary. **B = Breathing:** Patient requires ventilation with oxygen and bag mask technique during tracheal intubation. **C = Cardiovascular instability** or even cardiac arrest may occur in sick patients. An intravenous line must be secured with 18G or 16G cannula and normal saline or Ringers' lactate should be running unless contraindicated. **D = A number of drugs** are needed; midazolam, or anaesthetic like thiopentone, muscle relaxants usually succinylcholine are used to calm and relax the patient for tracheal intubation. Adrenaline and atropine should be ready for immediate use. **E = Equipment** must be checked in advance and includes laryngoscopes, oropharyngeal airways, tracheal tubes, manual resuscitator (Ambu bag), ventilator and a patient monitor.

Management of Ventilation

Airway is secured with oral or nasal tracheal tube and ventilation of both the lungs is ensured with careful auscultation. Orotracheal tubes require deeper levels of sedation and cause excessive salivation whereas nasotracheal tubes are tolerated better, require less sedation, but there is increased risk of epistaxis, bacteraemia and sinusitis. The V_T, RR and airway pressure should be appropriate for the size of the patient and lung pathology. It is safe to use 100% oxygen during first few minutes followed by gradual reduction to a level necessary to maintain pulse oximetric saturation (SpO_2) more than 90%. Humidification of inhaled gases is essential for optimal mucociliary function and is achieved with a heated humidifier (e.g. Fischer Paykel humidifier) or a disposable heat and moisture exchanger (HME). Blood gas analysis should be done 1 to 2 hours after starting ventilation make further adjustments in ventilation. Lung physiotherapy with chest wall percussion, postural drainage of lungs and tracheobronchial suctioning is done through tracheal tube intermittently.

CARE OF THE PATIENTS ON MECHANICAL VENTILATION

General Care

The patients on ventilator are totally dependant on nursing staff and meticulous maintenance of hygiene is essential for control of infection and optimal outcome of the patients. General measures include dressing of hair, cleaning of eyes and use of lubricant eye ointment, oral hygiene with brush or small pea-nut gauge soaked in chlorhexidine 2% and oral suctioning, catheterisation of bladder, and diapers for prevention of soiling with faecal matter. Skin is kept clean with daily sponge bath, change of wet clothing or linen, talcum powder and wrinkle free sheets. Use of pneumatic mattresses combined with change of posture every 2 hours reduces the risk of bedsores. These patients are susceptible to stress induced gastrointestinal bleeding and an H_2 blocker, proton pump inhibitor or mucosal barrier like sucralfate should be administered regularly.

Sedation and Analgesia

In the initial phase of ventilation, sedation with narcotics, midazolam or propofol, etc. is required to suppress respiratory efforts of the patient and fighting with ventilator. In post-operative, traumatised and other painful conditions, adequate analgesia is required. Muscle relaxants may cause myopathy, complicate weaning and are avoided, except in neurosurgical patients. Sedatives and muscle relaxants interfere with neurological assessment of the patient. Sedation is reduced gradually as the patient recovers and weaning from the ventilator is started. The sedatives may be with held in the morning to allow the patients to wake up (daily sedation vacation).

Nutrition

Maintenance of proper nutrition with sufficient calorie content is mandatory in patients on MV. ESPEN 2004 guidelines state that enternal nutrition should be started within 24 hours in hemodynamically stable patient's. Enteral feeding is preferred because it is natural, emotionally satisfying and prevents sepsis by maintaining integrity of gut mucosa. Diet should be adequate in calorific value which should be maintained at 25-30k cal/kg body weight per day for the patients. These calories are distributed as 50% carbohydrate, protein at 1g/kg per day and rest comprises of fat. Excessive carbohydrates increase carbon dioxide production and respiratory workload which may be harmful in COPD patients. Dietary composition in diabetics and hepatorenal disease requires additional considerations. Patients on ventilator start tolerating Ryle's nasogastric tube (RT) feed after 24 to 48 hours and require insertion of RT. RT feed is started at 3 to 4 hourly intervals with volumes of 4-5 ml/kg. RT feeds are not available in a number of hospitals in our country (especially, after H_1N_1 epidemic, ventilators have been installed in district hospitals), and therefore, relatives may have to be trained to prepare RT feed using common ingredients.

Communication with Patient

Most patients undergoing MV are conscious, they should be re-assured and informed about their progress, explained about the procedures to be done on them and taught to co-operate, especially during weaning. Intubated patients cannot speak and often use tapping of bed rails or may sometimes write. Their calls should always be attended with sympathetic and re-assuring attitude.

Monitoring of Vital Signs

Continuous monitoring of vital signs like, electrocardiogram (ECG), SpO_2, and non-invasive blood pressure is required. Arterial blood gas analysis and electrolyte status is needed in metabolic disorders, like diabetes. Unstable patients require monitoring of intra-arterial pressure, central venous pressure and cardiac output. Non-invasive technology has largely replaced pulmonary artery catheterisation. Neurological patients may require monitoring of electroencephalogram or intracranial pressure. Urine output is recorded at hourly intervals in case of renal dysfunction otherwise at 3 to 4 hourly intervals.

Monitoring of Ventilation

Most of the modern ventilators monitor and display parameters like exhaled V_T, minute volume, waveforms breath rate and peak airway pressure and display simple pressure/time or volume/time waveforms on screen (**Figure 1**). Small variations (± 10%; read user manual of ventilator) from set values are acceptable and, therefore, alarms limits should be set accordingly.

Sophisticated ventilators display real time pressure, volume and flow graphics in the form of waveforms or as loops, which are utilised for diagnosing changes in resistance (resistive load, e.g. in asthma), compliance (elastance load, e.g. ARDS, pulmonary oedema), air trapping and auto-PEEP (e.g. COPD). Basic waveforms (open and loop) illustrating important findings are shown in **Figures 2A and B**.

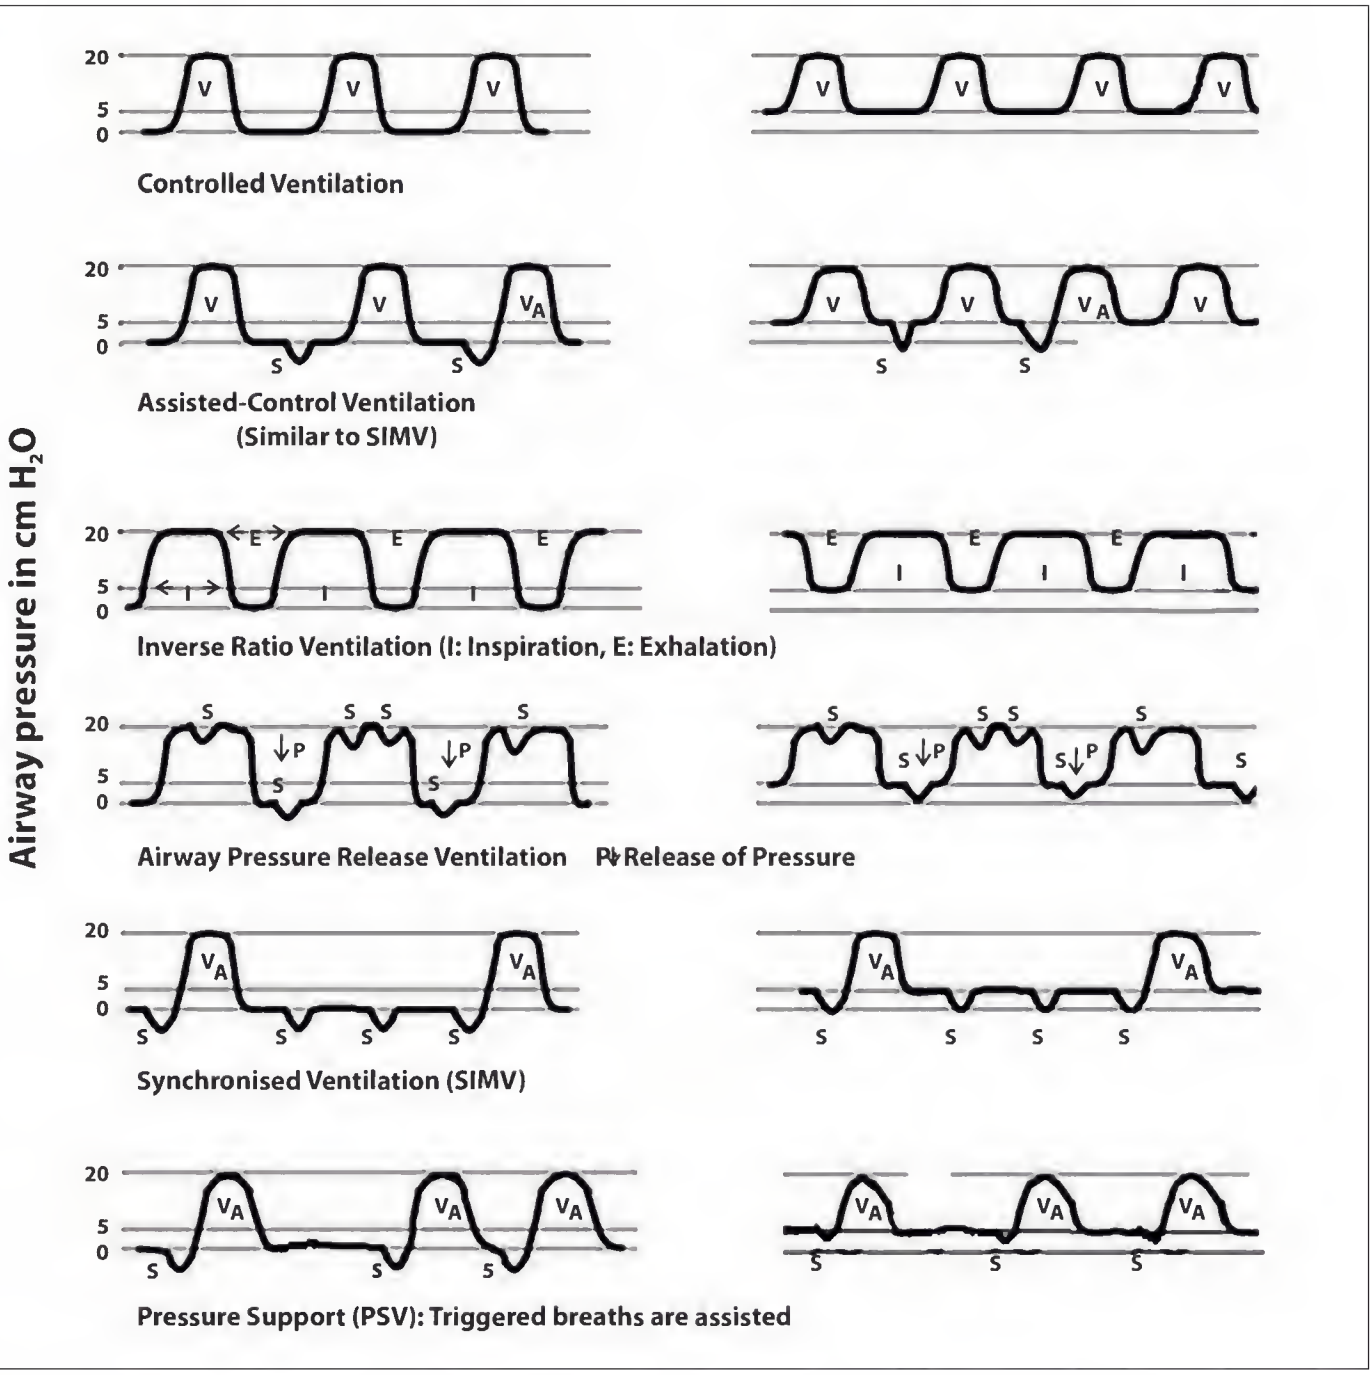

Figure 1: Airway pressure waveforms with different modes of ventilation left panel, right panel shows waveforms with 5 cm PEEP/CPAP.

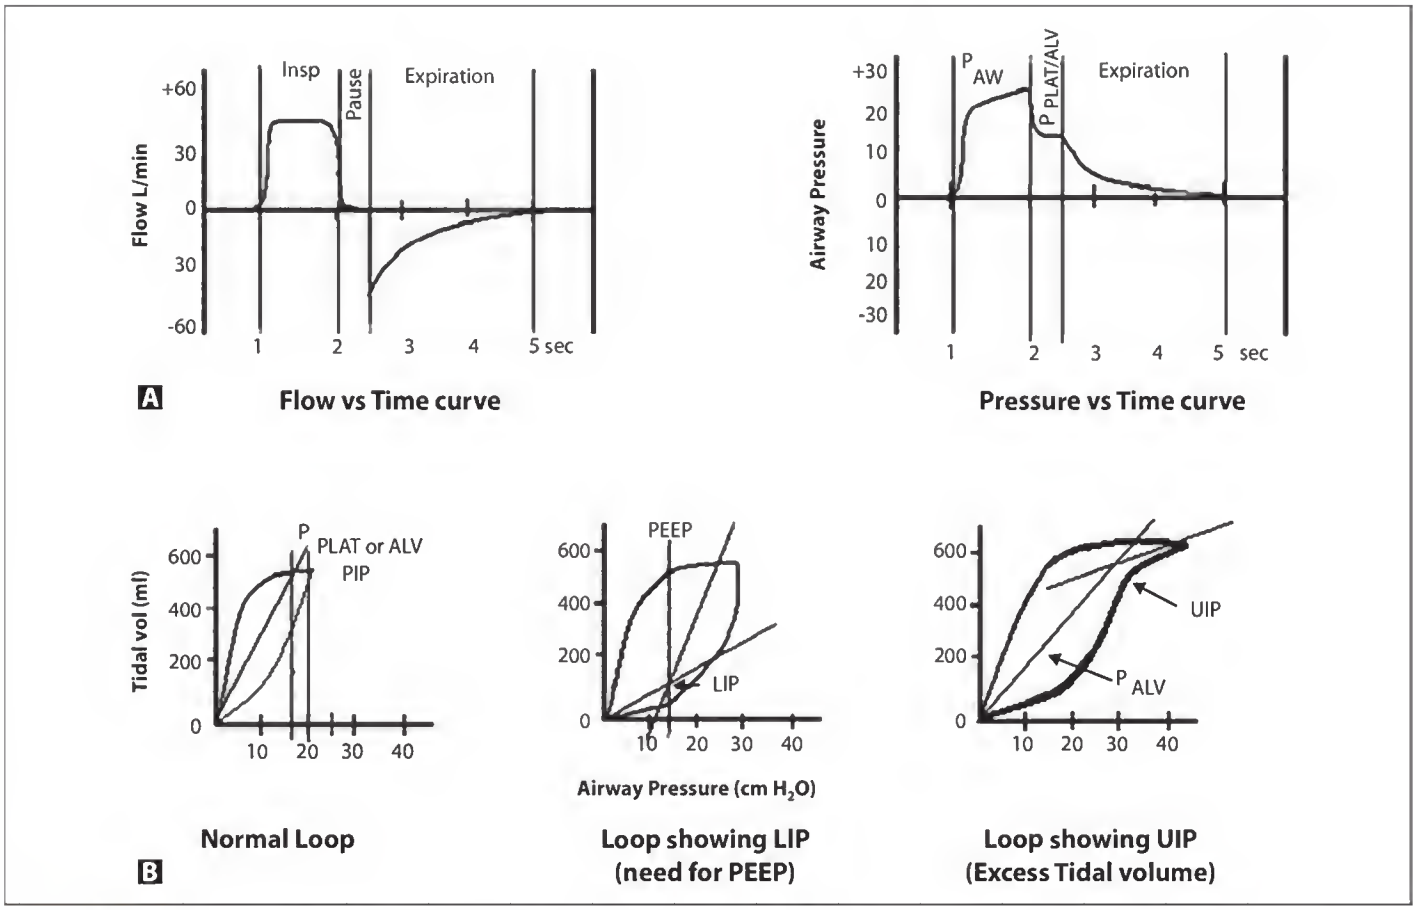
V_A = Assisted breath; S = Spontaneous breath

Hysteresis



The pressure and volume curves are not linear due to variable resistive and elastic properties of the lungs and chest wall. As a result inspiratory curve assumes sigmoid shape and the lung volume is always higher during expiratory phase at any given pressure.

Upper inflection point (UIP)

Over filling of alveoli leads to abrupt rise in pressure and the upper part of inspiratory pressure curve deviates the curve to the right (pressure axis). The upper part of pressure volume curve assumes a 'duck-bill' shape. UIP is an abnormal finding and V_T needs to be decreased so that the shape of the curve/loop becomes normal.

Lower inflection point (LIP)

Pressure volume curve deviates towards pressure axis due to resistance of closed airways and after opening up of airways the curve becomes steep owing to the compliance of alveoli. This shift creates a distinct point on the axis of airway pressure called LIP or initial point of inflection (iPI). It denotes excessive airway closure and requires application of external PEEP (ePEEP). It has been recommended earlier that ePEEP value should be 2 to 3 cm more than the airway pressure corresponding to LIP, but recognition of air trapping has led to recommendation of lower value of ePEEP based on detection of airway closure or autoPEEP on expiratory curve.

Figures 2A and B: (A) Typical flow and pressure waveforms. (B) Loops showing points of inflection.

Insp = Inspiration; PIP = Peak inspiratory pressure; LIP = Lower inflection point; PEEP = Positive end-expiratory pressure

Titration of applied PEEP or ePEEP

There is no fixed method to determine the value of 'best PEEP or optimal PEEP' which would provide maximum gas exchange without side effects, like air trapping and haemodynamic compromise. Airway closure and iPEEP, both occur during expiration and the fact, that lung volume (at corresponding point on expiratory curve) at any given value of pressure on inspiratory curve is much higher. Application of PEEP/ CPAP the basis of LIP may lead to the worsening of air-trapping (iPEEP) particularly in COPD patients. The recent trend is to set ePEEP value up to 70-85% of iPEEP. A number of methods like monitoring of oesophageal pressure, monitoring airway pressure and expiratory flow/ volumes, haemodyanamic status, computed tomography and trans-thoracic-electric impedance and values of PaO_2, FiO_2/PaO_2 ratio etc are being used with reasonable success. Transthoracic impedance is directly proportional to the lung volume and its monitoring is somewhat similar to ECG monitoring. This non-invasive method may become a useful tool for monitoring and real time display of resting lung volume in future.

Pressure and flow volume loops

Advanced ventilators display these curves in the form of pressure/volume or flow/volume loops, which are very useful in diagnosing various problems.

Schedule for Investigations or Tests

A bi-weekly or as per protocols of the hospital, schedule for clinical tests like haemogram, cell counts, cultures and radiography, etc. should be followed. Appearance of new signs and invasive procedures should be appropriately investigated.

WEANING FROM MECHANICAL VENTILATION

The process of discontinuation of lung ventilation is called 'weaning from ventilation' and can take several hours to days. The patient should have substantially recovered from respiratory distress, underlying disease and haemodynamically stable with minimal cardio-respiratory support. Objective assessment of readiness for weaning a patient from ventilator is based on a number of criteria given in **Table 2**. Common methods used for weaning from ventilation are as under:

Table 2: Criteria to Assess Readiness for Weaning a Patient from Mechanical Ventilation

Clinical parameters	RR: ≤35 per minute with RSBI: <100 Stable haemodynamic state
Spirometric values	Tidal volume: ≥5 mL/kg Vital capacity: ≥10 mL/kg Minute ventilation ≤10 L/min Inspiratory pressure: < –25 cm H_2O (e.g. –26 to –50 cm H_2O)
Blood gas values	SpO_2: ≥ 90% with FiO_2: ≤0.5 Alveolar-arterial O_2 gradient: <400 mmHg on 100% oxygen

T-Piece Trial

After short duration of ventilation, the ventilator is stopped abruptly and oxygen (4 to 5 L/min) is administered through a T-piece attached to tracheal tube and after a successful trial of 90 min to 2 hours, trachea is extubated.

Spontaneous Mode

Instead of attaching a T-piece, the ventilator is switched over to spontaneous mode, PSV value is reduced to 5-6 cm H_2O (to overcome the resistance of breathing circuit) and FiO_2 30% to 40% and extubation can be done after 90 min to 2 hours trial.

Gradual Weaning

Patients after prolonged ventilation are weaned by gradually decreasing ventilatory support. Sustained tolerance of SIMV rate ≤4, PSV or iPAP level <8 and PEEP ≤5 alongwith FiO_2 of less than 50%, is followed by spontaneous mode or T-piece trial and extubation of trachea. Weaning is not always straight forward and on several occasions it becomes difficult to wean. Risk factors include advancing age, COPD, malnutrition, sepsis, electrolyte imbalance and neuro-muscular diseases. Strategies like more gradual weaning, optimisation of nutrition and electrolyte balance, intermittent nocturnal ventilation, non-invasive CPAP or BiPAP may be helpful. Ventilator dependence is both physical and psychological and should be treated accordingly.

Post-Ventilation Care

After termination of ventilation, the patient should be monitored in ICU or in high dependency unit for next 24 to 48 hours to rule-out recurrence of respiratory distress.

NON-INVASIVE VENTILATION

Non-invasive ventilation (NIV) is accomplished with an airtight interface, e.g. facemask, nasal mask or NIV helmet and invasive airways like tracheal tubes are not used. Two methods of NIV are available, one employs positive airway pressure and the other applies negative pressure to the chest wall (for complete review, refer to the chapter on NIV).

OTHER METHODS OF VENTILATION

High Frequency Jet Ventilation

High frequency jet ventilation employs a jet of gas into the upper airway with air entrainment and is based on Bernoulli's principle.

High Frequency Positive Pressure Ventilation

High frequency positive pressure ventilation delivers RR between 60 to 180 per minute and $V_T \geq$ anatomical dead space (V_D).

High Frequency Oscillations

High frequency oscillations deliver RR 180 to 3000 per minute and $V_T \leq V_D$.

The above three are un-conventional modes, require different types of ventilators and mechanism of gas exchange is not clear. Various mechanisms, like Taylor dispersal, gas velocity, convection, pendelluft, mass diffusion, and mixing due to cardiac pulsations may be responsible for gas exchange. Successful oxygenation has been reported in some patients where conventional ventilation proved ineffective.

VENTILATOR SETTINGS FOR COMMON CLINICAL CONDITIONS

Acute Respiratory Distress Syndrome

Initial ventilator settings for these patients should be high FiO_2, V_T 6 to 8 mL/kg, RR 12 to 15 per minute and a PEEP of 5 to 7 cm H_2O. Further ventilator adjustments should be done on the basis of blood gas analysis after about one hour of ventilation. PaO_2 ≥60 mmHg, permissive hypercapnoea with $PaCO_2$ ≥50 mmHg and a pH ≥7.2 should be the objective. Acute rise in $PaCO_2$ can cause ventricular arrhythmias, therefore, careful monitoring of ECG is essential. Since ARDS is one of the most complex lung conditions, all modes, e.g. APRV, IRV and non-conventional modes have been used with variable success. Neuromuscular blockers should be considered for first 48 hours.

Acute Severe Asthma

These patients have hyper-reactive airways and tracheal intubation further worsens the bronchospasm. Intravenous ketamine (2 mg/kg) is the drug of choice due to its sympathomimetic and bronchodilator properties. Intravenous lignocaine 1.5 to 2 mg/kg, administered 90 to 120 seconds before intubation may also be effective (evidence weak) in controlling the bronchospasm. Initial ventilator settings include V_T 6 to 8 mL/kg, RR 8-10 per minute, higher flow rate (80-100 L/min), plateau pressure of 25-30 cm H_2O and peak inspiratory pressure 30-35 cm H_2O. Although higher flow rate decreases inspiratory time, it might increase peak inspiratory pressure. Alternatively, pressure control mode with cycling pressure up to 40 cm H_2O may be used. Permissive hypercapnoea ($PaCO_2$ ≤50 mmHg and a pH >7.2 may also be allowed. Since these patients are likely to receive high doses of steroids, therefore muscle relaxants should be avoided unless absolutely necessary due to increased risk of myopathy. Ventilator with in-built nebuliser should be preferred, otherwise provision for attaching a nebuliser should be made.

Chronic Obstructive Pulmonary Disease

COPD patients are better managed with NIPPV using CPAP or BiPAP modes. ePEEP should be 75% to 80% of auto-PEEP or 6 to 8 cm H_2O. Since these patients are accustomed to hypercapnoea, $PaCO_2$ ≤ 90 mmHg with a pH ≥7.2 may be allowed with vigil for CO_2 narcosis and cardiac arrhythmias. Ketamine and lignocaine as described above should be preferred for laryngoscopy and tracheal intubation. The V_T of 8 to 10 mL/kg and RR of 10 to 12 per minute with moderate FiO_2 is usually sufficient. Ventilator is disconnected briefly in case of hypotension. Improvement in pulse volume and blood pressure indicates air trapping and the need for reduction of PEEP, V_T or RR to prolong exhalation.

Cardiogenic Pulmonary Oedema (CPO)

Administer high FiO_2, morphine and keep the patient propped up during transport, intubation and ventilation. Initial ventilator settings should include V_T of 8 to 10 mL/kg, RR of 12 to 15 per minute, high FiO_2 usually 100% and PEEP of 10 cm. Bladder catheterisation should precede administration of diuretics and aggressive treatment of underlying cardiac defect should commence along with. Role of NIPPV continues to be controversial in CPO despite certain reports of successful oxygenation.

Interstitial Fibrosis

These patients have fast time constants for inflation and emptying of lungs along with severe diffusion block. Ventilator

should include V_T of 5 to 6 mL/kg, RR of ≥ 16 per minute (I:E ratio 1:1 and IRV is well tolerated) and high FiO_2 are required along with PEEP of 5 to 10 cm. Treatment of interstitial fibrosis comprises of immunosuppressants and steroid administration. Muscle relaxants should be avoided and strict aseptic precautions are needed.

Normal Lungs

This group of patients includes poisoning, snake bite, tetanus, head injury and Guillain-Barré syndrome, etc. These patients have normal lung mechanics and maintain oxygenation with FiO_2 of 30% to 40%. $PaCO_2$ of 35 to 40 mmHg (30 to 35 mmHg in head injury patients) and a basal PEEP of 5 cm is usually sufficient. High FiO_2 reduces the half-life of carboxyhaemoglobin, therefore, CO poisoning should be treated with FiO_2 of 100% oxygen the first few hours (6 to 8 hours).

Progressive Neurological Diseases

Motor neuron disease and lateral sclerosis patients develop nocturnal dyspnoea due to decreased muscle tone and fatigue. These patients are managed with night time NIPPV using CPAP or BiPAP modes. Ventilation eventually needs to be terminated by observing 'care of the dying patient' protocols.

SPECIAL SITUATIONS

Pregnancy

Institution of MV imposes stress and may result in premature expulsion of foetus. Obstetrician and paediatrician should also be involved in the management. Viable foetus may require surgical extraction.

Paediatric Patients

Paediatric patients are more vulnerable to ventilator-induced lung injury. Usually pressure cycled ventilators are used and pediatric breathing circuits should be used below 25 kg body weight. Neonates and infants require different types of ventilators.

COMPLICATIONS OF MECHANICAL VENTILATION

MV can result in or contribute to a number of complications. Major complications are listed in **Table 3** and discussed below.

Respiratory System

The diseased lung units have low compliance and or high resistance. MV is preferentially delivered to normal lung units, which may be damaged by excessive pressure or volume delivered by mechanical ventilators. Rupture of alveoli can lead to life-threatening conditions, like tension pneumothorax and pneumomediastinum. Surfactant depletion and oxygen toxicity have also been implicated as reasons for lung damage. Prolonged ventilation leads to disuse atrophy of respiratory muscles and may contribute to ventilator dependence.

Cardiovascular System

Positive intrathoracic pressure impairs the venous return, increases right ventricular afterload and may cause left ventricular dysfunction leading to reduced cardiac output and hypotension. Institution of MV relieves the respiratory distress and levels of circulating catecholamines fall rapidly, leading to further hypotension and sometimes cardiac arrest. These cardiac effects are directly related to the mean airway pressure, and therefore, modes like PEEP/CPAP and IRV have more pronounced effect. This compromised haemodynamic state with decreased cardiac output and low perfusion pressure results in decreased delivery of oxygen and nutritional substrates to vital organs and contributes to multi-organ failure.

Table 3: Complications of Mechanical Ventilation

Organ System	Complications	Prevention/Treatment
Respiratory system	Volume trauma, tension pneumothorax, deterioration of blood gas status	Use appropriate ventilator modes and settings Optimise PEEP, flow rate, FiO_2 and I:E ratio
Cardiovascular system	Hypotension, cardiac arrest	Optimise volume status, adjust ventilator settings, PEEP
Psychological	Acute stress and post-traumatic stress disorder (PTSD)	Sedation, communication and reassurance
Immunological	Infection, sepsis	Use of VAP bundle approach handwashing, aseptic precautions, good hygienic status, avoid re-use of disposable items
Aspiration of gastric contents	Pneumonia, gastric acid aspiration syndrome	Early securing of airway, regularly check tracheal tube cuff leakage, observe NPO before change of tracheal tubes, regularly check Ryle's tube position Use of PPIs/ H2 Blockers/ sucralfate, Head end elevation to 30-45°
	Long-term complications	
Prolonged intubation	Vocal cord polyps and granulomas	Use appropriate size tracheal tubes, early tracheostomy
Tracheostomy	Tracheal stenosis	Decanulation with gradually decreasing diameter of tracheostomy tubes (while in hospital), tracheal dilatation or resection of affected segment
Psychological	PTSD	Psychologist/Psychiatrist consultation

PEEP = Positive end-expiratory pressure; FiO_2 = Fraction of inspired oxygen; NPO = Nil per os

Psychological

Artificial airways, mechanical breaths and suctioning are both physically and emotionally distressing. Sleep deprivation, invasive procedures, tones and alarms of monitors, inability to communicate and isolation from family impose additional stress. A state of post-traumatic stress disorder may follow even after discharge from hospital.

Infection

Nosocomial infections and ventilator-induced pneumonia are well known. Patients are vulnerable to infection due to invasive procedures, indwelling lines and catheters and stress.

Aspiration

Despite tracheal intubation, the patients remain at high-risk for aspiration of gastric contents. Checking of nasogastric tube position and residual gastric residual volume (GRV) before administration of feed or enteral drugs is important. Positive pressure NIV may cause gastric inflation especially in debilitated and comatose patients.

Long-Term Complications

Prolonged intubation and tracheostomy may cause tracheal stenosis, vocal cord polyps and granulomas in the long run. There is no consensus as to whether tracheal intubation or tracheostomy is better. However, tracheostomy should be done early if ventilation or airway protection is anticipated for longer than 3 weeks.

CONCLUSION

In critical situations it is important to secure the airways at first possible opportunity to prevent aspiration and its associated complications. Oxygen should be given till the time of start of ventilation. Use high (100%) concentration of oxygen before tracheal intubation. Once the ventilation has started, send ABG after 1 hour. Strictly avoid using the same catheter for suction and its size be appropriate. Time of suction should preferably be not beyond 5-10 second each time. Nasogastric suction should be done before emergency interventions. In case of ventilation malfunction use manual ventilation. Patient should be kept NPO for 4-6 hours before change of tubes.

Maintain and constantly monitor all pulmonary and circulatory parameters.

7.9 Non-Invasive Ventilation

Dhruva Chaudhry, Inderpaul Singh

INTRODUCTION

Non-invasive ventilation (NIV) is the delivery of the mechanical ventilation to the lungs using techniques that do not require an endotracheal airway. Three basic methods of applying NIV are: negative pressure ventilation, abdominal displacement ventilation and positive pressure ventilation (PPV). However, for practical purposes, NIV now refers to PPV administered via mask or interface that directs pressurised gas into the upper airway.

The use of PPV goes back as far as 1780, when the first bag-mask apparatus was designed for resuscitative efforts. Over the years, it has evolved as being used as a means to deliver aerosolised medications periodically, to being used in patients with acute respiratory failure (ARF) due to chronic obstructive pulmonary disease (COPD) and asthma. Today NIV is used in both acute and chronic care settings, like COPD, asthma, neuromuscular diseases, heart failure, obstructive sleep apnoea, etc.

EQUIPMENT FOR NON-INVASIVE POSITIVE PRESSURE VENTILATION (NPPV)

The equipment needed for NPPV generally includes ventilators, humidifiers and the interfaces or masks.

Types of Ventilators

NPPV has been successfully applied using portable volume ventilators, adult intensive care ventilators and portable pressure support (pressure-targeted) ventilators. The choice of ventilator depends on the level of support required and the advantages and disadvantages of the appropriate machines.

Pressure targeted ventilators

Portable pressure-targeted ventilators (PTVs) are also known as continuous positive airways pressure (CPAP) ventilators, pressure support ventilators or bilevel pressure ventilators. These ventilators are microprocessor controlled, electrically powered units that use a blower to regulate gas flow into the patient's circuit to maintain the preset pressure at the patient's connection. PTVs have a single circuit gas delivery system that uses an intentional leak port for patient exhalation instead of a true exhalation valve.

PTVs are pressure limited, flow and time triggered, flow and time cycled ventilators. These are designed to increase minute ventilation and improve gas exchange capabilities with the delivery of an inspiratory positive airway pressure (IPAP), and an expiratory positive airway pressure (EPAP). Most portable PTVs offer the CPAP, assist mode, assist/control (A/C), control (or timed) mode of ventilatory support.

In CPAP mode, the patient breathes spontaneously at a set baseline pressure and controls both the rate and depth of breathing. Flow sensors and pressure transducers respond to patient's inspiratory and expiratory efforts, and increased or decreased flow through circuit to maintain a stable pressure.

In the assist mode, a change in the set IPAP occurs in response to the patient's inspiratory efforts. In A/C mode, all respiratory efforts initiated by the patient are supported to the IPAP level, as in the assist mode, but a minimum breathing rate may also be set. If a patient fails to make an inspiratory effort within a set interval, the machine triggers inspiration to set the IPAP.

The control mode delivers pressure support breaths based on control settings, not patient's efforts. The clinician sets the IPAP and EPAP, the number of breaths per minute and the inspiratory time percentage. The breaths are time triggered to the IPAP, based on the rate set. IPAP then cycles to EPAP based on the IPAP percentage. In all modes, delivered tidal volume (V_T) depends on the gradient between the IPAP and the EPAP, the inspiratory time, patient's inspiratory effort, and the patient's lung characteristics. PTVs ability to deliver flow in response to patient demand is the same as or superior to that of intensive care unit (ICU) adult ventilators and portable volume ventilators. PTV's also allow adjustment of the amount of time required to reach the IPAP. Two other comfort features of PTVs include RAMP and delay time controls. RAMP allows positive pressure to increase gradually over a set interval (delay time) of time. The RAMP rate generally can be set in increments of 1, 2, or 3 cm H_2O, and delay time can be set in 5 minutes increments from 5 to 30 minutes.

Portable PTVs have certain limitations that may restrict their use in ARF. The oxygen delivery is not standard on most portable PTVs. Therefore, fraction of inspired oxygen (FiO_2) can vary and is affected by flow rate, type of leak port in the system, site where oxygen is bled into the circuit, and IPAP and EPAP. Higher oxygen flow rate results in higher oxygen concentrations. Lower IPAP and EPAP levels also yield higher oxygen concentrations. If leak port is in the circuit, higher oxygen concentrations can be obtained, if the oxygen is bled into the patient's mask.

Rebreathing of carbon dioxide (CO_2) is a concern with any type of PTVs that use a single circuit gas delivery system. The flow of gas through the leak port depends upon the EPAP settings and the patient's inspiratory to expiratory ratio. At low EPAP settings (< 4 cm H_2O) and at a high respiratory rate, flow may not be adequate to flush CO_2 from the circuit.

Portable volume ventilators

Portable volume ventilators were designed originally for invasive ventilation in home and extended care facility. These are patient or time triggered, pressure limited and volume cycled.

The newer generation of these ventilators has both volume and pressure targeted modes with positive end-expiratory pressure (PEEP) capabilities. These ventilators are more responsive to patient flow needs and can be used for either invasive or NIV. These are not equipped with an internal blender, hence precise oxygen concentrations are not possible and like portable PTVs

oxygen must bled into the system through an adaptor from a separate oxygen source. As such they are ideal for achieving a seamless transition from the extended care facility to the home.

Adult acute care ventilators

Ventilators used in adult critical care settings offer more ventilator support options, more alarms, a precise FiO_2 and more monitoring features than portable PTVs. Although pressure support mode is the most commonly used to administer NPPV, volume or pressure controlled modes combined with PEEP can also be administered via mask interface.

The most significant disadvantage of these ventilators is the inability of some machines to compensate for leaks. Although studies have demonstrated no significant differences in gas exchange between volume and pressure targeted modes, volume control modes are seldom used to deliver NPPV in acute care settings. However, volume control modes are more likely to be used in the chronic care settings in patients with neuromuscular disorders.

Humidification during Non-Invasive Pressure Ventilation

Excessive drying of the nasal mucosa with the administration of nasal CPAP or NPPV has been associated with nasal congestion and increased resistance. This is a leading cause of patient's discomfort and non-compliance. Humidification can prevent and improve mucosal dehydration. A passover type of heated humidifier should be used because heated bubble humidifiers, and heat and moisture exchangers, increase airway resistance in the ventilator circuit and may also interfere with patient triggering.

Interfaces

The effectiveness of NPPV is greatly influenced by the interface chosen to deliver the PPV. Various commonly used interfaces are described in **Table 1**.

RATIONALE OF VENTILATION

In ARF, NPPV is considered a life-saving application that offers a number of benefits over invasive ventilation (**Table 2**). The most significant is the avoidance of intubation. The physiological goal of NPPV in ARF is to improve gas exchange by resting respiratory muscles and increasing alveolar ventilation. NPPV reduces diaphragmatic swings, which suggests that respiratory muscles are being rested. In addition, when PEEP is applied during the pressure support ventilation, it helps offset intrinsic PEEP (PEEPi), thereby reducing the work to initiate inspiration. Like-wise pressure support facilitates inspiration, thus increasing V_T. Resting of respiratory muscles and improved V_T lead to a lower arterial partial pressure of CO_2 ($PaCO_2$), better oxygenation and decreased respiratory rate (**Figures 1 and 2**).

Table 2: Benefits of Non-invasive over Invasive Ventilation

Acute care
Reduces need for intubation
Reduces incidence of hospital acquired pneumonia
Shortens ICU and hospital stay
Reduces mortality
Preserves airway defenses
Improves patient comfort
Reduces need for sedation
Chronic care
Alleviates symptoms of hypoventilation
Improves sleep quality
Improves functional capacity
Prolongs survival

INDICATIONS AND CONTRAINDICATIONS OF NON-INVASIVE VENTILATION

The goals of NPPV and the indications for its use are based upon decades of clinical expertise and systemic research. The various

Table 1: Various Interfaces in Non-Invasive Positive Pressure Ventilation

Interface	Advantages	Disadvantages
Nasal mask	Easy to fit Less feeling of claustrophobia Low-risk of aspiration Allows patient to cough and clear secretions Maintains ability to speak and eat Less mechanical dead space More useful for chronic lung conditions	Mouth leaks Eye irritation Facial skin irritation Ulceration over nose bridge Oral dryness Nasal congestion Increased resistance through nasal passages Not used in acute lung conditions
Full face (oronasal) mask	Reduces air leakage through the mouth Less airway resistance Used in acute lung conditions	Increased risk of aspiration Increased risk of asphyxia Increased dead space Claustrophobia Difficult to secure and fit Facial skin irritation Ulceration over nasal bridge Patient must remove mask to eat, speak, or expectorate secretions
Nasal pillows or seals	Same as for nasal mask	Pressure sores around nares
Mouth piece	Facilitates communication Less feeling of claustrophobia Low-risk of aspiration Allows patient to cough and clear secretions Low-risk of carbon dioxide rebreathing No head gear requirements	Nasal air leakage Hypersalivation Possibility of orthodontic deformity

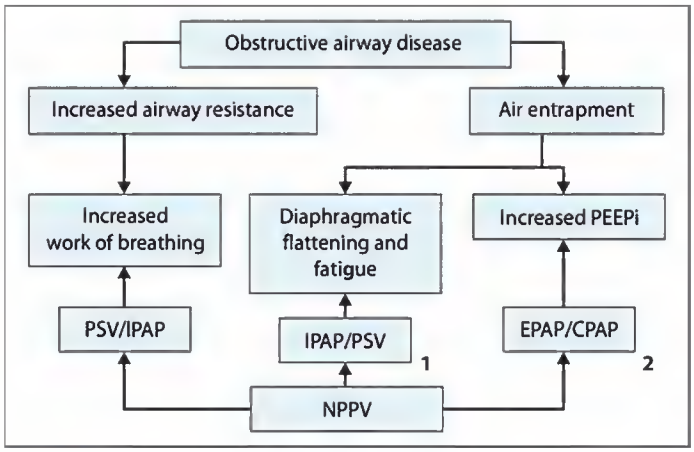

Figure 1: Mechanism of action of NPPV in obstructive airway disease.

1. Augments tidal volume; 2. Decreases inspiratory threshold
PEEPi: Intrinsic Positive end-expirotory pressure; IPAP = Inspiratory positive airwoy pressure; EPAP = Expirotory positive airway pressure; CPAP = Continous positive oirway pressure; NPPV = Non-invosive positive pressure ventilation

1. Improves FRC/Oxygenation; 2. Decreases work of breathing, rests muscles, decreoses CO_2

indications both in acute as well as chronic respiratory failure are mentioned in **Table 3**.

Table 3: Indications for Non-Invasive Ventilation

Obstructive Diseases	Hypoxaemic Respiratory Failure
COPD (A)	Acute pulmonary oedema (A)
Asthma (B)	Pneumonia (B)
Cystic fibrosis (C)	ARDS (C)
Upper airway obstruction (C)	Trauma (C)
Restrictive diseases (mainly long-term setting)	**Categories of acute respiratory failure**
Kyphoscoliosis (C)	Facilitation of weaning (A)
Neuromuscular disease (C)	Immunocompromised patients (A)
Obesity-hypoventilation syndrome (C)	Post-operative respiratory failure (B)
	Extubation failure (B)
	Do not intubate patients (C)

Letter in parenthesis indicote level of evidence: A = Multiple controlled trials; B = A single supportive controlled trial; C = Uncontrolled triols, case reports
COPD = Chronic obstructive pulmonary disease; ARDS = Acute respirotory distress syndrome

SPECIFIC INDICATIONS

Acute Indications

Chronic obstructive pulmonary disease

The main objective of NIV in acute exacerbation of COPD is not only to relieve symptoms of the disease but also to reduce associated mortality and morbidity. During an acute exacerbation, there is an increase in airway resistance and an increased respiratory rate which together lead to hyperinflation and development of PEEPi. As hyperinflation increases, respiratory muscle activity also increases leading to an increase in the work of breathing, and hence, oxygen consumption. This together with impaired diaphragmatic mechanics leads to a vicious cycle of hypoventilation, air trapping and muscle fatigue. By combining high inspiratory pressure with low expiratory pressure, NIV effectively reduces the diaphragmatic work of breathing, and hence, benefit the patient during acute exacerbations by acting as a crutch to support the patient while medical treatment is given time to work.

Unless contraindicated, NIV is to be preferably given to patients with acute exacerbations having respiratory distress and respiratory failure instead of conventional therapy alone, as NIV has been shown to reduce respiratory rate, improve dyspnoea and gas exchange, cause improvement of arterial blood gas levels, shortens duration of hospital and ICU stay, reduces intubation rate by three-fourth as well as complication and mortality rates. The indications of NPPV are mentioned in **Table 4**.

Table 4: Indications of Initiating NPPV in Acute Exacerbations of Chronic Obstructive Pulmonary Disease*

Respiratory distress with moderate-to-severe dyspnoea
Use of accessory muscles of respiration
Abdominal paradox
Respiratory rate > 30/min
pH <7.35; $PaCO_2$ >45 mmHg; PaO_2 <60 mmHg

** Any two of the above if present, NPPV should be initiated.*

NIV can also facilitate early weaning in those intubated patients with COPD who could not be extubated due to multiple failed "T" piece breathing trials. By facilitating early extubation in such patients, NIV reduces occurrence of nosocomial pneumonias, improves breathing rates, and shortens duration of ventilator use, NIV cap prevent re-intubation when used immediately after extubation for COPD patients at high risk of extubation failure and also reduce hospital stay and mortality.

Acute cardiogenic pulmonary oedema

CPAP has been in use to treat acute cardiogenic pulmonary oedema (CPE) since 1930s. The increased intrathoracic pressure reduces transmyocardial pressure, as well as the pre-load and after-load; thereby enhancing cardiac function in patients with left ventricle dysfunction who are dependent on after-load. CPAP leads to an increase in functional residual capacity, secondary to opening of collapsed alveoli and rapidly improves compliance and oxygenation. It is highly effective in improving oxygenation, lowering respiratory rate, decreasing sensation of dyspnoea, and thereby, helps in avoiding intubation.

Studies comparing NPPV with CPAP demonstrated more rapid improvement in $PaCO_2$ and pH in the former, but the mortality and intubation rates were almost similar. A disconcerting finding

was a higher incidence of myocardial infarction in NPPV group (71% *versus* 31%). The current recommendation is to use CPAP (10-12 cm H_2O) initially for the treatment of CPE and that NPPV be used only in patients who continue to be hypercapnic and dyspnoeic thereafter.

Hypoxaemic respiratory failure

Evidence of the efficacy of NPPV in the treatment of hypoxic respiratory failure has been inconsistent. Various studies comparing NPPV plus usual medical care have shown better gas exchange, reduced need for ventilation and decreased mortality rate. On the other hand, some studies found no significant improvement in the patients' overall outcomes unless the patients were also hypercapnic. Due to heterogeneity of disorders in this group, these findings cannot be applied to individual patients and need further studies for application of NPPV in these patients.

Acute respiratory distress syndrome

Mixed success has been reported in patients with acute respiratory distress syndrome treated with NIV. It can be tried in patients with mild oxygenation defects, but otherwise stable with only a single organ dysfunction. NIV should be started only in carefully selected patients within this group and intubation should be contemplated if there is no substantial improvement in oxygenation within the first hour.

Pneumonia

Use of NIV in community-acquired pneumonia is becoming more common. Various studies have outlined significant benefits of early use of NIV in patients with severe community-acquired pneumonia which include reducing the need for intubation, shortening stay in ICU and decreasing nosocomial infections. However, the advantages of NIV in community-acquired pneumonia are seen mostly in patients with underlying COPD. Further studies are needed to define the optimal mode of ventilation and the specific patient population (especially, patients without COPD) who might benefit the most.

Chest trauma

Rapid improvement in gas exchange and low intubation rates are expected among patients with chest trauma. NIV can also be used to facilitate extubation in such patients.

Post-operative patients

NIV in post-operative patients has the potential to improve many physiological parameters without apparent serious side-effects. After high-risk surgeries, especially of thorax and upper abdomen, NIV can be used to prevent complications like hypoxaemia, pneumonia and atelectasis, and reduces the rate of intubation. NIV can also be used to treat frank respiratory failure in these patients.

Difficult to wean/facilitation of weaning

NIV can be used to facilitate weaning as well as in supporting patients who develop ARF after extubation. Current data support the use of NIV in patients with risk factors for extubation failure, particularly if they have co-existing COPD, congestive heart failure and/or hypercapnia. However, early indiscriminate use of NIV in patients who have risk factors for extubation failure, but do not meet standard criteria for initiation of NIV should be discouraged. Patients with extubation failure treated with NIV should be monitored closely and if intubation is needed, delay should be avoided.

Do not intubate

The argument in favour of NPPV with "do not intubate status" is that NPPV may relive severe dyspnoea and preserve patient comfort. It may also reverse the acute process in disorders, such as COPD or pulmonary oedema, and allow the patient to live longer. The argument against NPPV is that it could actually prolong the dying process, adds to patient discomfort and consume valuable resources, and may be deemed unethical. It is necessary for patients' family and care-givers to understand these goals and to cease promptly if the goals are not being accomplished.

Long-Term Indications

Chronic respiratory failure due to restrictive thoracic diseases

Patients with restrictive thoracic diseases presenting with features of chronic respiratory failure like symptoms of hypoventilation such as morning headache or day-time hypersomnolence, severe pulmonary dysfunction may benefit from NIV. NIV ameliorates decline in lung function and improves gas exchange, cognitive function and overall survival in such patients.

Guidelines for initiating NIV in patients with chronic respiratory failure due to restrictive thoracic diseases are mentioned in **Table 5**.

Table 5: Guidelines for Non-Invasive Positive Pressure Ventilation Therapy in Restrictive Lung Disease on Long-term Basis*

1. Symptomatic despite optimal medical therapy AND
2. Severe pulmonary dysfunction OR
   - FVC ≤50% predicted
   - MIP ≥60 cm H_2O
3. Gas exchange disturbance
   - Chronic CO_2 retention ($PaCO_2$ >45) or
   - Nocturnal hypoventilation (as evidenced by O_2 saturation <88% for ≥5 consecutive minutes while breathing room air)

** 1 plus any of 2 or 3 if present, NPPV is indicated*

Patients with chronic hypoventilation syndromes due to neuromuscular diseases, chest wall or spinal deformity and obesity hypoventilation syndrome also respond gradually over a few weeks after initiation of mechanical NIV. Amelioration of nocturnal hypoventilation and improvement of sleep quality are the major consequences of this therapy and probably the major reasons for daytime improvement.

Chronic respiratory failure due to chronic obstructive pulmonary disease

Evidence of the efficacy of long-term nocturnal NPPV is vague and often contradictory in patients with severe stable COPD. Although evidence is inconclusive, the current professional consensus and guidelines recommend that patients with severe day-time CO_2 retention ($PaCO_2$ >52 mmHg) and nocturnal hypoventilation despite nocturnal oxygen therapy should be considered for NPPV therapy.

Obstructive sleep apnoea

Obstructive sleep apnoea is a life-threatening condition where nasal CPAP is the treatment of choice. Positive pressure may

provide a mechanical stent to the upper airway in such patients and prevent apnoea in all sleep stages, preferably in supine and lateral positions. As higher pressure can be uncomfortable for sleep, the minimal pressure that reasonably eliminates most respiratory disturbances like snoring and arousal together with elimination of oxygen desaturation is recommended. The American Academy of Sleep Medicine guidelines for CPAP recommend its use in patients who have apnoea-hypopnoea index (AHI) greater than 20 and for symptomatic patients who have an AHI or respiratory arousal index greater than 10.

CONTRAINDICATIONS

NIV should not be used in unconscious patients or in patients unable to protect upper airways, intractable hypotension and facial burns (**Table 6**).

Table 6: Contraindications of Non-Invasive Positive Pressure Ventilation

Respiratory arrest or need for intubation
Haemodynamic instability
Inability to protect the airway
Excessive secretions
Agitated and confused patient
Facial deformities or conditions that prevent mask from fitting
Uncooperative or unmotivated patient
Brain injury with unstable respiratory drive
Severe respiratory acidosis
Facial trauma or burn

INITIATION OF NON-INVASIVE VENTILATION

After selecting the ventilator and interface, the physician is responsible for initiating NPPV. Steps for initiation of NIV have been described in **Table 7**. The initial ventilator settings usually consist of an IPAP of 10 cm H_2O and an EPAP of about 4 to 5 cm H_2O. The difference between the IPAP and EPAP is the level of inspiratory support. IPAP augments the tidal volume and hence alveolar ventilation, increases airway pressures and decreases fatigue. EPAP prevents airway and alveolar collapse, prevents atelectasis and maintains functional residual capacity at increased level and maintains oxygenation. Slowly increasing IPAP to maintain an exhaled V_T at 5 to 7 mL/kg or higher may result in decrease in the respiratory rate. If EPAP is increased, IPAP may also need to be increased to maintain the same gradient between IPAP and EPAP, and thus ensure adequate V_T delivery.

Table 7: Steps for Initiating Non-Invasive Positive Pressure Ventilation

1. Place the patient in an upright or sitting position. Carefully explain the procedure for NPPV, including goals and possible complications.
2. Using a sizing gauge, make sure a mask is chosen that is the proper size and fit.
3. Attach the interface and circuit to the ventilator. Turn on the ventilator and adjust it initially to low pressure settings (e.g. IPAP 10 cm H_2O/ EPAP 4 cm H_2O).
4. Hold or allow the patient to hold the mask gently to the face until the patient becomes comfortable. Encourage the patient to use proper breathing technique.
5. Monitor oxygen saturation; adjust the FiO_2 to maintain saturation above 90%.
6. Secure the mask to the patient
7. Titrate the IPAP and EPAP to achieve patient comfort, adequate exhaled tidal volume. Do not allow peak pressures above 20 cm H_2O.
8. Check for leaks and adjust the straps, if needed.
9. Monitor heart rate, respiratory arte, level of dyspnoea, minute ventilation and exhaled tidal volume.
10. Obtain blood gas within 1 hour.

Monitoring during Non-Invasive Positive Pressure Ventilation

Several studies have identified possible indicators of success of NPPV in both the acute and chronic care settings (**Table 8**). A patient of ARF must be closely monitored in ICU/emergency department so that if NPPV is unsuccessful, patient can be immediately intubated (**Table 9**). The indications of intubation and termination of NPPV in favour of invasive ventilation are mentioned in **Table 10**.

Table 8: Indicators of Successful Non-Invasive Positive Pressure Ventilation

Higher level of consciousness
Younger age
Less severe illness
Less severe gas exchange abnormalities (pH 7.10–7.35; $PaCO_2$ < 92 mmHg)
Minimal air leakage around interface
Intact dentition
Synchronous breathing efforts with ventilator
Lower quantity of secretions
Absence of pneumonia
Positive response to NPPV within 1 to 2 hours
Correction of pH
Decreased respiratory rate
Reduced $PaCO_2$

Table 9: Parameters to be Monitored during Non-Invasive Positive Pressure Ventilation

Subjective responses
Patient comfort
Discomfort related to the mask
Respiratory distress
Vital signs and physical findings
Respiratory rate
Blood pressure
Ability to cough and raise secretions
Accessory muscle use
Ventilator function
Patient-ventilator synchrony
Tidal volume ≥ 6 ml/kg
Air leaking
Waveforms (if available)
Gas exchange
Continuous oximetry
Change in $PaCO_2$ if hypercapnic
Change in pH

Table 10: Indicators to Terminate Non-Invasive Positive Pressure Ventilation and Switching to Invasive Ventilation

Worsening pH and $PaCO_2$
Tachypnoea (> 30/min)
Haemodynamic instability
Oxygen saturation > 90%
Decreased level of consciousness
Inability to clear secretions
Inability to tolerate interface

Complications

NPPV is considered much safer than invasive ventilation. Complications with NPPV usually are related to mask discomfort, air pressures or gas flows (**Table 11**).

Table 11: Complications Associated with NPPV/CPAP Therapy

Complications	Corrective Action
Mask discomfort	Check mask for correct size and fit
Excessive leak around mask	Minimise headgear tension
Pressure sores	Use spacers or change to another style of mask Use wound care dressing over nasal bridge
Nasal and oral dryness or nasal congestion	Add or increase humidification Irrigate nasal passages with saline Use chin strap to keep mouth closed Apply topical decongestants Change to full face mask
Mouthpiece/lip seal leakage	Use nose clips Use custom made oral appliances
Aerophagia, gastric distention	Use lowest effective pressures for adequate tidal volume delivery Use simethicone agents
Aspiration	Make sure patients are able to protect the airway
Mucous plugging	Ensure adequate patient hydration Ensure adequate humidification Avoid excessive oxygen flow rates (>20 L/min) Allow short breaks from NPPV to permit directed coughing techniques
Hypotension	Avoid excessively high peak pressures ($\leq$ 20 cm H_2O)

Patient Weaning and Discontinuation of Non-Invasive Positive Pressure Ventilation

The duration of ventilator assistance with NPPV depends on how quickly the cause of respiratory failure can be reversed. The most common approach involves increasing periods of time off mask ventilation. If signs of respiratory distress occur, the patient is placed back on mask ventilation immediately. Prolonging the periods of ventilator interruption, when the patient is experiencing respiratory distress, may lead to rapid decompensation and need for emergency intubation. Another approach to wean is to gradually reduce the level of pressure support to a minimum level, allowing the patient to assume more of the work of breathing. Regardless of the method of weaning, the reversibility of the disease process that caused respiratory failure is the most important factor for successful weaning.

CONCLUSION

Evidence supports the use of NPPV in the treatment of respiratory failure secondary to COPD, CPE, immunocompromised state in acute care settings and weaning in COPD. Evidence is weak for use of NPPV in other indications and should not be used routinely, patients should be selected carefully. NPPV is used to avoid intubations and not replace it. Therefore, threshold for intubation should be low in acute care settings. It should be avoided in patients having multiple organ dysfunction syndrome, unconscious patients and patients with burn and facial trauma; whereas in chronic care, NPPV is the modality of choice in managing respiratory failure in patients having thoracic disorders and neuromuscular disorders.

Proper fitting of interface is essential for the success of NPPV. Proper ventilator settings and mask are more important than ventilation for patient comfort and compliance.

7.10 Hypotension and Shock

Anil Dhall, Sanjat S Chiwane

DEFINITION

Definition of shock includes the following haemodynamic parameters to be identified:

1. Persistent hypotension [systolic blood pressure (SBP) <80 to 90 mmHg or mean arterial pressure (MAP) 30 mmHg lower than baseline].
2. Severe reduction in cardiac index (CI) <1.8 L/min/m^2 without support or <2.0 to 2.2 L/min/m^2 with support.
3. Adequate or elevated filling pressure [(e.g. left ventricular (LV) end-diastolic pressure >18 mmHg or right ventricular (RV) end-diastolic pressure >10 to 15 mmHg].

The diagnosis is usually made with the help of pulmonary artery catheterisation; however, echocardiography may also be used to confirm elevation of LV filling pressures. The clinical manifestations are due to hypoperfusion such as cold extremities, decreased urine output, and/or alteration in mental status.

CLASSIFICATION

Hinshaw and Cox classification based on cardiovascular characteristics, is the most practical classification of shock. It divides the syndrome into four major categories: hypovolaemic, cardiogenic, extracardiac obstructive, and distributive (**Table 1**).

Hypovolaemic Shock

It is characterised by a loss in circulatory volume which results in decreased venous return, decreased filling of the cardiac chambers, and decreased cardiac output (CO) which leads to increase in the systemic vascular resistance (SVR). The haemodynamic profile on monitoring of flow pressure variables shows low central venous pressure (CVP), a low pulmonary capillary wedge pressure (PCWP), low CO and CI, and high SVR. The arterial blood pressure may be normal or low.

Cardiogenic Shock

This is primarily dependent on poor pump function. Cardiogenic shock (CS) due to acute catastrophic failure of LV pump function is characterised by high PCWP, low CO and CI, and generally a high SVR.

Distributive or Vasogenic Shock

This type of shock is associated with not only poor vascular tone in the peripheral circulation but maldistribution of blood flow to organs within the body also. The CO varies, but is usually raised. A common haemodynamic profile is a low or normal PCWP, a high CO, a low arterial blood pressure, and a low SVR.

Extracardiac Obstructive Shock

It is associated with reduced forward circulatory flow involving mechanisms different than primary myocardial or valvular dysfunction. The haemodynamic patterns observed, depend on the cause, from significant decrease in filling pressures (as in mediastinal compression of great veins); to equalisation of pressures as in cardiac tamponade; or to increased RV filling pressures with low PCWP in the case of pulmonary embolism. CO is usually decreased with an increase in SVR.

Table 1: Classification of Shock

Hypovolaemic (Oligaemic)
Haemorrhagic
Fluid Depletion (Non-haemorrhagic)
Extensive fluid loss (dehydration)
Vomiting
Diarrhoea
Polyuria
Interstitial Fluid Redistribution
Thermal injury
Trauma
Anaphylaxis
Cardiogenic
Myopathic:
Myocardial infarction
Myocarditis
Cardiomyopathy
Septicaemia
Mechanical:
Valvular
VSD
Arrhythmia:
Severe bradycardia
Marked prolonged tachycardia
Extracardiac Obstructive
Cardiac tamponade
Constrictive pericarditis
Post-MI rupture of ventricular wall
Vena caval obstruction
Acute pulmonary hypertension
Impaired Systolic Contraction
Pulmonary embolism
Aortic dissection
Distributive
Septic shock
Anaphylaxis
Neural spinal shock
Adrenal crisis
Toxic

MI = Myocardial infarction; VSD = Ventricular septal defect

Parameters in various types of shock are shown in **Table 2**.

Table 2: Haemodynamic Parameters in Various Types of Shock

	CO	PCWP	ABP	SVR
Hypovolaemic	↓	↓	↓	↑
Cardiogenic	↓	↑	↓	↑
Vasogenic	Nor ↑	Nor ↓	↓	↓
Extracardiac	↓	Nor ↓	↓	↑

CO = Cardiac output; PCWP = Pulmonary capillary wedge pressure; ABP = Arterial blood pressure; SVR = Systemic vascular resistance; Nor = Normal.

PATHOPHYSIOLOGY

Shock of all forms involve common pathophysiological mechanisms that end in cell injury, organ failure and death. The pathogenesis of shock involves multiple inter-related factors including cellular ischaemia, circulating or local inflammatory mediators, and free radical injury.

1. Hypoperfusion decreases the delivery of nutrients to the cells leading to diminished ATP production. Essential ATP dependent intracellular metabolic processes that may be affected include maintenance of transmembrane potential, mitochondrial function and other energy-dependent enzyme reactions.

   Liver and kidney are particularly sensitive as intracellular levels of ATP fall and ATP-dependent processes are impaired.

2. The effect of inflammatory mediators on cellular metabolism is of prime importance in organ dysfunction resulting from sepsis and septic shock and also haemorrhagic shock associated with extensive trauma. Generally, it is the endotoxin from Gram-negative bacteria that triggers the inflammatory cascade but bacterial antigens and cell injury itself can also initiate the cascade. Macrophage production of cytokines such as tumour necrosis factor-alpha (TNF-α) and interleukin-1beta (IL-1β) appear to be the prime mediators. Other substances involved in the inflammatory process include IL-2, IL-6, interferon-γ, endothelin-1, leukotrienes, thromboxanes, prostaglandins and complement fragments C3a and C5a. Two other mediators, i.e. circulating myocardial depressant substance and nitric oxide have a role to play in septic shock.

3. Free radical injury induced by reperfusion or neutrophil activity is another mechanism by which cell and organs suffer a damage. Tissue ischaemia leads to accumulation of adenosine, inosine and hypoxanthine. With resuscitation, reperfusion of ischaemic areas occurs.

The availability of O_2 generates superoxide (O_2-) by xanthine oxidase which is converted to hydrogen peroxide (H_2O_2) which further reacts to produce the highly reactive tissue damaging hydroxyl radicals. These in turn interact with critical cell targets resulting in cell lysis and tissue injury. Oxidant activity, directly and through endothelial damage attracts and activates neutrophils causing amplification of superoxide generation and further tissue damage due to neutrophil protease release.

Other microvascular pathologic processes occurring in shock include disruption of integrity of endothelial cell barrier leading to loss of plasma proteins, decrease in plasma oncotic pressure, interstitial oedema and fall in circulating volume. In addition, there is microvascular clotting and microthrombi leading to further inadequate distribution of perfusion within tissue.

COMPENSATORY RESPONSES TO SHOCK

Various compensatory mechanisms are detailed in **Table 3**. With the onset of haemodynamic dysfunction, hemostatic compensatory mechanisms engage to maintain adequate tissue perfusion. These responses are similar for varying classes of shock and are divided into four categories: (a) maintenance of mean circulatory pressure, (b) maximising cardiac function, (c) redistributing perfusion to vital organs, and (d) optimising unloading of oxygen at tissues.

Table 3: Compensatory Responses to Shock

Volume
Fluid redistribution to vascular space
From interstitium (Starling effect)
From intracellular space (Osmotic effect)
Decreased renal fluid losses
Decreased glomerular filtration rate (GFR)
Increased aldosterone
Increased vasopressin
Pressure
Decreased venous capacitance
Increased sympathetic activity
Increased circulating (adrenal) epinephrine
Increased angiotensin
Increased vasopressin
Maximise Cardiac Performance
Increased contractility
Sympathetic stimulation
Adrenal stimulation
Redistribution of Perfusion
Extrinsic regulation of systemic arterial tone
Dominant autoregulation of vital organs (heart, brain)
Optimise Oxygen Unloading
Increased RBC 2, 3 DPG
Tissue acidosis
Pyrexia
Decreased tissue PaO_2

Diagnostic Approach and Evaluation

It is imperative, that clinicians recognise the early stages of shock at a time when it is more responsive to treatment. A monitored physiologic approach to therapy provides the best opportunity for successful outcome and avoidance of organ dysfunction. Not only is the initial resuscitative technique important but also continuous evaluation of the patient's condition.

Clinical Presentation

This varies with the previous level of organ function, compensatory mechanisms, severity of organ dysfunctions and the cause of shock syndrome. Impending shock is characterised by the typical compensatory response to cardiovascular stress. Tachycardia, tachypnoea and oliguria are the hallmark. Cold extremities are seen in hypodynamic shock. With progression, blood pressure falls and frank hypotension (MAP < 60 to 65 mmHg) ensues. With further progression, anuria, mottled, dusky extremities and altered sensorium occurs. (Detailed in **Table 4**).

Laboratory Studies

These are used not only for the confirmation of diagnosis of shock but also to know the aetiologic factors. Initial laboratory tests should include a complete blood count. Leucocyte count is frequently elevated early in shock and leucopaenia is found in sepsis and late shock. Haemoglobin level varies with the type of shock. Stress of circulatory shock increases platelet count initially, but with progression thrombocytopaenia occurs. Complete chemistry profile with serum electrolytes, creatinine, blood urea nitrogen (BUN), liver function tests, calcium, magnesium and phosphate levels, serum lactate levels, prothrombin and activated partial thromboplastin times, urinalysis with a detailed sediment analysis, serum amylase level, and arterial blood gases (ABG) must be done. BUN and creatinine

Table 4: Organ System Dysfunction in Shock

Central Nervous System: Encephalopathy (ischaemic or septic), cortical necrosis
Cardiovascular System: (Heart) tachycardia, bradycardia, supraventricular tachycardia, ventricular ectopy, myocardial depression
Pulmonary: Acute respiratory failure, adult respiratory distress syndrome
Kidney: Prerenal failure, acute tubular necrosis
Gastrointestinal: Ileus, erosive gastritis, pancreatitis, acalculous cholecystitis, colonic submucosal haemorrhage
Liver: Ischaemic hepatitis'Shock' liver, intrahepatic cholestasis
Haematologic: Disseminated intravascular coagulation, dilutional thrombocytopaenia
Metabolic: Hyperglycaemia, glycogenolysis, gluconeogenesis, hypoglycaemia (late), hypertriglyceridaemia
Immune System: Gut barrier function depression, cellular immune depression, humoral immune depression

rarely change after the acute onset of shock, even if renal injury is present. ABG determines the adequacy of oxygenation and acid-base status. Serial serum lactate levels are used in the assessment of prognosis and levels of > 2 mEq/L represent tissue ischaemia. A 12-lead electrocardiogram (ECG) is critical for diagnosis of ischaemic cardiac injury. Chest radiograph is also a must. Other studies should be considered in specific conditions and may include detailed imaging studies like computed tomography (CT), abdominal radiographs or ultrasound, surface or transoesophageal echocardiography, ventilation/perfusion scan, angiograms and cardiac isoenzymes may be ordered for as and when required.

Invasive Haemodynamic Monitoring

Arterial pressure line is a must for all patients. Marked peripheral vasoconstriction makes the assessment of pressure by manual or non-invasive techniques inaccurate. Flow directed balloon-tipped pulmonary artery catheter with thermodilution cardiac output determination capability have become the standard practice for the haemodynamic assessment of circulatory shock. Continuous monitoring of central venous and pulmonary artery waveforms and pressures is also provided by them. Mixed venous oxygen saturation provides an assessment of adequacy of resuscitation of low output states before the presence of anaerobic metabolism. Oxygen delivery and oxygen consumption variables can also be determined using pulmonary artery catheter-derived data. But, the utility of this data is controversial when applied to individual patients.

Ancillary Monitoring Techniques

Echocardiography in the intensive care unit (ICU) not only detects the anatomic lesions but also allows direct measurement of cardiac output, stroke volume, pre-load, systolic contractility, diastolic function and regional motion abnormalities. There are other promising non-invasive monitoring devices, i.e. near-infrared spectroscopy to detect oxygen availability and utilisation at tissue level.

Management and Therapy

Patients in shock should be managed in an ICU with continuous ECG monitoring and close nursing support. Invasive haemodynamic monitoring with arterial and pulmonary artery catheters should be instituted in those indicated, laboratory tests as mentioned before should be performed at the earliest possible. Management of shock can be divided into specific therapy for triggering injury and general therapy of the shock syndrome.

Therapeutic Goals

1. Haemodynamic MAP >60 to 65 mmHg (higher in the presence of coronary artery disease or chronic hypertension)
2. PCWP = 12 to 18 mmHg (may be higher for cardiogenic shock)
3. CI >2.1 L/min/m^2 for cardiogenic and obstructive shock >3.0 to 3.5 L/min/m^2 for septic and resuscitated traumatic/haemorrhagic
4. Optimisation of haemoglobin >8 g/dL
5. Oxygen delivery arterial saturation >92%, SvO_2 > 60%
6. Normalisation of serum lactate (<2.2 mEq/L)
7. Maintain urine output >0.5 mL/kg/hr

The basic goal of circulatory shock therapy is the restoration of effective perfusion and oxygen supply to vital organs and tissues before the onset of cellular injury.

Airway management and mechanical ventilation

A critical first step in the treatment of shock is to ensure adequate alveolar ventilation and oxygenation. Most patients with the fully developed shock syndrome require tracheal intubation and mechanical ventilatory support, even if acute respiratory failure has not yet occurred. Mechanical ventilation allows blood flow to be redistributed, tends to reverse lactic acidosis and supports the patient until other therapeutic measures can be effective. Tracheal intubation also is indicated if mental status changes make airway unprotected or for inadequate respiratory compensation for metabolic acidosis. Positive-pressure ventilation and positive-end expiratory pressure (PEEP) may produce further haemodynamic compromise, if volume status of the patient is not maintained. PEEP may also be desirable in patients with acute respiratory distress syndrome (ARDS) or pulmonary oedema to ensure adequate oxygenation.

Acid-base balance

The previous standard practice of administering bicarbonate to patients with shock and lactic acidosis has been revised. The optimal approach to the management of lactic acidosis is to improve organ and systemic perfusion so that anaerobic metabolism is limited and the liver as well as kidneys can clear the accumulated lactate. If not effective, it has been suggested to restrict the use of sodium bicarbonate to situations with pH less than 7.1 to 7.15.

Fluids

Common to all aetiologies of haemodynamic instability and shock is the need to provide optimal intravascular volume to ensure adequacy of pre-load. Thus, it is appropriate to begin fluid administration in all shock patients who lack signs of pulmonary oedema and LV overload. Substantial controversy exists regarding the appropriate use of crystalloid and colloid fluids for resuscitation. What is most important when either type of fluid is used is to determine responses to these fluid

challenges. Optimal therapy generally means administering the quantity of fluid that maximises DO_2 while avoiding LV overload and pulmonary oedema. Also, sufficient preload should be there before or during institution of pharmacologic therapy for hypoperfusion.

Vasopressor agents

The term pressor refers to any substance that raises blood pressure (BP). These agents are divided into 3 categories: (i) Inotropes/chronotropes (i.e. drugs that increase CO by increasing cardiac contractility and heart rate); (ii) vasoconstrictors (i.e. agents that raise BP by increasing systemic vascular resistance); (iii) mixed pressor agents (i.e. drugs that act through both mechanisms).

1. Inotropic/chronotropic agents:

   Dobutamine hydrochloride, a synthetic β1, β2 receptor agonist is often used for inotropic support in cardiogenic shock. It increases myocardial contractility and CO, reduces afterload through peripheral vasodilatation and decreases LV filling pressures with improvement in diastolic coronary blood flow. It also prevents increase in infarct size in patients with acute myocardial infarction by improved collateral blood flow and balance between oxygen supply and demand. Because of β2-mediated vasodilatation caution should be observed if it is administered to hypotensive patients, especially with coexistent hypovolaemia. Milrinone lactate, a selective phosphodiesterase III inhibitor increases ionotropy and decreases systemic vascular resistance by preventing the degradation of cyclic adenosine monophosphate. The haemodynamic effects are similar to those of dobutamine. Amrinone, is rarely used because of excessive vasodilatation and thrombocytopaenia following long-term use. Dopexamine, a synthetic catecholamine, augments cardiac performance through both β2-mediated afterload reduction and baroreceptor reflex-mediated inotropy. Also, added benefit is its dopaminergic-mediated increase in renal blood flow. Isoproterenol hydrochloride, a pure β receptor agonist produces CO augmentation by increasing both heart rate and contractility. Dysrhythmias and increased myocardial oxygen requirement limit the use. Digitalis has limited use in treating acute states of hypoperfusion due to its slow onset of action and lower potency.

2. Vasoconstrictor agents:

   Phenylephrine is a pure adrenergic agonist. It causes vasoconstriction, thereby increasing BP, generally decreasing CO and often reflex slowing of heart rate. It should be used as a first-line agent in neurogenic shock. It can also be useful in patients who, despite maximal fluid and ionotropic support, remain hypotensive with evidence of organ hypoperfusion. Pure vasoconstrictors may compromise flow and perfusion, thus attention to renal function, acid-base balance, serum lactate and DO_2 is imperative. Vasopressin is used as an alternative therapy for vasodilator shock especially where a stimulation does not produce a satisfactory vasoconstrictor response. Most studies have used doses between 0.01 and 0.1U per minute. Other vasoconstrictor is noradrenaline (norepinephrine).

3. Mixed pressor agents:

   Dopamine, a precursor of norepinephrine, is commonly used as an initial pressor agent, acting at several receptors in a dose-related manner. It can be titrated towards achieving different aims of therapy: dopaminergic effects at less than 4 to 5 mcg/kg/min (e.g. vasodilatation of renal and splanchnic vascular beds), β effect at 5 to 10 mcg/kg/min (e.g. augmentation of cardiac contractility and heart rate) and α effects at more than 10 mcg/kg/min (e.g. vasoconstriction). There has been a decreased enthusiasm for its routine use to protect the kidneys from hypoperfusion insults or as a means to promote urine output in post-hypoperfusion oliguria. However, at a dose of 2 to 3 mcg/kg/min, it can reverse vasoconstrictor—induced increases in renal vascular resistance during vasoconstrictor infusion. Norepinephrine exerts both powerful inotropic (cardiac α and β1 adrenoreceptors) and peripheral vasoconstriction effects (α adrenoceptors). It can be used for persistent hypotension despite high-dose dopamine during septic and obstructive shock. It may also improve splanchnic oxygen dynamics in patients with sepsis. Epinephrine is occasionally used when other inotropes/vasopressors have failed to support blood pressure and/or cardiac output in circulatory shock. It is the first-line agent for management of anaphylactic shock. All currently used vasopressor agents ultimately produce their effects by increasing intracellular ionised calcium concentration. Thus, normal ionised calcium concentration should be maintained in patients who are on vasopressor support.

   The American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend norepinephrine for more severe hypotension because of its high potency. Although both dopamine and norepinephrine have inotropic properties, dobutamine is often needed in addition. Pharmacological treatments that warrant further investigation include vasopressin, levosimendan —a calcium-sensitising agent that has so far shown little additional value in randomised heart failure trials, and/or activated protein C, which has been tried in conjunction with mechanical support in myocarditis patients.

Vasodilator agents

These drugs reduce afterload and improve CO in acute and chronic ventricular failure. For acute vasodilatation and preload reduction, nitroglycerin is the agent of choice; for afterload reduction, sodium nitroprusside, nitroglycerin, hydralazine hydrochloride, angiotensin converting enzyme inhibitors and fenoldopam are preferable. Patients with right-sided heart failure may benefit from pulmonary vasodilators, i.e. prostacyclin, prostaglandin E1 and inhaled nitric oxide.

Steroids

Prospective, double-blind, randomised, multicentre studies have demonstrated no benefit of steroid administration in hyperdynamic/septic shock. Thus, the practice of routine administration of high-dose steroids was abandoned. Stress doses of glucocorticoids are appropriate for treating shock when it is associated with adrenal insufficiency, hypothyroidism, in patients with impaired adrenal pituitary axis, or in those who

require steroids for treatment of an underlying immunologic disease (e.g. vasculitis). Conversely, steroids are relatively contraindicated in patients with cardiogenic shock as they alter the healing process of the myocardium and predispose to myocardial rupture. But recent reports also suggest a decrease in the endogeneous production of stress steroids in sepsis, causing vasopressor dependence and failure to respond to therapy. Administration of 50 mg of hydrocortisone 6 hourly indicates benefit. The mechanism for benefit may be reversal of catecholamine receptor down regulation or prevention of inflammatory mediated induction of nitric oxide synthase. Patients with shock, who require increasing doses of vasopressors or do not respond within 24 hours of therapy, may be administered steroids. However, this topic still remains controversial.

Mechanical support: intra-aortic balloon pump (IABP)

Intra-aortic balloon counterpulsation has long been the mainstay of mechanical therapy for cardiogenic shock. Use of an IABP improves coronary and peripheral perfusion via diastolic balloon inflation and augments LV performance via systolic balloon deflation with an acute decrease in afterload. Accurate timing of inflation and deflation provides optimal support. Not every patient has a haemodynamic response to IABP; response predicts better outcome. IABP support should be instituted as quickly as possible, even before any transfer for revascularisation if a skilled operator is available and insertion can be performed quickly. In the large US National Registry of Myocardial Infarction, IABP use was independently associated with survival at centres with higher rates of IABP use—whether PCI, fibrinolytic therapy, or no reperfusion had been used; however, no completed trials demonstrate benefit. Complications associated with IABP are less common in the modern era; in the largest series, the overall and major complication rates were 7.2% and 2.8%, respectively. Risk factors for complications include female sex, small body size, and peripheral vascular disease.

Reperfusion

The survival benefit of early revascularisation in CS, reported in several observational studies, was shown convincingly in the randomised SHOCK trial, which found a 13% absolute increase in 1-year survival in patients assigned to early revascularisation. This corresponds to a number needed to treat 8 patients to save 1 life. The benefit was similar in the incomplete, randomised Swiss Multicenter Study of Angioplasty for Shock. Numerous registry studies have confirmed the survival advantage of early revascularisation, whether percutaneous or surgical, in the young and the elderly. Thrombolytic therapy is less effective but is indicated when PCI is impossible or if a delay has occurred in transport for PCI and when myocardial infarction and CS onset were within 3 hours.

Timing of PCI

As in myocardial infarction without shock, earlier revascularisation is better in cardiogenic shock. Presentation 0 to 6 hours after symptom onset was associated with the lowest mortality among CS patients undergoing primary PCI in the Arbeitsgemeinschaft Leitende Kardiologische Krankenhausarzte (ALKK) registry, in which door-to-angiography times was 90 minutes in approximately three-fourths of patients. In the SHOCK trial, there appeared to be increasing long-term mortality as time to revascularisation increased from 0 to 8 hours. However, there is a survival benefit as long as 48 hours after myocardial infarction and 18 hours after shock onset.

Total Circulatory Support: LV Assist Devices and Extracorporeal Life Support

Temporary mechanical circulatory support with LV assist devices (LVADs) is theoretically appealing to interrupt the vicious spiral of ischaemia, hypotension and myocardial dysfunction, allowing for recovery of stunned and hibernating myocardium and reversal of neurohormonal derangements. Device-related complications and irreversible organ failure remain major limitations. LVAD support involve circulation of oxygenated blood through a device that drains blood from the left-side of the heart and returns blood to the systemic arteries with pulsatile or continuous flow. Surgically implanted LVADs remove blood through a cannula placed at the LV apex and return blood to the ascending aorta. Percutaneous LVADs are also available. Extracorporeal life support involves extracorporeal circulation of blood through a membrane oxygenator, which relieves both the right and left heart and the lungs of part of their workload. Anticoagulation is required for extracorporeal life support and for percutaneous LVADs but may be optional with surgically placed LVADs. Extracorporeal life support and LVADs have been used sequentially in CS patients, usually as a bridge to heart transplantation. In the largest reported LVADs series to date, 74% of 49 patients survived to transplantation, and 87% of transplanted patients survived to hospital discharge after receiving a variety of surgical LVADs. These devices need further large trials for different use.

7.11 Cardiopulmonary Resuscitation

Ashit M Bhagwati

INTRODUCTION

Sudden cardiac arrest is a leading cause of death worldwide. Recognition of this emergency is imperative to initiate prompt resuscitation of the victim. It was in the 19th Century, Doctor HR Silvester described a method (The Silvester Method) of artificial respiration in which the patient was laid on his back, with arms raised above the head to aid inhalation and then pressed against the chest to aid exhalation. The procedure was repeated 16 times per minute. A second technique, called the Holger-Neilson technique, was described in the first edition of the *Boy Scout Handbook* in the United States (US) in 1911. It is essentially the Silvester Method with the patient flipped over. This form was well used into the 1950s. The technique was later banned from first-aid manuals in the United Kingdom.

However, it was not until the middle of the 20th Century that artificial respiration combined with chest compressions as a key part of resuscitation following cardiac arrest was recognised. In 1957, Peter Safar wrote the book *ABC of Resuscitation*. In USA, it was first promoted as a technique for the public to learn in the 1970s.

Artificial respiration was combined with chest compressions based on the assumption that active ventilation is necessary to keep circulating blood oxygenated, and the combination was accepted without comparing its effectiveness with chest compressions alone. However, research over the past decade has shown that assumption to be faulty, resulting in the American Heart Association's (AHA) acknowledgement of the effectiveness of chest compressions alone.

PATHOPHYSIOLOGY

Most of the cardiac arrest cases occur as a result of ventricular fibrillation (VF) precipitated by an acute coronary event. Needless to say that timely recognition and defibrillation of the victim leads to excellent survival results. However, it needs to be realised that the goal of CPR is not just a functioning heart, but a functioning heart in a functioning person, i.e. revival of heartbeat with intact neurological function. It has been observed that outcome of the victim is better with VF than asystole or pulseless electrical activity (PEA), which in turn is influenced by the cause of the arrest and the promptness in the availability of resuscitation.

MANAGEMENT

Survival of the victim depends on the chain of interlinked processes referred to as 'chain of survival'. The 2010 AHA guidelines emphasise the importance of post-cardiac care, and hence, a fifth chain has been added to the chain of survival. The chain of survival for adults is now given below in **Figure 1**.

When these links are implemented, survival rates can approach 50% following witnessed out of hospital VF arrest.

The 2010 AHA guidelines for CPR and emergency cardiovascular care (ECC) are based on an extensive international evidence evaluation process. The ILCOR 2010 International Consensus on CPR and ECC Science with treatment recommendations summarises the international consensus after interpreting a vast number of peer reviewed resuscitation studies. The modifications recommended are for both BLS and ACLS to provide effective resuscitation outcomes.

The modifications in the protocols and resuscitation in children and infants, including current modifications, will not be discussed in this chapter.

Adult Life Support

Adult life support involves two sequences, viz. adult basic life support and adult advance life support. Here, the discussion will be restricted to techniques meant for healthcare personnel only.

Adult basic life support

This involves resuscitation of the victim without any specialised equipment or complex understanding of the pathophysiology of cardiac arrest. The objective is to maintain adequate circulation and ventilation of vital organs until specialised assistance is available. This minimises anoxic damage to the vital organs.

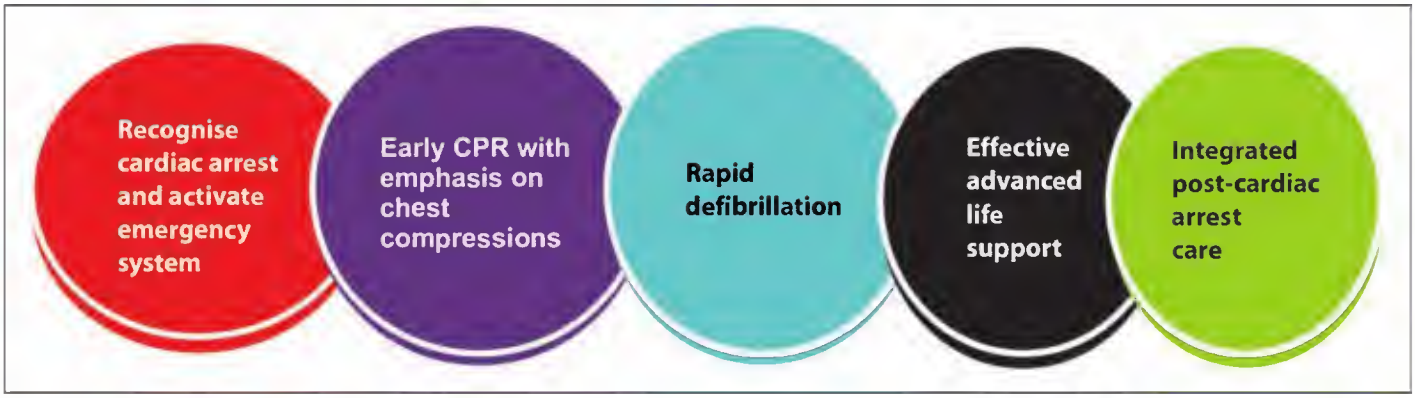

Figure 1: AHA ECC adult chain of survival.

Prompt Recognition of Arrest

Before approaching the victim the rescuer should ensure scene safety. Thereafter, the rescuer should check for response. Tap the victim on the shoulder and shout 'Are you alright'. The healthcare provider should also check for no breathing or abnormal breathing (i.e. only gasps) while checking for responsiveness. If unresponsive, then activate emergency medical system, get AED/defibrillator or ask second rescuer (if available to get it).

Circulation

Pulse check

The 2010 AHA guidelines for CPR and ECC do not emphasise the pulse check as a mechanism to identify cardiac arrest. This is because studies have shown that both lay person and healthcare providers have difficulty in detecting a pulse. Healthcare providers may take too long to appreciate a pulse, thereby delay in initiating chest compressions. To avoid this, healthcare provider should not take more than 10 seconds. If no pulse is felt during that period then proceed to closed chest compression immediately.

The ABC approach has been replaced by CAB approach, i.e. initiation of chest compressions before ventilation, since setting up of airway equipment takes time.

Closed chest compression

The process involves effective application of closed chest compression to maximise the quality of CPR. If done properly and cyclically, nearly 25% to 30% cardiac output is maintained. Closed chest compressions cause forward flow by direct pressure on the cardiac chambers (cardiac pump) or by the cyclical evacuation of the pulmonary vasculature (thoracic pump). The low flow that is generated provides protective circulation to the brain for a brief period and enhances coronary perfusion. The adequacy of the latter is the best predictor of successful restoration of spontaneous cardiac activity and circulation. Properly performed closed chest compression can produce systolic arterial pressure of 60 to 80 mmHg, diastolic pressure is low and mean arterial pressure in the carotid artery seldom exceeds 40 mmHg.

Changes from 2005 guidelines regarding compression stipulates that the compression rate should be at least 100 per minute and not 'approximately' 100 per minute. The compression depth should be at least 2 inches (5 cm) in adults and not 1½ to 2 inches as was being practised earlier for adults. Allow complete chest recoil after each compression. Minimise interruptions in chest compressions, i.e. continuous chest compressions for effective outcomes. Also, there is need to avoid excessive ventilation.

Method

To give effective chest compressions, push hard and push fast. Compress the adult chest at a rate of at least 100 compressions per minute, with a depth of 2 inches (5 cm). Allow the chest to recoil completely after each compression, and allow approximately equal compression and relaxation times. Please minimise/avoid interruptions in chest compressions and avoid excessive ventilation. Healthcare providers should interrupt chest compressions as infrequently as possible and try to limit it to no longer than 10 seconds, except for insertion of advanced airway or use of a defibrillator. When two or more rescuers are present switch chest compressors approximately every 2 minutes or after 5 cycles of compressions and ventilations at a ratio of 30:2. This is done to avoid rescuer fatigue. This switch should be accomplished in less than 5 seconds.

Managing the airway

Also the 2010 AHA guidelines regarding airway management has eliminated 'Look, Listen and Feel' from BLS algorithm.

Open airway

The healthcare rescuer should open airway using head-tilt chin lift manoeuvre after ruling out head and neck trauma. If cervical spine injury is suspected then open airway using 'jaw thrust without head extension'. If this method fails to open the airway, then use head-tilt chin lift method. Maintaining a patent airway and providing adequate ventilation is a priority in CPR.

Rescue breathing

Rescue breaths can be given through either mouth-to-mouth, mouth-to-barrier device, mouth-to-nose and mouth-to-stoma ventilation with bag and mask. Each rescue breath should ensure the following:

1. Deliver each rescue breath over 1 second.
2. Give sufficient tidal volume to produce visible chest rise.
3. Use compression to ventilation ratio of 30:2.
4. When advance airway is in place, during two person CPR, give 1 breath every 6 to 8 seconds without attempting to synchronise breaths between compressions (i.e. delivery of 8 to 10 breaths/min). There should be no pause in chest compressions for delivery of ventilations.

The algorithms presented in **Figure 2** summarise the adult BLS sequence.

Defibrillation

Early defibrillation is critical for survival in sudden cardiac arrest (SCA) victims for several reasons: (1) most frequent rhythm in SCA is VF, (2) treatment for VF is defibrillation, (3) probability of successful defibrillation diminishes rapidly with passage of time, and (4) VF tends to deteriorate to asystole within a few minutes. The success of defibrillation is time-dependent, with rates of failure increasing by about 10% for every minute of delay after the cardiac arrest.

Defibrillation works by depolarising all the myocardium and eliminating fibrillatory activity. This enables the patient's intrinsic pacemaker to take over and establish a stable rhythm. Also, the current has to be delivered in a mode that minimises trans-thoracic impedance, which can be achieved by: (a) applying firm pressure to assure contact with the skin (8 kg in adults), and (b) using a conducting gel to minimise resistance at the skin interface (Avoid ultrasound gel as it has poor conductance).

Appropriate size of the defibrillator paddle (12 cm diameter is ideal for adults) and shaving of the chest if possible, without delaying the initial shocks. Alternately, electrode pads should be placed. Alternately electrode pads should be placed on the exposed chest in an antero-lateral position. Alternate acceptable positions are antero-posterior, anterior-left infrascapular, and anterior-right infrascapular.

Conventional defibrillators deliver the current as a monophasic waveform (current flows in one direction between electrodes),

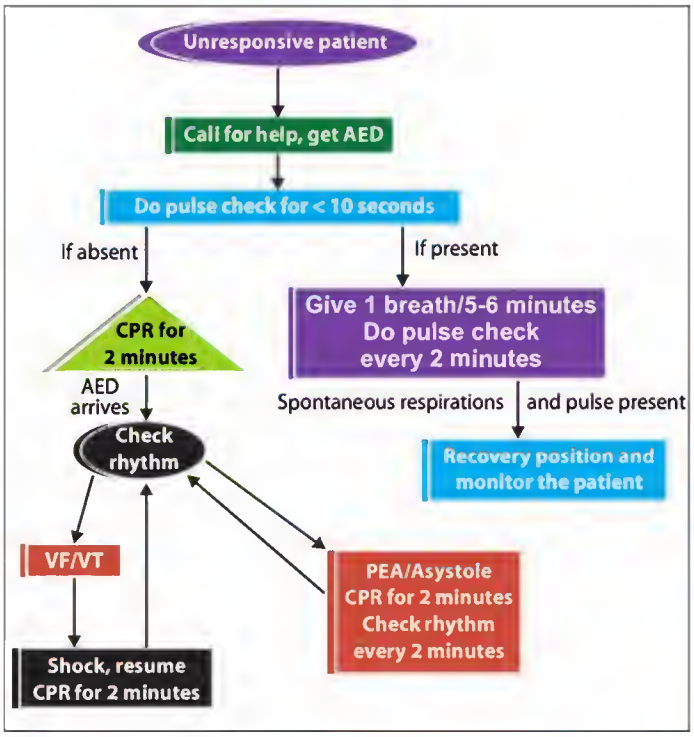

Figure 2: Adult basic life support (BLS) algorithm with AED.

VF = Ventricular fibrillotion; VT = Ventricular tochycardio; PEA = Pulseless electrical octivity

but biphasic currents (flowing first in one direction between paddles and then returning in the reverse direction) are more effective at cardioversion using much lower levels of energy. The resulting reduction in myocardial injury is of benefit.

In the absence of biphasic defibrillators, use of monophasic defibrillators can be permitted. For monophasic defibrillators, recommended energy is 360 Joules. However, the ideal recommendation is to use a biphasic defibrillator. The energy recommendation as per manufacturer is 120 to 200 Joules; if unknown then to use maximum available. Second and subsequent doses should be equivalent.

Recovery Position

The recovery position is used for unresponsive adult victims who clearly have normal breathing and effective circulation. This position is designed to maintain a patent airway and reduce the risk of aspiration. The victim is placed on his or her side with the lower arm in front of the body. Unfortunately no single position is perfect for all victims. As there are several variations of the recovery position, the goal is to see that the patient should be stable, near a true lateral position, with the head dependent and no pressure on the chest to impair breathing.

Advance Cardiac Life Support

Cardiac arrest can be caused by four rhythms; VF, pulseless ventricular tachycardia (VT), PEA, and asystole. Neither of these rhythms generate cardiac output. For a victim to survive this catastrophe a well coordinated BLS and a system of advanced cardiovascular support (ACLS) with integrated post-cardiac arrest care is essential. ACLS interventions are based on the foundation of efficient BLS intervention, namely, immediate recognition and activation of the emergency response system, early CPR, rapid defibrillation to further increase the likelihood of return of spontaneous circulation (ROSC) with drug therapy, advance airway management, and physiological monitoring. It is essentially a team-work carried out by trained healthcare workers/providers in ACLS and not by a single individual.

Various steps in ACLS process as per the guidelines of AHA 2010 are shown in **Figure 3** and described below.

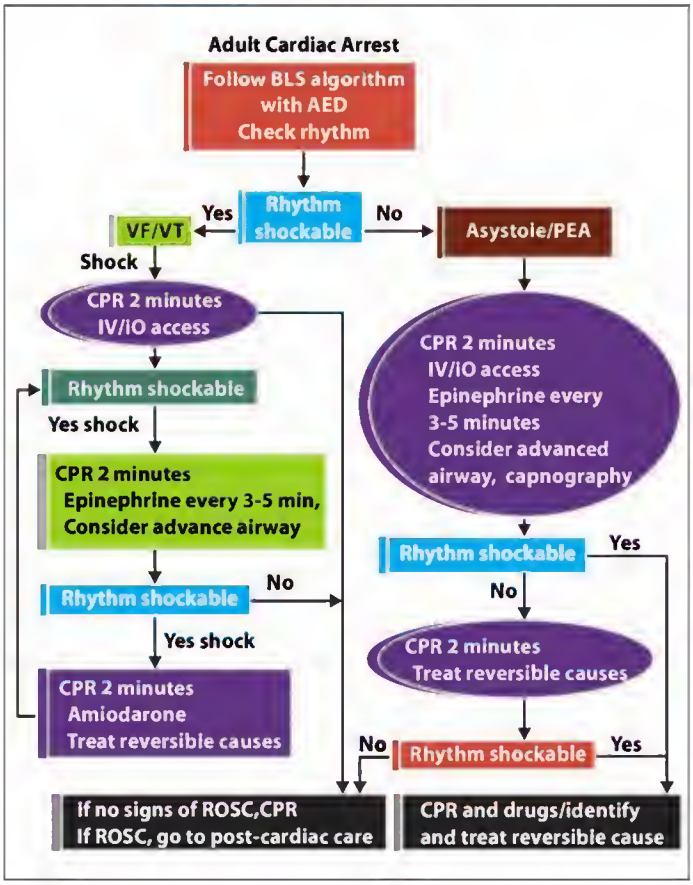

Figure 3: Advanced cardiovascular support pulseless arrest algorithm.

BLS = Bosic life support; AED = Automated externol defibrillotion; VF = Ventricular fibrillotion; VT = Ventricular tochycordio; PEA = Pulseless electricol activity; CPR = Cordiopulmonory resuscitotion; IV = Introvenous; IO = Introosseous; ROSC = Return of spontoneous circulation

Effective Steps as Recommended in BLS

1. After defibrillator is attached, check cardiac rhythm.
2. Rhythm: VF/VT or PEA or asystole.
3. If VT/VF, treatment of choice is defibrillation with continuous CPR. For refractory VF/VT use amiodarone. Drug therapy prior to amiodarone during CPR includes epinephrine every 3 to 5 minutes with vasopressin to replace 1st or 2nd dose of epinephrine.
4. For PEA/asystole shock is not indicated. Only drug therapy, i.e. epinephrine every 3 to 5 minutes with vasopressin to replace 1st or 2nd dose of epinephrine is indicated.
5. Check for any treatable/reversible causes of cardiac arrest (**Table 1**).
6. During CPR it is important to check rhythm after every 2 minutes to analyse whether the rhythm is shockable or non-shockable.
7. Consider after 2 minutes of CPR, advance airway management and physiological monitoring of the patient.

Table 1: Treatable Causes of Cardiac Arrest: The Hs and Ts

Hs	Ts
Hypoxia	Toxins
Hypovolaemia	Tamponade (Cardiac)
Hydrogen ion (Acidosis)	Tension pneumothorax
Hypo- or Hyperkalaemia	Thrombosis – Pulmonary
Hypothermia	Thrombosis – Coronary

Adult Cardiac Arrest

Advance airways

During CPR, breathing is normally maintained with bag-mask ventilation as a part of BLS algorithm, which during ACLS advance invasive airway placement is done to deliver effective oxygenation. The problem with this is interruption of chest compressions and the need for the healthcare provider to be sufficiently trained in insertion of the advance airway. Also the choice of the airway depends on the skill of the healthcare provider and the condition of the victim. Accordingly, there are two types of advance airways as descried below:

(a) Supraglottic airways
(b) Endotracheal intubation

Supraglotic airways: Insertion of supraglottic airways is easier, as it does not require direct visualisation of the glottis and can be done without interruption of chest compressions. These are very effective in maintaining an open airway, thereby facilitating ventilation. The commonly used supraglottic airways are laryngeal mask airway, oesophageal-tracheal tube (combitube), and the laryngeal tube.

Endotracheal intubation: This is ideal for a variety of reasons including to keep the airway patent, permits effective respiratory toilet, and effective for providing invasive ventilation and an alternative route for cardiac arrest drug administration. However, the drawback is in the hands of untrained healthcare worker who could cause complications like oropharyngeal trauma, prolonged interruptions in chest compressions or oesophageal intubation.

Clinical confirmation of the tube placement can be done by visual confirmation during intubation by noticing the tube passing through the vocal cords and bilateral chest expansion following bagging the victim by attaching an Amboss bag to the ET, 5 point auscultation (presence of air over the chest bilaterally and absence over the epigastric region). Various devices are used for tube placement confirmation, viz. oesophageal detector device and non-wave-form exhaled carbon dioxide (CO_2) detector if waveform capnography is not available.

Once advance airway is in place with confirmation, the two healthcare providers should no longer follow cycles of CPR, but provide continuous chest compressions at the rate of 100 per minute. Ventilation should continue at the rate of 1 breath every 6 to 8 seconds, i.e. 8 to 10 breaths per minute with the same criteria to avoid excessive ventilation. To avoid fatigue of the compressor and subsequent deterioration of CPR quality, the two healthcare providers should rotate the compressor role every 2 minutes.

Medications for Cardiac Arrest Rhythms

Drugs Routinely Administered in CPR

Vasopressors

Vasopressors are the only drugs routinely indicated in prolonged arrests irrespective of the rhythm. They enhance coronary perfusion by raising aortic root pressures and help in restoration of spontaneous circulation. However, till date no placebo-controlled trials have shown that administration of any vasopressor agent at any stage during management of VF/PVT, PEA, or asystole increases the rate of neurological integrity and survival leading to hospital discharge. However, there is evidence that they are associated with an increased rate of ROSC.

Epinephrine hydrochloride: Epinephrine hydrochloride produces beneficial effect due to its alpha-adrenergic receptor stimulating (i.e. vasoconstrictor) effect. This effect increases coronary and cerebral perfusion pressure during CPR. However, the value and safety of the β- adrenergic effects of epinephrine are controversial as it may increase myocardial work and reduce subendocardial perfusion.

The recommended dose is 1 mg intravenous/intraosseous (IV/IO) every 3 to 5 minutes during adult cardiac arrest until ROSC is achieved. Endotracheal route at a dose of 2 to 2.5 mg is used if IV/IO access is delayed or cannot be established.

Vasopressin: Vasopressin is a non-adrenergic peripheral vasoconstrictor that acts on smooth muscle V-1 receptors and increases cerebral and coronary perfusion without increasing myocardial oxygen demand. Despite its seeming benefit, current evidence is inadequate to support its use as an alternative to epinephrine in CPR. A recent meta-analysis showed no statistically significant differences between vasopressin over epinephrine for return of spontaneous circulation, 24-hour survival, or survival to hospital discharge.

One randomised controlled trial (RCT) found that repeated doses of vasopressin during cardiac arrest did not improve survival rates compared with repeated doses of epinephrine. Since effects of vasopressin have not been shown to differ from those of epinephrine in cardiac arrest, it is recommended that one dose of vasopressin 40 U IV/IO can replace either the first dose or second dose of epinephrine in the treatment of cardiac arrest.

Other vasopressors: There are no alternative vasopressors (norepinephrine, phenylephrine) with proven survival benefit compared with epinephrine.

Antiarrhythmics

There is no evidence that any antiarrhythmic drugs given during cardiac arrest can increase survival to hospital discharge. However, amiodarone has been shown to increase short-term survival to hospital admission when compared to placebo and lidocaine.

Amiodarone: Amiodarone is a membrane-stabilising drug that significantly slows conduction over the AV nodal and accessory pathways. It has complex actions on sodium, potassium, and calcium channels along with effects on alpha and beta-adrenergic receptors. It produces both hypotension and bradycardia. It is effective in enhancing responses to defibrillation in refractory VF/PVT.

Amiodarone is administered for VF or PVT unresponsive to CPR, defibrillation, and vasopressors at initial dose of 300 mg IV/IO bolus followed by an additional 1 dose of 150 mg IV/IO only.

Lidocaine: Initial animal studies did support the use of lidocaine for ventricular arrhythmias, however subsequent studies showed that compared with amiodarone; amiodarone was superior to lidocaine in restoring spontaneous circulation with improved rate of survival to hospital admission and that lidocaine was associated with more asystole after defibrillation.

Lidocaine should be considered as an alternative to amiodarone only, if amiodarone is not available. The initial dose is 1 to 1.5 mg/kg IV. If VF/pulseless VT persists, additional doses of 0.5 to 0.75 mg/kg IV push may be given at an interval of 5 to 10 minute to a maximum dose of 3 mg/kg.

Magnesium: Use of magnesium sulphate is considered only in refractory VF, *torsades de pointes*, in chronic alcoholics with unresponsive VF/pulses VT and digoxin toxicity.

Interventions and Drugs Not Recommended for Routine Use during Cardiac Arrest

Atropine

The drug reverses cholinergic-mediated decrease in heart rate, systemic vascular resistance and blood pressure. Lower level clinical studies provide conflicting evidence regarding the benefit of routine use of atropine in cardiac arrest. In fact as per available evidence, routine use of the drug during PEA and asystole is unlikely to have a therapeutic benefit. Therefore, atropine has been removed from the cardiac arrest algorithm.

Sodium bicarbonate

During cardiac arrest and resuscitation tissue acidosis with resulting acidaemia occur due to absence of blood flow during arrest with low blood flow during CPR. ROSC following high quality CPR restores acid-base balance. Except for two studies, majority of the studies have shown no benefit or found to have poor outcomes with the use of sodium bicarbonate during CPR. However, use of it can be made in special resuscitation circumstances, like pre-existing metabolic acidosis, hypothermia, hyperkalaemia, or tricyclic antidepressant overdosage.

Calcium

Routine use of calcium for the treatment of in-hospital and out-of-hospital cardiac arrest is not recommended, as routine use of calcium has not been proved to be of beneficial value in survival in any trials.

Intravenous fluids

Administration of normothermic fluid, hypertonic and chilled fluids during CPR has no advantage in survival benefit of the victim, as observed in various animal and small human studies. However, volume administration should be promptly given, if cardiac arrest is associated with severe volume losses because these patients develop signs of circulatory shock advancing to PEA.

Pacing

No studies have shown survival benefits from pacing in cardiac arrest. Existing evidence suggests that pacing by transcutaneous, transvenous, or transmyocardial means in cardiac arrest victims does not improve the likelihood of ROSC or survival outcomes regardless of the timing of pacing administration or location of arrest. As a result, electrical pacing is not recommended for routine use in cardiac arrest.

Monitoring during CPR

Physiological monitoring to optimise CPR quality and detect ROSC now plays an important role in the new 2010 AHA guidelines. Needless to say with ROSC the victim is shifted to intensive care unit (ICU) or if the event has occurred in the ICU setting monitoring of physiological parameters is done aggressively, using clinical parameters and sophisticated equipments. The age-old arterial pulse palpation, manual or intra-arterial BP monitoring, 12-lead ECG including rhythm monitoring on bedside monitor cannot be ignored.

The 2010 AHA guidelines emphasise particularly the use of $PETCO_2$ for monitoring in ACLS once advance airway placement has been done. Other parameters include coronary perfusion pressure (CPP), central venous oxygen saturation (SVO_2), SpO_2 monitoring, and arterial blood gas analysis (ABG).

Continuous Quantitative Waveform Capnography

The 2005 AHA guidelines laid emphasis on 5 points auscultation for ET placement and confirmation with an exhaled CO_2 detector or an oesophageal detector device to confirm placement of ET. The continuous quantitative waveform capnography monitoring was being referred to as a useful non-invasive indicator of cardiac output that is generated during CPR. The 2010 AHA guidelines for CPR and ECC now recommend continuous quantitative waveform capnography monitoring for confirmation and monitoring of endotracheal tube placement include in algorithm for ACLS once advance airway placement is done. The advantage of $PETCO_2$ monitoring is also for monitoring quality of CPR and detection of ROSC based on $ETCO_2$ values.

The rationale is that $PETCO_2$ provides a continuous waveform with ventilation to confirm the presence of ET. Also, it serves to play a major role in the 5th chain of survival, i.e. in post-cardiac arrest care. It plays a vital role in detecting the effectiveness of chest compressions and cardiac output in the recovery phase. Falling $PETCO_2$ during chest compressions indicate ineffective chest compressions and during ROSC may indicate falling cardiac output or rearrest.

Central Venous Oxygen Saturation (SVO_2)

Measurement of SVO_2 is done by placing oximetric tipped central venous catheters in the superior vena cava. The normal values are 60% to 80%. It is an effective tool for assessing the adequacy of blood flow during cardiac arrest, because during cardiac arrest the SVO_2 is between 25% to 35% indicating poor blood flow. The advantage of SVO_2 during cardiac arrest is to detect ROSC as it is a useful indicator of cardiac output and oxygen delivery without interruption of chest compressions for pulse and rhythm checks. If during CPR, SVO_2 is > 30% it indicates the need to improve CPR quality by improving the chest compressions. Limitations in the use of SVO_2 monitoring is the availability of the catheter and knowledge of use in all ICUs, and particularly its accuracy depends on oxygen consumption, SaO_2 values and haemoglobin levels.

Coronary Perfusion Pressure and Arterial Relaxation Pressure

Coronary perfusion pressure (CPP) is defined as aortic relaxation pressure minus right atrial relaxation pressure. Measured during CPR it correlates well with myocardial blood flow and ROSC. It requires simultaneous recording, measurement and calculation of both aortic and central venous pressures. Unfortunately, in our set-up its availability is a problem. Alternatively intra-arterial pressure monitoring is preferred to detect ROSC during chest compression or when organised rhythm is restored.

Post-Cardiac Arrest Care

A healthy brain and a functional patient are the primary goals of CPR. Post-effective CPR, significant haemodynamic instability as well as laboratory abnormalities can occur. Every organ system is at risk during this time and patients may develop multi-organ dysfunction. Therefore, optimise cardiopulmonary function to provide effective systemic perfusion, particularly perfusion to the brain. This is best achieved in critical care unit. Therefore, transport the victim to the hospital in the ICU for monitoring and management. Post-admission management measures include the following:

1. Identify the precipitating cause of arrest.
2. Adopt measures to prevent recurrence of arrest.
3. Institute measures to treat neurological complications and measures to improve long-term neurological function including control of body temperature to optimise survival and neurological recovery.
4. Do serial 12-lead ECG and cardiac biomarkers for the detection of acute coronary syndromes.
5. Do serial ABGs. Provide adequate mechanical ventilation to minimise lung injury.
6. Assess acid-base and fluid electrolyte imbalances and correct the same.
7. Monitor HGT/blood glucose levels to prevent hypoglycaemia. If hypoglycaemia is present, correct it. Maintain HGT around 140 to 180 mg/dL.
8. Avoid hypotension. Monitor central venous pressure (CVP). If low, give fluid challenge. If CVP normal and low blood pressure, start vasoactive/inotropic/inodilator drugs as the case may be, dose titrated to optimise BP, cardiac output and systemic perfusion (**Table 2**).
9. Adopt measures to reduce the risk of multi-organ injury by assessing routine biochemical parameters.
10. Assess prognosis for recovery.
11. Provide rehabilitation services to survivors.

Brain injury is a common cause of morbidity and mortality of post-cardiac arrest victims. Studies have shown that brain injury accounts for around 68% deaths of victims in out-of-hospital cardiac arrest and around 23% deaths in in-hospital cardiac arrest. Presentations of post-cardiac arrest brain injury include coma, seizures, myoclonus, various degrees of neurocognitive dysfunction (ranging from memory deficits to persistent vegetative state) and brain death.

Management of seizures involves prompt EEG with interpretation and frequent EEG monitoring or continuous monitoring in comatose patients. Treatment regimens for post-cardiac arrest seizures follow the same pattern as with seizures due to other causes. However, no studies have shown that anticonvulsant therapy improves the outcome after cardiac arrest; with several studies showing that post-cardiac arrest seizures were refractory to traditional anticonvulsant therapy.

Unfortunately, large clinical studies of brain resuscitation (BRCT trials) have shown that administration of barbiturates (thiopental), steroids (glucocorticoids) or calcium channel blockers (lidoflazine, nimodipine), diazepam and magnesium sulphate during the resuscitation have no effect on neurological recovery. One trial using coenzyme Q10 in patients receiving hypothermia failed to show improved survival with good neurological outcomes. Hence, routine use of it in patients with hypothermia is uncertain.

PROGNOSIS

While ACLS can result in the restoration of circulation in over 40% of victims, less than 5% of pre-hospital arrests and about 15% of in-hospital sudden cardiac arrest (SCA) survive to be discharged alive from the hospital. Survival-to-discharge is strongly correlated with recovery of neurological function and prognostication of such recovery is a major concern after CPR. Though this is predominantly a clinical exercise, a few diagnostic tests have been added, with little impact on predicting good outcomes. In general, it is difficult to predict good neurological outcomes after CPR, but poor outcomes can be identified by clinical/investigational features.

A recent meta-analysis of 11 studies involving 1,914 patients documented 5 clinical signs that were found to strongly predict

Table 2: Drugs for Management of Hypotension

Drug	Dose	Remarks
Epinephrine	0.1 mcg/kg/min	Used in severe hypotension
Norepinephrine	0.1 to 0.5 mcg/kg/min	Used in severe hypotension, contraindicated in hypovolaemia (low CVP)
Phenylephrine	0.5 to 2 mcg/kg/min	Used in severe hypotension and low total peripheral resistance
Dopamine	5 to 20 mcg/kg/min	Used in hypotension particularly with symptomatic bradycardia. Avoid in patients with low CVP
Dobutamine	5 to 20 mcg/kg/min	Used in hypotension with cardiogenic shock
Milrinone	50 mcg/kg over 10 minutes as loading dose then infuse at a rate of 0.375 mcg/kg/min	Used for low cardiac output states. Causes less tachycardia than dobutamine

death or poor outcomes, with 4 out of 5 predictors detectable at 24 hours after resuscitation, as given below:

1. Absent corneal reflex at 24 hours.
2. Absent pupillary response at 24 hours.
3. Absent withdrawal response to pain at 24 hours.
4. Absent motor response at 24 hours.
5. Absent motor response at 72 hours.

In another meta-analysis, it was observed that bilateral absence of cortical responses to median nerve somato-sensory evoked potentials was associated with a poor outcome in normothermic patients who were comatose for at least 72 hours.

CONCLUSION

The primary aim of CPR is to rigidly follow the chain of survival, prompt CPR with defibrillation, rapid transport of the victim to hospital emergency department for advanced support. Proper intensive care management with proper post-cardiac arrest care can contribute to restoration of a healthy brain and a functional patient which are the primary goals of CPR. Therefore, the comprehensive treatment of diverse problems after cardiac arrest involves multi-disciplinary aspects of critical care, cardiology, and neurology. It is for this reason it is mandatory to manage such victims in fully equipped critical care units.

7.12 Brain Death and Support of the Brain-Dead Organ Donor

Rajesh Chawla, Guneet Singh

INTRODUCTION

Recent advances in resuscitative and life support techniques have led to the definition of death and its concept. The progress in organ transplantation and the increasing number of patients who have a living body but non-functioning brain, which is a consequence of discoveries in resuscitative and life support techniques, has led to study brain death more precisely. Such refinements in critical care medicine mean that neurologists, neurosurgeons, and anaesthesiologists must be able to make an appropriate diagnosis of death. The cultural and religious diversity may lead to great differences in attitudes toward brain death and there is no global consensus in diagnostic criteria. The concept of brain death as defining the death of an individual is widely accepted, and many countries have published recommendations or legal requirements for the diagnosis of brain death as a necessary pre-requisite for organ donation.

DEFINING BRAIN DEATH

Brain death has been traditionally defined as irreversible cessation of all brain functions including brainstem. The advent of effective artificial cardiopulmonary support for severely brain injured persons, however, created some confusion about the determination of death. Loss of heart and lung function was an easily observable and sufficient basis for the diagnosis of death. However, with availability of measures to support circulation and respiration by a mechanical respirator and other medical interventions, it is important to diagnose individuals who have lost all brain functions, i.e. have a dead brain in an otherwise living body. This diagnosis of determining neurological death is also important in view of the developments in transplant surgery raising ethical and legal attention on the desirability of agreeing on the medical criteria of brain death.

CRITERIA FOR CLINICAL DETERMINATION OF BRAIN DEATH

Determination of brain death clinically should include the following:

1. Eliminate error in classifying a living individual as dead.
2. Allow as few errors as possible in classifying a dead body as alive.
3. Allow a determination to be made without unreasonable delay.
4. Be acceptable to a variety of clinical situations.
5. Be explicit and accessible to verification.

Pre-Requisites for Clinical Determination

1. Clinical or neuroimaging evidence of an acute catastrophic cerebral event consistent with clinical diagnosis of cerebral death.
2. Exclusion of conditions that may confound clinical assessment of brain death, e.g. acute metabolic or endocrine derangements, hypothermia and shock.
3. Confirmation of absence of drug intoxication or poisoning.
4. Core body temperature ≥32°C (90°F)

Testing of brainstem function can proceed only after these pre-requisites have been fulfilled.

Cardinal findings in brain death which need to be established are: coma or unresponsiveness, absence of brainstem reflexes, and apnoea. **Figure 1** gives the algorithm for evaluation of coma and brainstem function.

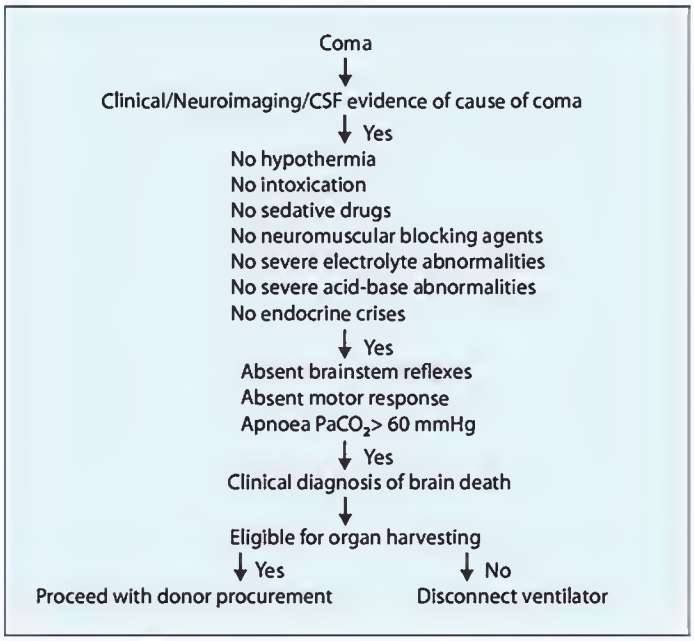

Figure 1: Testing algorithm for evaluation of coma and brainstem function.

CSF = Cerebrospinal fluid; PCO_2 = Partial pressure of carbon dioxide

Coma or Unresponsiveness

Motor responses of the limbs

Testing: Motor responses of the limbs to painful stimuli should be absent after supraorbital pressure and nail-bed pressure stimulus.

Pitfalls: Motor responses ("Lazarus sign") may occur spontaneously during apnoea testing, often during hypoxic or hypotensive episodes, and are of spinal origin. Neuromuscular blocking agents can produce prolonged weakness. If neuromuscular blocking agents have recently been administered, examination with a bedside peripheral nerve stimulator is needed. A train of – four stimuli should result in four thumb twitches.

Absence of Brainstem Reflexes

Pupils

Testing: The response to bright light should be absent in both eyes.

Round, oval or irregularly shaped pupils are compatible with brain death.

Most pupils in brain death are in middle position (4 mm to 6 mm), but the size of the pupils may vary from 4 mm to 9 mm. Dilated pupils are compatible with brain death.

Pitfalls: Many drugs can influence pupil size, but light response remains intact. In conventional doses, atropine given intravenously has no marked influence on pupillary response. Because nicotine receptors are absent in the iris, neuromuscular blocking drugs do not noticeably influence pupil size. Topical ocular instillation of drugs and trauma to the cornea or bulbous oculi may cause abnormalities in pupil size and can produce non-reactive pupils. Pre-existing anatomic abnormalities of the iris or effects of previous surgeries should be excluded.

Ocular Movements

Testing

Ocular movements are absent after head - turning and caloric testing with ice water (testing is done only when no fracture or instability of the cervical spine is apparent, and in patients with head injury, the cervical spine must be imaged to exclude potential fractures or instability or both) the oculocephalic reflex, elicited by fast and vigorous turning of the head from middle position to 90° on both sides, normally results in eye deviation to the opposite side of the head-turning. Vertical eye movements, should be tested with brisk neck flexion. Eyelid opening and vertical and horizontal eye movements must be absent in brain death.

Caloric testing

It should be done with the head elevated to 30° during irrigation of the tympanum on each side with 50 mL of ice water. Tympanum irrigation can be best accomplished by inserting a small suction catheter into the external auditory canal and connecting it to a 50 mL syringe filled with ice water. Tonic deviation of the eyes directed to the cold caloric stimulus is absent. The investigator should allow up to one minute after injection and the time between stimulation each side should be at least five minutes.

Pitfalls

Drugs that can diminish or completely abolish the caloric response are sedatives, aminoglycosides, tricyclic antidepressants, anticholinergics, antiepileptic drugs, and chemotherapeutic agents. After closed head injury or facial trauma, lid oedema and chemosis of the conjunctiva may restrict movement of the globes. Clotted blood or cerumen may diminish the caloric response, and repeat testing is required after direct inspection of the tympanum. Basal fracture of the petrous bone abolishes the caloric response only unilaterally and may be identified by an ecchymotic mastoid process.

Facial Sensation and Facial Motor Response

Testing

Corneal reflexes should be tested with a cotton swab. Corneal reflex and jaw reflex should be absent. Grimacing to pain can be tested by applying deep pressure with a blunt object on the nail beds, pressure on the supraorbital ridge, or deep pressure on both condyles at the level of the temporomandibular joint.

Pitfall

Severe facial trauma may limit interpretation of all brainstem reflexes.

Pharyngeal and Tracheal Reflexes

Testing

The gag response, tested by stimulation of the posterior pharynx with a tongue blade, should be absent. Lack of cough response to bronchial suctioning should be demonstrated.

Pitfall

In orally intubated patients, the gag response may be difficult to interpret.

Apnoea

Apnoea test (guidelines for the test)

Pre-requisites: Important changes in vital signs (e.g. marked hypotension, severe cardiac arrhythmias) during the apnoea test may be related to lack of adequate precautions. Therefore, the following pre-requisites are suggested:

1. Core temperature greater than or equal to 36.5°C (4.5°C higher than the required 32 °C for clinical diagnosis of brain death).
2. Systolic blood pressure greater than or equal to 90 mmHg.
3. Euvolaemia (option: preferably positive fluid balance in the previous 6 hours).
4. Eucapnia (option: arterial $PCO_2 \geq 40$ mmHg).
5. Normoxaemia (option: arterial $PO_2 \geq 200$ mmHg). A pulse oximeter is connected to the patient.

Testing (Figure 2)

1. Ventilate with FiO_2 of 100% for 10 minutes.
2. Disconnect the ventilator.
3. Deliver 100% oxygen at a rate of 6 L/min by placing a cannula at the level of the carina.
4. Look closely for respiratory movements. Respiration is defined as abdominal or chest excursions that produce

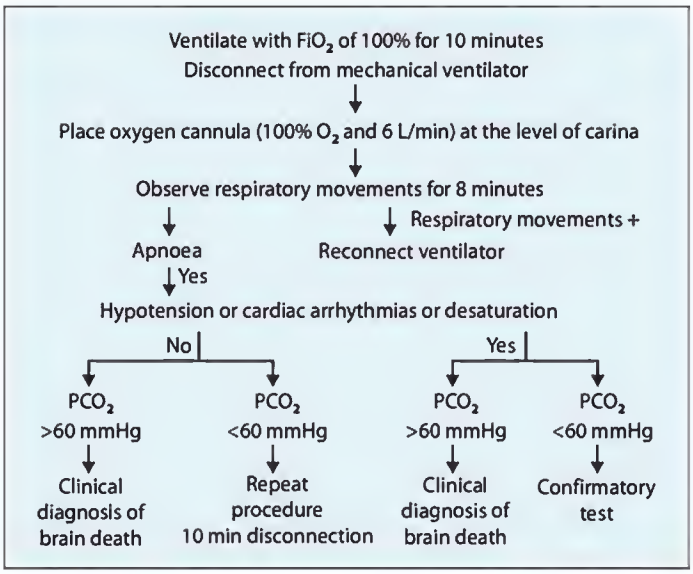

Figure 2: Procedure for the apnoea test in brain death.

FiO_2 = Fraction of inspired oxygen; PCO_2 = Partial pressure of carbon dioxide

adequate tidal volumes. If present, respiration can be expected early in the apnoea test. When the result is in doubt, a spirometry can be connected to the patient to confirm that tidal volumes are absent.

5. Measure arterial PO_2, PCO_2 and pH after approximately 8 minutes and reconnect the ventilator.
6. If respiratory movements are absent and arterial $PCO_2 \geq 60$ mmHg (option: 20 mmHg increase in PCO_2 over a baseline normal PCO_2), the apnoea test result is positive (i.e. it supports the clinical diagnosis or brain death).
7. If respiratory movements are observed, the apnoea test result in negative (i.e. it does not support the clinical diagnosis of brain death).
8. If during apnoea testing, systolic blood pressure becomes <90 mmHg, the pulse oximeter indicates marked desaturation, and cardiac arrhythmias occur, immediately draw a sample, connect the ventilator, and analyse arterial blood gas. The apnoea test result is positive if arterial PCO_2 is ≥60 mmHg or PCO_2 increase is equal ≥20 mmHg above baseline normal PCO_2. If arterial PCO_2 is < 60 mmHg or PCO_2 increase is <20 mmHg over baseline normal PCO_2, the result is indeterminate.
9. If no respiratory movements are observed, PCO_2 is <60 mmHg and no significant cardiac arrhythmia or hypotension is observed, the test may be repeated with 10 minutes of apnoea.

DURATION OF OBSERVATION

Brain death is a clinical diagnosis and irreversibility should be documented by an extended period of observation. The patient must undergo two brain death determinations at least 6 hours apart. However, this internal decision is arbitrary. The two examinations must be performed by different licensed physicians.

CONFIRMATORY LABORATORY TESTS

A repeat clinical evaluation 6 hours later is advised (option), but a firm recommendation cannot be given and the interval is arbitrary. A confirmatory test is not mandatory in most situations. All clinical tests are needed to declare brain death and are likely equally essential. A confirmatory test is needed for patients in whom specific components of clinical testing cannot be reliably evaluated. Clinical experience with confirmatory tests other than EEG, transcranial Doppler ultrasonography, and conventional angiography is limited. Many tests need costly equipment and well-trained technicians.

Conventional Angiography

Technique

A selective four-vessel angiogram is done in the radiology suite. Iodinated contrast medium is injected under high pressure in both the anterior and the posterior circulations.

Result

Intra-cerebral filling is absent at the level of carotid bifurcation or circle of willis. The external carotid circulation is patent, and at times delayed filling of the superior longitudinal sinus is seen.

Electroencephalography (EEG)

Technique

Usually a 16- or 18-channel instrument is used with guidelines developed by the American Electroencephalo-graphic society for recording brain death.

Result

No electrical activity occurs above 2 μV at a sensitivity of 2 μV/mm with filter setting at 0.1 or 0.3 second and 70 Hz. Recording should continue for at least 30 minutes.

EEG

Nevertheless in one consecutive series of patients fulfilling the clinical diagnosis of brain death, 20% of 56 patients had residual EEG activity that lasted up to 168 hours.

Disadvantage

Considerable artifacts in the intensive care unit can limit interpretation.

Isotope Angiography

Technique: Rapid intravenous injection of serum albumin labeled with technetium 99^m is followed by bedside imaging with portable gamma camera.

Results: Intracranial radioisotope activity is absent. Filling of saggittal and transverse sinuses may occur in delayed images from connections between the extracranial circulation and venous system.

Technetium 99^m Hexamethylpropylenamineoxime (99^m TcHMPAO)

Technique

The procedure can be performed at the bedside and takes approximately 15 minutes. The isotope should be injected within 30 minutes of reconstitution. A portable gamma camera produces planar views within 5 to 10 minutes. Correct intravenous injection can be checked by taking additional chest and abdominal images.

Result

No uptake occurs in brain parenchyma.

Disadvantage

The tracer should be injected immediately. Because the costs are currently high and technique is not widely available, experience is limited.

Transcranial Doppler Ultrasonography

Technique

A portable 2 MHz pulsed Doppler instrument can be used at bedside. Intra-cranial arteries should be insonated bilaterally (e.g. main carotid artery through the temporal bone above zygomatic arch and vertebral or basilar arteries through the suboccipital transcranial window). Alternatively a combination of one ophthalmic artery through transorbital window and the MCA can be tried.

Results

Transcranial Doppler signals that have been reported in brain death are as follows:

1. Absent diastolic or reverbating flow that indicates flow only through systole or retrograde diastolic flow. This pattern is caused by contractive forces of the arteries.
2. Small systolic peaks in early systole indicate very high resistance. This pattern is associated with greatly increased intracranial pressure. Lack of transcranial Doppler signals cannot be interpreted as confirmatory of brain death, because 10% of patients may not have temporal insonation

windows. An exception possibly can be made in patients who had transcranial Doppler signals during admission that disappeared at the time of brain death.

Disadvantage

Transcranial Doppler velocities can be affected by marked changes in PCO_2, hematocrit and cardiac output. Transcranial Doppler ultrasonography requires practice and skill.

Somatosensory Evoked Potentials

Technique

A portable instrument can be used at bedside. Median nerve stimulation is performed on both sides.

Result

N20-P22 response is bilaterally absent.

Miscellaneous Tests

Many of these tests have been done in small series of patients only and are not widely adopted as confirmatory tests.

Contrast computed tomograph with bolus of meglumine diatrizoate, 1 mL/kg of body weight, does not visualise intra-cranial vessels. A good correlation with cerebral angiography has been demonstrated in a few anecdotal reports.

Many other confirmatory tests are variants or modifications. Experience is limited, as these tests produce similar results in patients with neurological catastrophes who do not fulfil the clinical criteria for brain death.

COMMUNICATION WITH THE FAMILY

Critical care nurses and resident doctors should become familiar with the concept of brain death and its medical and legal criteria, because they may need to explain brain death to family members who are confused and in crisis. Sometimes the use of certain terminology appears to conflict with reality when the terminology is applied to cases in which patients are pronounced dead on the basis of neurological criteria. In order to avoid confusion, it is more helpful to tell family that their loved one is 'dead' because use of this word can help the family understand that neurological death has occurred. A clear definition of brain death must be given and reinforced.

SUPPORT OF THE POTENTIAL ORGAN DONOR

Once established, a brain dead case who is a potential donor is to be handled very carefully so as to prevent any organ damage before procuring them. After brain death since central regulation to circulation is lost, invasive haemodynamic monitoring is mandatory to avoid fluctuations and help guide fluid and vasopressor therapy.

Circulation

Inotropes and vasopressors both can be used to maintain haemodynamic parameters. Vasodilator infusion should be avoided in hypertension; rather short-acting beta blockers can be used. In patients with decreased left ventricle function and acute respiratory distress syndrome, pulmonary artery catheter is advocated. Targets to be maintained are: (i) systolic blood pressue >90 mmHg; mean arterial pressure >65 mmHg; (iii) central venous pressure 8 cm to 12 cm H_2O; pulmonary capillary wedge pressure <12 mmHg.

Respiratory Support

Ventilatory support should continue to maintain a normal blood gas picture. Intravenous steroids should be given in case lung transplant is planned. Lung protective strategy in ventilation to maintain P/F ratio is advisable. A minimum SpO_2 of 95% should be maintained.

Endocrinal Support

Injury to the hypothalamic-pituitary axis impairs the release of arginine vasopressin. The sequelae of this damage leads to occurrence of *Diabetes Insipidus* as most common abnormality.

The evaluation of the organ donor should be carried out in a step-wise approach as depicted in **Figure 3**.

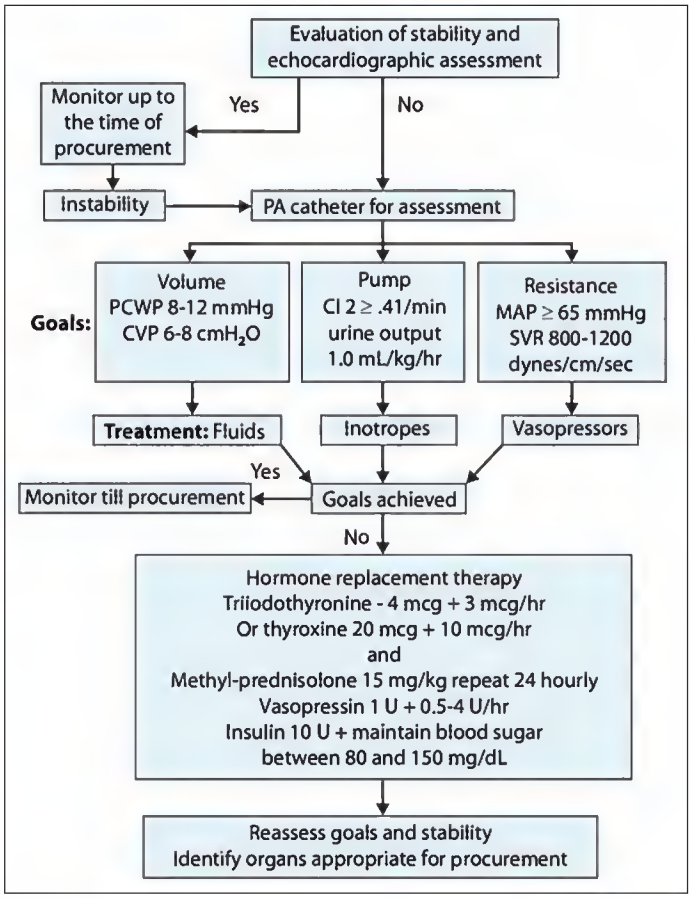

Figure 3: Stepwise approach for evaluation of organ donor patient.

PA = Pulmonary artery; PCWP = Pulmonary capillary wedge pressure; CVP = Central venous pressure; CI = Cardiac index; MAP = Mean arterial pressure; SVR = Systemic vascular resistance

PHYSIOLOGY OF THE BONE

Bone is a special form of connective tissue with a collagen framework impregnated mineralized matrix in the form of hydroxyapatite crystals and also small, but highly active cellular fraction. Bone is involved in overall Ca^{2+} and PO_4^{3-} homeostasis. It also protects vital organs, permits locomotion with its rigidity, involved in acid-base balance, and provides the environment for hematopoiesis within the marrow spaces. Bone is of two types: compact or cortical bone, and trabecular or spongy bones. Cortical bone is the dense bone that is found in the shafts of long bones, whereas trabecular bone is composed of a honeycomb like network interspersed in the bone marrow compartment. The adult human skeleton is composed of 80% cortical bone and 20% trabecular bone. Bone is composed of 50% to 70% mineral, 20% to 40% organic matrix, 5% to 10% water and less than 3% lipids. The mineral content of bone is mostly hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$. Approximately 85% to 90% of bone protein is composed of collagenous proteins and the noncollagenous proteins is composed of rest 10% to 15%.

There are three cell types in bone: (1) bone forming osteoblasts, (2) osteocytes, and (3) bone resorbing osteoclasts. Osteoblasts are derived from mesenchymal cells, whereas osteoclasts are derived from mononuclear precursor cells of the monocyte-macrophage lineage. Bone undergoes modelling and remodelling during life. Longitudinal and radial growth occurs during childhood and adolescence. Modelling is the process by which bones change their overall shape in response to physiologic influences or mechanical forces, leading to gradual adjustment of the skeleton to the stress that it has to face. During bone modeling, bone formation and resorption are not tightly coupled. Bone remodelling is the process by which bone is renewed to maintain bone strength and mineral homeostasis. The bone remodelling units (BRUs) or bone multicellular units (BMUs) are composed of a tightly coupled group of osteoclasts and osteoblasts that sequentially carry out continuous removal of discrete packets of old bone and replacement of these packets with newly synthesised proteinaceous matrix and subsequent mineralisation of the matrix to form new bone. The remodelling cycle can be divided into four steps: (1) activation, (2) resorption, (3) reversal, and (4) formation.

The process of bone remodelling is highly regulated by mechanical forces, hormones and cytokines. One of the most important cytokine in osteoclastogenesis is receptor activator of nuclear factor-κB ligand (RANKL), which is a member of the tumor necrosis factor (TNF) family and is expressed in the bone-lining cells or osteoblast precursors that support osteoclast recruitment. Interaction of RANKL with its receptor (RANK) on osteoclast progenitors and osteoclasts then stimulates their recruitment and activation, and delays their degradation. Measurement of product of osteoblast and osteoclast activity can be helpful in diagnosis and management of metabolic bone diseases. These biochemical markers of bone remodelling are summarised in **Table 1**.

Table 1: Biochemical Markers of Bone Formation and Resorption

Bone formation markers	Serum bone specific alkaline phosphatase Serum osteocalcin Serum propeptide of type 1 procollagen
Bone resorption markers	Urine and serum cross linked N-telopeptides Urine and serum cross linked C-telopeptides Urine deoxypyridinoline

CALCIUM PHYSIOLOGY

Calcium is involved in important cellular functions like cell division, cell adhesion, integrity of plasma membrane, muscle contraction, neuronal excitability, secretion of proteins and coagulation cascade. A normal adult body contains about 1 kg of calcium, of which approximately 99% is present in the skeleton as hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ and 1% in soft tissues and extracellular fluids. A normal calcium balance is summarised in **Figure 1**.

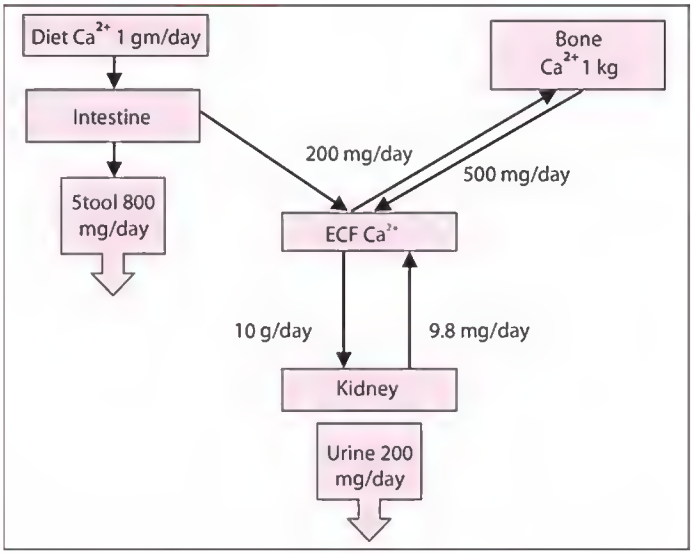

Figure 1: Normal calcium balance.

In spite of large movements of calcium between body compartments, serum calcium is maintained constant at about 10 mg/dl (2.5 mgm). The essential fraction is the biologically active free, ionized one which equals 50% of the total serum calcium (1.3 mgm). Forty percent of total serum calcium is protein-bound, principally to albumin, and the remaining 10% of calcium is complexed with various anions such as citrate, sulfate, bicarbonate, lactate and phosphate. A decrease in serum albumin of 1 g/dl results in a decrease in total serum calcium of 0.8 mg/dl without affecting the ionized fraction significantly.

As calcium is bound to carboxyl groups on albumin, pH changes affect ionised calcium. Acidosis decreases binding and increases ionized calcium, whereas alkalosis increases binding and decreases ionised calcium. The constancy of extracellular fluid concentration of calcium is maintained by hormonal regula-tion of the absorption of calcium from the gastrointestinal tract, the mobilization of skeletal calcium and the reabsorption of filtered calcium in kidney tubules. Vitamin D, parathyroid hormone (PTH) and calcitonin are the regulators of these processes.

Intestinal Calcium Absorption

Intestinal calcium absorption occurs through both an active transcellular pathway and a passive paracellular pathway. The paracellular pathway is dependent on calcium moving through tight junctions in the intestinal epithelium, which is a passive, nonsaturable process and is favored during states of high calcium intake. However, transcellular pathway, an active transport, is particularly important at low and normal calcium intake. It is summarised in **Figure 2**.

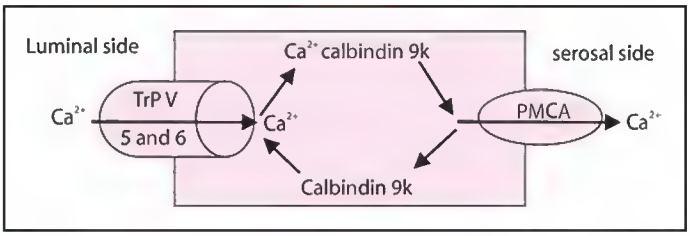

Figure 2: Intestinal absorption of Ca^{2+} via the transcellular pathway. Ca^{2+} enters through Ca^{2+} channel TrPV5 or TrPV6, in the luminal membrane of the enterocyte. Once absorbed, the transcellular movement of calcium to the basolateral membrane is dependent on binding to an intracellular protein known as calbindin-D_{9k}. The egress of calcium from the intestinal epithelium occurs through the actions of the plasma membrane calcium-dependent ATPase (PMCA1b). This transcellular movement of calcium is closely regulated by $1,25(OH)_2D_3$, which regulates the gene transcription of TRPV6, calbindin and PMCA1b.

Renal Handling of Calcium

Approximately 98% to 99% of the filtered Ca^{2+} is reabsorbed in kidney. About 60% of the reabsorption occurs in the proximal tubules via a passive, paracellular route, which follows sodium reabsorption. Rest of active calcium reabsorption takes place in the thick ascending limb of the loop of Henle and in the distal convoluted tubule and the connecting tubule. About 20% to 25% of the filtered calcium is reabsorbed in the loop of Henle through both transcellular and paracellular routes. The primary site for PTH regulation of renal calcium reabsorption is the distal nephron, which normally reabsorbs nearly all of the remaining 10% of filtered calcium by a unique transcellular active transport mechanism.

PHOSPHORUS PHYSIOLOGY

Phosphate, comprises 1% approximately of total body weight, is widely distributed in the soft tissues of the body. It is both in inorganic form and as a component of organic molecules including nucleic acids, membrane phospholipids and other phosphoproteins. However, 85% of body phosphate is stored in the bone matrix. Calcium and phosphorus are regulated by the controlled interactions of the intestine, renal tubules and bone. However, there are several important differences between phosphorus and calcium balance. Dietary phosphorus is present in abundance in most foods. This is in contrast to calcium, which is restricted to a few dietary items. Also, dietary phosphorus is absorbed almost twice as efficiently as dietary calcium. Thus, phosphorus absorption, unlike calcium, is rarely a nutritional problem. The normal range for serum phosphate level in adults is 2.5 to 4.5 mgm/dL. In children, serum phosphate levels are higher and decrease with age. Unlike plasma calcium, phosphorus is not protein bound and is filtered almost completely at the glomerulus.

Intestinal Phosphate Absorption

The average adult ingests approximately 1,000 mg/day of phosphorus, with 80% being absorbed by the intestine and the remaining 20% being excreted directly into the stool. Intestinal absorption of phosphorus can be either through paracellular or transcellular pathways. Paracellular absorption is largely dependent on the luminal concentration of phosphorus and does not appear to be saturable. Transcellular absorption occurs through the sodium-phosphate type IIb cotransporters, which have been shown to be upregulated by increasing $1,25(OH)_2D$.

Renal Handling of Phosphate

Approximately 70% of filtered phosphate is reabsorbed within the proximal tubule, which involves uptake across the brush border membrane, translocation across the cell and efflux at the basolateral membrane. The overall rate-limiting step in the reabsorptive process is phosphate uptake at the apical membrane; where the sodium-phosphate cotransporters (NPT) IIa and IIc actively transport phosphate from the lumens of nephrons into proximal tubular cells. Parathyroid hormone decreases the expression of the NPT IIa and IIc and decreases phosphate reabsorption. There are several other recently identified factors, termed phosphotonins like fibroblast growth factor 23 (FGF23), which induce renal phosphorus wasting by decreasing the expression of the NPT IIa and IIc. Human disorders associated with increased circulating concentrations of FGF23 are characterised by hypophosphataemia, and disorders associated with reduced FGF23 bioactivity, like tumoral calcinosis, are characterised by hyperphosphataemia.

PARATHYROID HORMONE

Structure and Biosynthesis

The parathyroid glands develop from the endodermal lining of the third and fourth branchial pouches. There are usually four parathyroid glands in man, two superior and two inferior each weighing about 40 mg, and located behind the thyroid gland. The predominant cell type in the parathyroid gland is the chief (also called principal) cell, which are primary endocrine cell. The primary function of parathyroid hormone (PTH) is to maintain extracellular calcium concentration in a narrow normal range. The hormone acts directly on bone and kidney and indirectly on intestine, by increasing the synthesis of $1,25(OH)_2D$ to increase serum calcium concentration. Rapid feedback effect on PTH secretion and production along with biological actions in multiple target tissues makes PTH as most important regulator for minute-to-minute control of extracellular calcium. In contrast, vitamin D is of importance in long-term, day-to-day, and week-to-week regulation of calcium balance.

PTH is synthesised as a part of the larger precursor protein containing a 25-amino acid hydrophobic residue-rich signal sequence and a 6-amino acid prosequence preceding the

amino terminus of PTH. These portions of the precursor are sequentially removed within the cell and mature 84-amino acid PTH is secreted from storage granules. A portion of the PTH secreted from parathyroid glands consists of carboxy-terminal PTH fragments. The carboxy-terminal fragments of PTH do not activate the PTH/PTHrP (parathyroid hormone-related protein) receptor and might even block bone resorption. Secreted intact PTH (1-84) is metabolised by liver and kidney and disappears from the circulation with a half-life of 2 minutes. However, rate of clearance of carboxy-terminal fragments occurs principally by glomerular filtration and much slower, with a half life of 20-40 minutes and these fragments accumulate in patients with renal failure. Older assays for PTH detected both intact 1-84 PTH and also carboxy-terminal fragments and therefore detected unreliably high levels of PTH, especially in patients with renal failure. These problems largely circumvented by use of current assays which utilise two antibodies recognising epitopes from both ends of the molecule, reliably measuring only intact PTH.

Biological Effects

PTH/PTHrP-receptor (PTHR1) binds both PTH and parathyroid hormone-related protein (PTHrP) and is primarily coupled to G_s, and via this heterotrimeric G protein activates adenylyl cyclase. PTHR1 is expressed on osteoblasts in bone and proximal and distal tubules of the kidney. A second PTH receptor, which can be activated by PTH but not by PTHrP, called the PTH2 receptor (PTH2R), is expressed in multiple tissues including brain, vascular endothelium and smooth muscle, endocrine cells of the gastrointestinal tract, and sperm. The functional role of the PTH2R is not clearly known.

PTH has multiple actions on bone, some direct and some indirect. PTHR1 is expressed on osteoblasts, but not on osteoclasts. Therefore, PTH stimulates osteoblast activity directly, whereas osteoclasts are stimulated indirectly through paracrine factors secreted by osteoblasts. PTH-mediated bone calcium release can occur within minutes. The chronic effects of PTH are to increase number of osteoblasts and osteoclasts, and to increase in bone remodelling. As PTH can increase both bone formation and bone resorption, net effect on bone mass varies according to whether PTH is administered continuously or intermittently, and also on type of bone. When PTH concentrations are persistently elevated like in primary hyperparathyroidism, significant bone loss occurs mainly in cortical bone with subperiosteal resorption, formation of bone cysts and spontaneous fractures. However, intermittent administration of low doses of PTH causes net increase in bone formation and increase in trabecular bone mass, with little effect on cortical bone mass and this concept has been utilised as use of PTH as anabolic therapy in patient with osteoporosis.

PTH has two major effects on the kidney: to increase calcium reabsorption in the distal nephron and to decrease proximal tubular reabsorption of phosphate. Calcium excretion depends both on the amount of calcium which reaches the distal tubule and on the concentration of circulating PTH. In hypercalcaemia, the filtered load of calcium increases so that more calcium is delivered to the distal tubule. In hyperparathyroidism, PTH increases fractional reabsorption of calcium, but because of the large calcium load delivered, hypercalciuria results. PTH decreases proximal tubular reabsorption of phosphate, so that increased urinary excretion of phosphate occurs. Sustained elevations in PTH thus result in hypophosphataemia in addition to hypercalcaemia. Both PTH and hypophosphataemia stimulate l α-hydroxylase activity to increase formation of $l,25(OH)_2D$.

Regulation of Synthesis and Secretion

The parathyroid gland has multiple methods for adaptation to change in extracellular calcium. Most rapid is secretion of preformed hormone, which occurs within minutes. Second, intracellular degradation of newly synthesised PTH provides an important regulatory mechanism by increasing the fraction of biologically inactive carboxy-terminal fragments of PTH. Third, PTH production is also regulated at the level of gene transcription and lastly, prolonged hypocalcaemia also elicits an increase in both the size and number of parathyroid cells. Secretion of PTH is primarily regulated by the concentration of ionized calcium in serum. Critically important to the process of calcium homeostasis is the G-protein-coupled calcium sensing receptor (CaSR), which is located on the surface of parathyroid chief cells. Increased serum ionised calcium leads to activation of CaSR causing activation of downstream signaling pathway leading to decrease in PTH secretion. Heterozygous and homozygous inactivating mutations in CaSR cause familial hypocalciuric hypercalcaemia (FHH) and neonatal severe hyperparathyroidism respectively. In these patients, CaSR fails to inhibit PTH secretion in hypercalcaemia because of defective calcium sensing in parathyroid and also inappropriate hypocalciuria occurs in presence of hypercalcaemia because of defective calcium sensing at renal level. Conversely, activating mutations in CaSR cause familial hypoparathyroidism with hypercalciuria. $1,25(OH)_2D$ has no direct effect on PTH secretion, but it dramatically suppresses PTH gene transcription. In hypomagnesaemia, in addition to impaired responsiveness of target tissues to PTH action, PTH secretion is decreased.

Parathyroid Hormone-Related Protein

Parathyroid hormone-related protein (PTHrP) is peptide with PTH like activity. PTHrP and PTH have marked homology at their amino terminal ends and they both bind to the PTH1R, yet their physiologic effects are very different. PTHrP is primarily an autocrine or paracrine factor, acting close to where it is produced. Other than important function during breast development and systemic calcium metabolism during lactation, it is also involved in Ca^{2+} transport in the placenta. Normally it appears to have little influence on calcium-phosphate homeostasis in an adult. However, secretion of PTHrP by a wide variety of tumors contributes to the humoral hypercalcaemia of malignancy by mimicking the systemic action of PTH.

VITAMIN D

Structure and Biosynthesis

Although initially discovered as a fat-soluble vitamin, vitamin D is a classical steroid hormone having both dietary and endogenous precursors. Vitamin D_3, cholecalciferol, is formed by solar ultraviolet B radiation (wavelength, 290-315 nm) of precursor 7-dehydrocholesterol in skin, which is present in large amounts in keratinocytes of the basal or spinous epidermal layers (**Figure 3**). Adequate exposure to UV light is necessary, with more exposure being required for darker skinned races. Ergocalciferol, vitamin D_2 is the compound formed in plants from precursor ergosterol and differs from vitamin D_3 by the

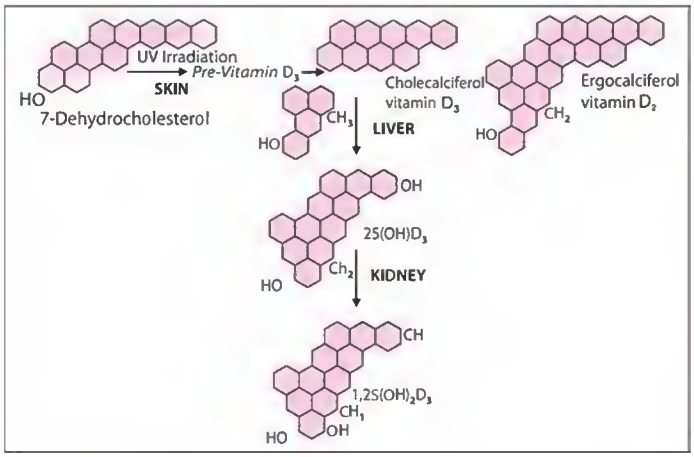

Figure 3: Biosynthesis of $1,25(OH)_2D$.

presence of a double bond between carbon 22 and 23 and a methyl group at carbon 24. Best dietary sources of vitamin D are fatty fish and its liver oils, although small amount is present in egg yolk and dairy products. Both vitamin D_2 and D_3 are prohormones and require subsequent modification to yield active hormone. As hormones derived from either vitamin D_2 or D_3 are equally active in man, the generic term vitamin D is generally used. In the liver, vitamin D is hydroxylated at C-25 by cytochrome P450 vitamin D 25-hydroxylases, resulting in the formation of 25-hydroxyvitamin D [25(OH)D]. In the proximal renal tubule, 25(OH)D is further hydroxylated, resulting in the hormonally active 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), which is responsible for most of the biologic actions of vitamin D. In addition to $1,25(OH)_2D$, the kidney can also produce 24,25-dihydroxyvitamin D3 ($24,25(OH)_2D$), a relatively inactive metabolite. Human vitamin D binding protein (DBP) is a 52 kd α globulin synthesised in the liver. Approximately 88% 25-hydroxyvitamin D (25(OH)D) circulates bound to DBP, 0.03% is free and the rest circulates bound to albumin. In contrast, 85% of the circulating $1,25(OH)_2D_3$ binds to the vitamin D binding protein, 0.4% is free and the rest binds to albumin.

The most plentiful and stable metabolite of vitamin D is 25(OH)D and 25(OH)D level in the serum is the best indicator of vitamin D status in an individual. A 25(OH)D level of 30 ng/ml (75 nmol/L) or greater is considered indicating sufficient vitamin D for an individual. Vitamin D deficiency is defined as a 25(OH)D level less than 20 ng/ml (50 nmol/L), while a level between 20 ng/ml and 29 ng/ml is considered to indicate a relative insufficiency. Reports from across the world in last decade indicate that vitamin D deficiency and insufficiency is widespread and is re-emerging as a major health problem globally.

Regulation of $1,25(OH)_2D$ Formation

The renal 1α(OH)ase represents a key target of vitamin D regulation. Low dietary calcium and phosphate result in enhanced activity of 1α(OH)ase. Elevated PTH resulting from hypocalcemia is a primary signal stimulating the transcription of 1α(OH)ase. The 1α(OH)ase gene is negatively regulated by $1,25(OH)_2D$ and fibroblast growth factor 23 (FGF23), a phosphaturic factor.

Biological Effects

The active metabolite $1,25(OH)_2D$ enters the cell and binds to the vitamin D receptor. This complex forms a heterodimer with the retinoid receptor and binds to a vitamin D responsive element on responsive genes and followed by their transcription and translation. Recently, it has been demonstrated that other than these genomic actions, vitamin D may have certain nongenomic actions, and may work through a plasma membrane receptor and second messengers such as MAP kinase or cAMP. The intestine is the principal target for $1,25(OH)_2D$, where it enhances calcium and phosphate absorption as discussed above. Bone is the second major target for vitamin D. By increasing intestinal absorption of calcium and phosphate, vitamin D provides sufficient calcium and phosphate to initiate the crystallisation process at bone surfaces. $1,25(OH)_2D$ also directly affects bone cells to facilitate mineralisation even without measurable changes in the plasma concentrations of calcium and phosphate. Vitamin D deficiency is characterised by defective mineralisation of bone osteoid. Vitamin D receptor (VDR) are expressed on parathyroid cells and $1,25(OH)_2D$ inhibits the transcriptional activity of PTH gene and prevents proliferation of parathyroid gland. In recent years, there has been great interest in the role of vitamin D in non-classical actions like decreasing the risk of many chronic illnesses, including autoimmune diseases like multiple sclerosis and Type 1 diabetes, infectious diseases, cardiovascular disease and even common malignancies. Brain, prostate, breast and colon tissues, among others, as well as immune cells, have a vitamin D receptor. $1,25(OH)_2D$ has been found to have potent immunomodulator action, inhibits renin synthesis, increases insulin production and increases myocardial contractility. **Table 2** summarises the major biological actions of PTH and $1,25(OH)_2D$, in relation to calcium and phosphate homeostasis.

Table 2: Actions of PTH and $1,25(OH)_2D$ on Calcium/Phosphate Homeostasis

Hormone	Small intestine	Bone	Kidney	Parathyroid gland
PTH	No direct action	Promotes osteoblastic growth and survival	Stimulates 1α hydroxylase Stimulates Ca^{2+} reabsorption	No direct action
		Chronic high levels promotes bone resorption	Inhibits phosphate reabsorption	
$1,25(OH)_2D$	Increases Ca^{2+} and phosphate absorption	Sensitises osteoblasts to PTH	Increases phosphate reabsorption	Directly inhibits PTH gene expression
		Regulates osteoid production and calcification	Minimal effect on Ca^{2+} reabsorption	

CALCITONIN

Structure and Biosynthesis

Calcitonin is a 32-amino acid polypeptide, whose two major biological effects are to lower serum calcium and phosphate. It is synthesised by the parafollicular cells of the thyroid gland, also known as the clear or C cells, which originate from the neural crest. It has a circulatory half-life of about 10 minutes. Interestingly,

salmon calcitonin is 10 to 100 times more potent than mammalian hormone and is the one that is used therapeutically.

Regulation of Synthesis and Secretion

Synthesis and secretion of calcitonin is controlled by the concentration of ionised serum calcium. The stimulus for calcitonin synthesis is thus opposite to that for PTH secretion. Thus, its secretion is increased, when ionised serum calcium rises and vice versa. The calcium-sensing receptor cloned initially from parathyroid cells is also expressed in C cells and it contributes to the regulation of calcitonin secretion.

Biological Effects

Calcitonin reduces bone resorption by inhibiting osteoclast function, through its receptors on these cells. Thus it has a direct action on osteoclasts in contrast to PTH, whose effects are mediated through osteoblasts. In spite of the reproducible effects of calcitonin on bone and serum mineral content, the hormone does not appear to be a major physiological regulator. After removal of the thyroid-containing C cells and documented calcitonin deficiency or after development of medullary thyroid carcinoma, a neoplasm of C cell origin which results in markedly elevated calcitonin production, serum calcium and phosphate concentrations remain normal. In addition, it has a central analgesic effect, directly in cells of hypothalamus and related structures. Calcitonin is used in treatment of bone disorders associated with accelerated rate of bone turnover like Paget's disease and osteoporosis, and in the treatment of hypercalcaemia of malignancy. Calcitonin can serve as a tumour marker in medullary carcinoma of the thyroid as well as other tumours, including insulinomas, VIPomas and lung cancers, which can secrete calcitonin ectopically. In addition, high molecular weight forms of calcitonin may be elevated in acute pancreatitis, burns and infections.

8.2 Investigations and Diagnosis of Bone Disorders

Sukumar Mukherjee

Bone is a highly dynamic tissue. About 70% of all bone mass contains inorganic material (calcium and phosphates) and 30% is of organic material (collagen and osteocalcin). Remodelling is a continuous process involving bone resorption and bone formation. The evaluation and diagnosis of metabolic bone disorders require the systematic elucidation of clinical history and thorough physical examination of musculo-skeletal system and other extra-skeletal features. The characteristics of bone pain, muscular weakness, anaemia, posture of the patient and deformities, linear-height, check-list of drug consumption and pre-existent risk factors need to be stressed; however, laboratory and radiological workup are usually necessary to clinch a diagnosis, even in early and asymptomatic stage of illness.

The laboratory aids for diagnosis and assessment are many but each one of them needs tailoring on the background of clinical information and risk factors assessment. These tests are:

I. Bone mineral profile
II. Calcitropic hormone profile
III. Imaging
IV. Bone biopsy and histomorphometry

BONE MINERAL PROFILE

The bone mass of women declines earlier than in men. Men have 30% to 50% more bone mass and are far less osteoporotic than woman. Preliminary workup consists of measurement of serum calcium, phosphorus, magnesium and alkaline phosphatase. The newer biochemical markers (bone markers) are classified depending upon their role on bone formation or bone resorption as in **Table 1**.

Table 1: Newer Biochemical Markers of Bone Formation and Bone Resorption

Bone Formation	Bone Resorption
Bone specific alkaline phosphatase	Urinary deoxypyridinoline (DPD)
Osteocalcin	Urinary N-telopeptide (NTX)
N - terminal propeptide of type 1 procollagen (PINP)	Serum C-terminal telopeptide (CTX) or β cross laps

These biochemical markers are sometimes useful in monitoring the response to treatment. They assess the risk for fracture in the stage of osteopaenia earlier than osteoporosis. The urinary NTX excretion, an indicator of bone resorption is to be determined on the second morning voiding, to predict early response to anti-resorptive therapy when compared to bone mineral density (BMD) follow-up every 1-2 years. The fall of NTX value by 35% from baseline is characteristic of effective anti-resorptive therapy. The resorption markers are also useful to identify patients with high risk of developing fractures. However, the limited availability of these newer markers are major hindrance towards their regular use in daily clinical practice.

Bone markers are reliable indicators of therapeutic success as early as three months after start of therapy. PINP (propeptide of type I procollagen) is the marker of osteoblastic activity for bone formation. The normal value is 26-110 microgram/L. Osteocalcin is a bone turnover marker and useful for therapy adherence and drug efficacy in bone diseases.

Serum Calcium

In circulation, the calcium is present in three forms namely ionised calcium (48% to 50%), protein-bound fraction (40%) and rest as complex calcium. The estimated normal value of calcium is around 9 to 10.6 mg/dL and because of diurnal variation, it reaches its peak value in mid-day and nadir in early morning. It is essential to correct serum calcium values to serum albumin levels as per formula.

Free Serum Calcium

Serum calcium (mg/dL) + [4 – serum albumin (gm%) × 0.8]. It is advisable to avoid tourniquet while drawing blood for serum calcium estimation irrespective of fasting or non-fasting state.

Ionised Calcium

It comprises 48% to 50% of total serum calcium, and is primarily responsible for physiological functions like muscle contraction, coagulation and bone mineralisation. The normal value of ionised calcium is around 4.5 to 5.2 mg/dL in fasting state (1.12 to 1.3 micromoles/L) with maximum at 10.00 hours and minimum at 18.00 to 20.00 hours. In heparinised samples, binding of calcium with heparin leads to low ionised calcium level. The significance of ionised calcium is of value in critical care patients with low albumin, altered acid-base balance and following massive blood transfusion.

The clinical disorders with hypercalcaemia and hypocalcaemia are mentioned as in **Tables 2 and 3**.

Table 2: Clinical Disorders with Hypercalcaemia

Hyperparathyroidism – Primary, tertiary
Prolonged immobilisation
Renal failure, Milk-alkali syndrome
Malignancies – Lung, Breast, Kidneys, Myeloma, Lymphoma
Endocrine – Thyrotoxicosis, Addison's disease, Pancreatic islet cell tumour
Granulomas – Tuberculosis, Sarcoidosis
Drugs – Vitamin D toxicity, Lithium, Thiazides, Foscarnet and Aluminium toxicity

Table 3: Clinical Disorders with Hypocalcaemia

Hypoparathyroidism, pseudohypoparathyroidism
Vitamin D deficiency – Nutritional, malabsorption, renal diseases
Drugs – Anti-convulsants (phenytoin and phenobarbitone), doxorubicin, bisphosphonates, cisplatin, calcitonin
Miscellaneous – Acute pancreatitis, tumour lysis syndrome, acute severe illness, toxic shock syndrome

Serum Phosphate

Out of total phosphorus in plasma, inorganic phosphate or phosphorus constitutes 1/3 fraction, the measurement of which is clinically useful for assessment of metabolic bone disorders. The normal range of inorganic phosphate is 2.5-4.5 mg/dL with higher values in elderly male and postmenopausal women. The inorganic phosphate is 20% protein bound and rest is free ionic form. The serum phosphorus level is higher in infants and children. Serum phosphorus level is measured by spectrophotometry from fasting plasma sample. The best index of phosphorus excretion is the maximal tubular reabsorption of phosphorus expressed as a function of GFR or TmP/GFR. This is decreased in primary hyperparathyroidism.

The clinical disorders associated with hyperphosphataemia and hypophosphataemia are listed below in **Tables 4 and 5**.

Table 4: Clinical Disorders Associated with Hyperphosphataemia

Disorders	Mechanism
Acute and chronic renal failure Hypoparathyroidism Pseudohypoparathyroidism Bisphosphonate therapy	Poor renal excretion
Hypothermia Acidosis Rhabdomyolysis Haemolysis	Intracellular to extracellular shift of phosphorus

Table 5: Clinical Disorders Associated with Hypophosphataemia

Disorders	Mechanism
Hyperparathyroidism Hypovitaminosis D Alcoholism Renal tubular acidosis	Increased renal excretion
Respiratory alkalosis Sepsis Recovery from diabetic ketoacidosis Salicylate toxicity	Extracellular to intracellular shift of phosphorus
Diuretics Steroids Calcitonin Beta agonists	Drug related adverse effect
Malabsorption Antacid abuse Vitamin D deficiency	Diminished intestinal absorption of phosphates

Serum Magnesium

Magnesium is present mostly in ionised form (55%), protein bound (30%) and rest in complex form. The normal value of serum magnesium is 1.7 to 2.6 mg/dL. The hypomagnesemia is observed in metabolic acidosis, prolonged diuretic therapy, prolonged nasogastric aspiration, hypoparathyroidism, acute pancreatitis, extensive bowel resection. Increase in serum magnesium level is seen in haemolysis. Severe and prolonged hypomagnesemia inhibits parathyroid hormone (PTH) release and induces resistance to PTH action on bones.

Serum Alkaline Phosphatase

The normal value in adults is 40-150 IU/L and in children 11-306 IU/L. The bone specific serum alkaline phosphatase (ALP) —a marker of osteoblastic activity is raised in Paget's disease of bones, metastatic bone disease, osteomalacia, osteoporosis. However, it is important to exclude hepatobiliary disease where ALP level is also high, especially in patients with cholestasis. The bone specific alkaline phosphatase fraction has better predictive value in evaluating bone disorders.

CALCITROPIC HORMONE PROFILE

Parathyroid Hormone (PTH)

The major 84-amino acid polypeptide hormone from parathyroid glands is metabolised in liver and present as intact PTH (iPTH) in circulation. PTH is measured by radioimmunoassay and the normal value ranges from 10-55 pg/mL (1-6.1 picomol/L). The sample for PTH assay is stored at –4°C and should be transported to laboratory in ice and centrifuged as early as possible and kept at –20°C or lower. The iPTH assay is indicated in: (a) to distinguish between PTH dependent versus PTH independent causes of hypercalcaemia; (b) to find out the cause of hypocalcaemia; (c) to evaluate Paget's disease and in hypophosphatemic rickets where iPTH level is normal.

Parathyroid Hormone-Related Protein (PTHrP)

The PTH-related peptide (PTHrP) is mainly significant in hypercalcaemia of malignancy. On the other hand, PTHrP levels are essentially normal in primary hyperparathyroidism and non-malignant causes of hypercalcaemia. This is measured by two-site isotopic immunoassay (IRMA) or by ELISA method.

Calcitonin

This 32-amino acid polypeptide is secreted by the parafollicular or C-cells of thyroid gland. It reduces bone resorption by inhibiting osteoclastic activity; and also reduces tubular resorption of both calcium and phosphorus and hence it has hypocalcaemic effect. Its estimation is useful in the diagnosis of hypercalcitoninaemia and medullary carcinoma of thyroid. The normal value is less than 0.08 microgram/L. The provocative tests for calcitonin estimation are done with calcium infusion and pentagastrin stimulation; calcitonin is the only hormone to actively lower serum calcium.

Vitamin D and Metabolites

Both vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) are prohormones and are inert until activated in the liver and kidney through sequential hydroxylation. The major transport form of vitamin D is 25(OH)D (calcidiol) hydroxylated in liver and its circulating concentration reflects nutritional status of vitamin D. This is further hydroxylated in kidney to produce the active form of the hormone 1, 25 dihydroxy D (Calcitriol).

In clinical disorders with vitamin D deficiency or excess the best method for assessing vitamin D status is measurement of serum 25(OH)D level and its normal value is between 8 and 50 ng/mL by RIA. The levels of 25(OH)D reflect the body stores of vitamin D more accurately than $1,25(OH)_2D$. The level rises in summer and declines in winter and more so in elderly.

Estimation of 25(OH)D is indicated in vitamin D deficiency/toxicity and in some subsets of hypercalcaemia with low PTH level. The value is low in clinical osteomalacia and subclinical vitamin D deficiency states. The cut-off value for overt osteomalacia is less than 5 ng/mL whereas values less than 15 ng/mL is suggestive of subclinical deficiency. The estimated values also vary

periodically with the quality of diet and duration of sun exposure in an individual. In patients with vitamin D toxicity serum 25(OH)D level is high along with hypercalcaemia but low PTH level.

The measurement of most biologically active form serum $1,25(OH)_2D$ (normal value 20-60 pg/mL) is indicated in hypercalcaemic states with normal iPTH, PTHrP and 25(OH)D, e.g. sarcoidosis, lymphoma and William's syndrome.

IMAGING

Standard Radiographs in Metabolic Bone Disease

This remains a useful and simple modality for the diagnosis of metabolic bone diseasae. The regions of the skeleton meant for diagnostic radiology are skull (lateral view), thoraco-lumbar spine (lateral view), pelvis with both hips (AP view), hands (AP view) and long bones (AP and lateral). Mostly conventional radiology is indicated in Paget's disease, primary hyperparathyroidism, osteomalacia, osteoporosis, fluorosis and osteosclerosis. However, the standard x-rays are unable to pick up decreased bone mass until there is 40% to 50% reduction of bone mass. However, these X-rays are useful to pick up compression fractures and other minimal injury fractures. The characteristic features are summarised as in **Table 6** (**Figures 1 to 5**).

Table 6: Summary of Characteristic Radiological Features in Common Disorders

Disease	Radiological features	Anatomical areas
Paget's disease (**Figure 1**)	Cortical thickening, areas of sclerosis and lucencies, bowing of legs and kyphosis of spine	Femur, skull, tibia, pelvis and spine
Primary hyper-parathyroidism (**Figure 2**)	Subperiosteal resorption, osteitis fibrosa cystica pathological fractures, tufting of distal phalanges and salt and pepper skull	Radial border of middle phalanges long bones, femoral neck, distal clavicle, skull
Osteomalacia (**Figures 3 and 4**)	Symmetrical pseudo-fractures or Looser's zones demineralisation, deformities, radiological features	Pubic rami, ribs, scapula, femoral neck shafts of long bones
Osteoporosis	Demineralisation, thin cortex, prominent trabecular lines, spinal deformities and stress fractures	Thoraco-lumbar spine, pelvis with femoral neck and wrists
Fluorosis (**Figure 5**)	Diffuse osteosclerosis interosseous membrane calcification	Long bones, pelvis
Osteosclerosis (Renal osteody-strophy, bone metastasis and hyper-vitaminosis A and D)	Diffuse thickening of cortices with gradual obliteration of medulla	Spine, long bones

Figure 1: Paget's disease of skull.

Figure 2: Bone cyst left femur in primary hyperparathyroidism.

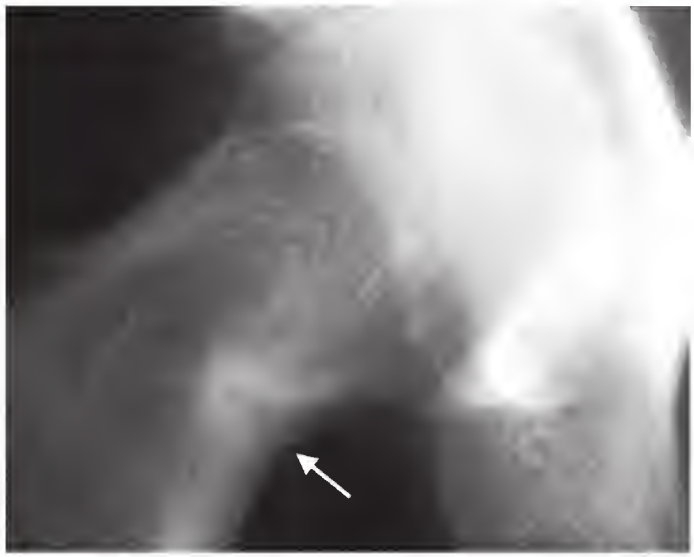

Figure 3: Pseudofracture or Looser's zone in osteomalacia.

Bone Scan or Scintigraphy

The principle behind metabolic bone scan is functional mapping of bone turnover and essentially it consists of accumulation of radioactive material in areas of bone depending upon blood flow and osteoblastic activity. The imaging is done with radioactive diphosphonates (DPN) labelled with technetium 99m. The bone scan is diagnostic in bone metastasis and vertebral fractures which are not always

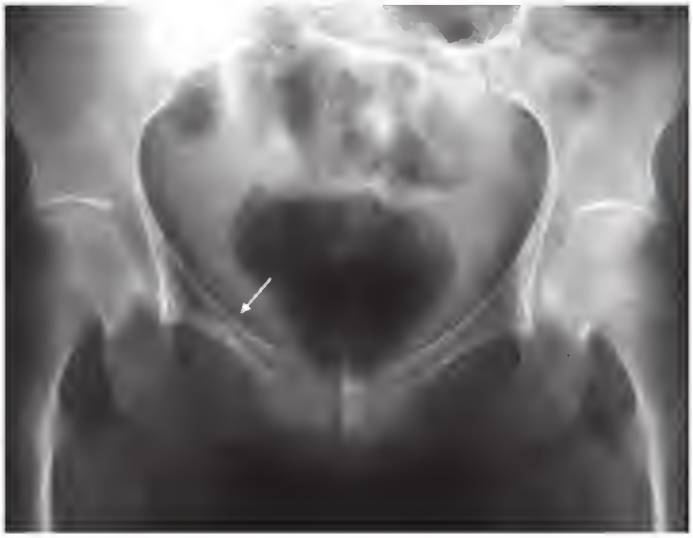

Figure 4: Pseudofracture in right pubic ramus in osteomalacia.

Figure 5: Fluorosis of spine

characteristic in conventional radiology (**Figure 6**). The 'hot spots' of vertebral fractures have time frame of two weeks to twelve months after the onset of fracture.

The metabolic 'superscan' with increased uptake in long bones, axial skeleton, skull, mandible is quite characteristic in primary hyperparathyroidism and renal osteodystrophy with secondary hyperparathyroidism. But this is negative in hypercalcaemia of malignancy. Bone scan is invaluable in Paget's disease for diagnosis and extent of disease; similarly it is useful to pick up Looser's zones in osteomalacia.

Bone Densitometry

The reduced bone mineral density (BMD) is the 'gold standard' for diagnosis with osteoporosis, yardstick of bone fragility and consequent risk of fracture. The correlation of BMD with risk of fracture is strong and sustained and comparable to hypertension and risk of stroke. It is estimated that 10% reduction of BMD doubles the risk of fracture.

There are number of methods to assess the BMD in a given individual which are mentioned in **Table 7**.

Table 7: Methodologies of BMD Measurement

Method	Common Anatomical Sites
Plain X-ray	Phalanges (hands) Thoracolumbar spine
Single energy X-ray absorptiometry (SXA)	Calcaneum, Radius/ulna
Dual energy X-ray absorptiometry (DEXA)	Lumbar spine Proximal femur Forearm
Quantitative computed tomography (QCT)	Lumbar spine
Broadband ultrasound attenuation (BUA)	Calcaneum, tibia

Out of all these modalities, DEXA is more accurate and consistent when compared with other methods.

The BMD measurement is recommended in several clinical states according to sex and age of the individuals as below in **Table 8**.

Table 8: Indications for BMD Measurement

1. Premenopausal women (Caucasian or Asian)
   (a) Long-term therapy with steroids, thyroxine, heparin
   (b) Primary or secondary amenorrhoea
   (c) Post-oophorectomy, organ transplantation
   (d) Malabsorption, chronic renal failure, hyperparathyroidism
2. Postmenopausal women
   (a) Patients not on oestrogen therapy
   (b) Vertebral or hip deformities or fractures plus premenopausal indications as above
3. Men
   (a) Hypogonadism
   (b) Unexplained fractures
   (c) Recurrent falls

Interpretation of BMD Measurement

The BMD reports express the standard deviation from the mean bone mass of normal 30-year-old young adults as the 'T' score and standard deviation from age and sex matched control as the 'Z' score.

WHO has established the following BMD-based diagnostic criteria for women:

- *Normal*—a BMD value within 1 (one) SD of the young adult mean.
- *Osteopaenia*—a BMD value more than 1 (one) SD but less than 2.5 SD below the young adult mean.
- *Osteoporosis*—a BMD value of 2.5 SD or more below the young adult mean.
- *Established or severe osteoporosis*—a BMD value 2.5 SD or more below the young adult mean with one or more fragility fractures.

Bone markers do not replace BMD, but are complimentary tools as they provide information about the rate of bone loss and not the patients' current bone mineral density.

Plain X-ray

It is insensitive to measure bone loss unless 30% to 50% of bone density has been lost. However, it is good to pick up fractures.

Figure 6: Bone metastasis in prostatic carcinoma in bone scintigraphy.

Single Energy X-ray or Photon Absorptiometry (SXA)

In this method the photon source is the digital X-ray system. The sites measured are the distal (90% cortical) and ultradistal (65% trabecular bone) radius of the forearm in prone position. However, it is inadequate to reflect the bone loss of BMD measurement.

Dual Energy X-ray Absorptiometry (DXA or DEXA) (Figure 7)

It is the gold standard for the diagnosis and monitoring treatment of patients with osteopaenia and osteoporosis. The sites commonly chosen are PA and lateral lumbar spine, hip, forearm and whole body. The positioning of femoral neck is critical to maintain good precision. The follow-up DXA after treatment is advisable after 1-2 years. Because of cost and non-availability of portable machines, its liberal use is somewhat limited.

Quantitative Ultrasound (QUS)

This method is portable, without any radiation risk which provides information both about bone quality and trabecular connectivity unlike DXA. The broadband ultrasonic attenuation (BUA) describes the increase in ultrasound attenuation and may be used for determination of bone density of calcaneum. The precision of this method is modest and the standardisation and quality control remains controversial. However, it can be utilised for community screening.

Quantitative Computed Tomography (QCT)

It takes the cross-sectional image of the vertebra and measures trabecular component in T_{12} to L_4 using regular CT scanner. Besides, volumetric QCT improves the spinal measurement.

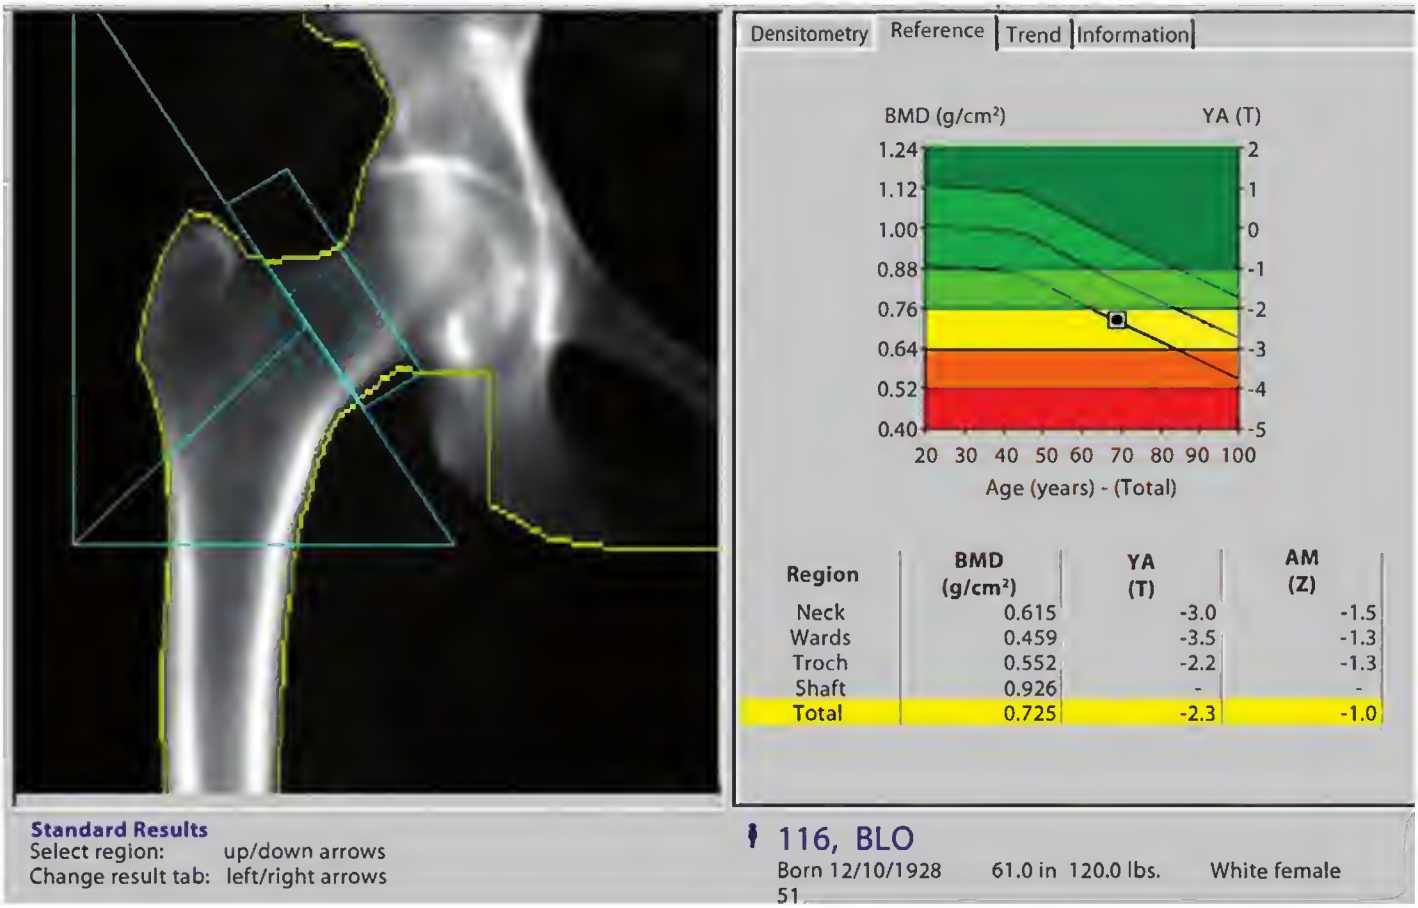

Figure 7: DEXA scan of right femur neck in osteoporosis.

The peripheral QCT gives higher spatial resolution which renders superior-modality when compared with other techniques.

Magnetic Resonance Imaging (MRI)

This is also valuable to recognise trabecular pattern more precisely but it is not cost effective for regular use.

BONE BIOPSY AND HISTOMORPHOMETRY

Bone biopsy is hardly indicated in metabolic bone disorders for diagnosis. In difficult situations of osteoporosis or osteomalacia of undetermined origin, it may be attempted to study the bone architecture under microscope with special histomorphometry. The biopsy is done through transilial approach on anterior superior iliac spine and processed in an undecalcified state prior to histologic evaluation. Rarely biopsy study is useful in follow-up of drug trial and other research purposes.

Lastly, in disease specific states with bone disorders additional tests may be carried out like serum protein electrophoresis, renal profile, serum thyroid hormones, cortisol, gonadal hormonal profile, genetic study on individual basis to settle the comprehensive diagnosis.

8.3 Rickets and Osteomalacia

Bindu Kulshreshtha, Sachin K Jain

OSTEOMALACIA AND VITAMIN D DEFICIENCY IN INDIA

A large amount of literature is available indicating a widespread occurrence of vitamin D deficiency, osteopaenia and osteoporosis among Indians. Studies from India have reported a high prevalence (84% to 90%) of hypovitaminosis D among healthy Indians across all age groups including pregnant population. Genetic factors are also believed to play a role in causation of osteomalacia.

Osteomalacia and rickets are widely prevalent in India. Due to widespread occurrence of 25(OH)D deficiency, 25(OH)D levels may not be considered the hallmark for diagnosing osteomalacia in Indian population. Also, financial constraints and lack of laboratory support make it difficult to get the 25 hydroxy vitamin D and parathormone (PTH) levels in all patients. Instead, an integrated approach taking into consideration the socioeconomic background and history, serum biochemistry and 24-hour urinary calcium estimation can help in the diagnosis.

AETIOPATHOGENESIS

Vitamin D is the major steroid hormone involved in bone mineral homeostasis. The sources of calcium include milk and milk products like butter, ghee, curd and animal products like eggs and meat. Vegetable sources of calcium include pulses and gram. Some fruits like coconut, apricot, guava, banana and pumpkin are also rich in calcium. Though not regularly calculated, spices are also rich source of calcium with *dhaniya*, asafoetida, cloves, coriander and cumin seeds accounting for about 100 mg of daily calcium intake among Indians.

Sunlight is a good source of vitamin D. Vitamin D is naturally obtained in the animal products like cod liver oil and fish liver oil. Other sources are meat, fish, eggs and milk. Thus, there is a tendency for vitamin D deficiency in pure vegetarians. Activation of inactive vitamin D to its active vitamin D3 form occurs under the influence of ultraviolet light. This activation may be prevented by melanin in the skin which explains occurrence of vitamin D deficiency in dark skinned individuals. The first step in the activation of vitamin D is 25 hydroxylation in the liver followed by 1-alpha hydroxylation in the kidney. The active 1,25 dihydroxy vitamin D exerts its effects by binding to the vitamin D receptor, a member of steroid/thyroid hormone superfamily. The major actions of vitamin D include mineralisation of the bony matrix and growth plates. It is also known to have immunomodulatory and anti-proliferative effects. The absence of biologic effects of vitamin D could be due to a lack of dietary intake, deficient production of active form of vitamin D in the skin, impaired vitamin D activation or resistance to the biologic effects of 1,25 dihydroxy vitamin D.

For skeletal mineralisation, adequate calcium and phosphate must be present at mineralisation sites. Calcium levels in the blood are regulated by vitamin D mediated absorption from the gut and resorption of calcium from the bone that is regulated by PTH. 1,25 dihydroxy vitamin D enhances calcium and phosphorus absorption from the intestine. Reduction in the absorption of calcium in vitamin D deficiency and the resulting hypocalcaemia stimulates parathyroid glands to increase PTH secretion. PTH acts on osteoclasts to mediate resorption of the bone. At the renal level, PTH facilitates calcium reabsorption and phosphorus excretion through the tubules. PTH also stimulates the renal conversion of 25 hydroxy vitamin D to 1,25 dihydroxy vitamin D which in turn stimulates more calcium and phosphorus absorption from the gut. Histopathology of osteomalacic bone shows an incompletely mineralised osteoid, an increase in the osteoid volume and thickness and a decrease in the calcification or mineralisation front.

Osteomalacia and rickets are disorders characterised by defective mineralisation of the bony matrix. Rickets occurs in the growing skeleton of children and both the long bones and the cartilaginous matrix of the growth plate are involved. Osteomalacia is defective matrix mineralisation of the bones in adults, in whom the epiphyseal bony fusion has occurred. The most common cause of these diseases in Indian population remains nutritional vitamin D deficiency. Inadequate sunlight due to *purdah* as practiced by Muslim women coupled with borderline vitamin D reserves could also result in osteomalacia. Other causes are enlisted in **Table 1**. Another common disorder in India is fluorosis. Excess fluoride mainly from water sources interferes with mineralisation of hydroxyapatite in bone.

Table 1: Aetiologic Profile of Osteomalacia

Vitamin D deficiency	Inadequate dietary intake Malabsorption Impaired cutaneous production
Impaired 25 hydroxylation	Liver disease Drugs like isoniazid ? Inherited mutation of 25 alpha hydroxylase
Impaired 1-alpha hydroxylation	Renal failure Renal tubular disorders, Fluorosis Vitamin D dependent rickets type 1 Oncogenic osteomalacia X-linked hypophosphatemic rickets
Accelerated vitamin D metabolism	Drugs, like phenobarbitone, primidone, phenytoin, rifampin, glutethimide
Vitamin D resistance	Vitamin D dependent rickets type II (receptor mutation)

Vitamin D dependent rickets type I (VDDR I) is a rare genetic disorder of mutation in the 1-alpha hydroxylase gene inherited in autosomal recessive fashion. Vitamin D dependent rickets type II (VDDR II), another inborn error of metabolism inherited in an autosomal recessive fashion, is due to mutations of the vitamin D receptor and is characterised by alopecia, vitamin D deficiency and lack of response to the conventional doses of vitamin D. Oncogenous osteomalacia is another rare cause of osteomalacia

where phosphaturic factor is secreted by tumours (usually of the mesenchymal origin) resulting in deficient mineralisation.

Calcipenic Rickets

Decrease in calcium intake or decrease in the intestinal calcium has also been associated with rickets. Such cases were reported from South Africa, also from India where children consumed no milk or dairy products and the intake of calcium was estimated to be less than 200 mg. Consumption of cereals and grain products high in phytate could lead to formation of intraluminal calcium phytate complexes and consequent calcium malabsorption. Other features and biochemistry is similar to vitamin D deficiency rickets except for 25 hydroxy vitamin D levels which are normal.

Clinical Features

Clinical signs may differ according to the age at presentation. Infants may present with hypotonia, feeding difficulties, irritability, or hypocalcaemic seizures. Clinical signs in infants include craniotabes (softened calvaria), widened fontanelle, frontal bossing, hypotonia, divarication of the recti and umbilical hernia. As the disorder progresses, the child finds increasing difficulty in walking and a progressive proximal muscle weakness. Pathological fractures may occur, growth is stunted. In children, the weight bearing joints may present with bowing deformities (genu valgum and varum) and wrist widening. Prominence of the costochondral junction (also known as rachitic rosary and indentation of the lower ribs (Harrison's groove) due to softening of skeleton may be present. Dentition is delayed and enamel hypoplasia may occur. Deformity of the back including kyphosis and lordosis along with limb bowing (**Figure 1**) can contribute to waddling gait. Patients with VDDR I and VDDR II usually present during infancy or childhood. Those with VDDR II also present with alopecia, multiple milia and epidermal cysts, milder defect could present during adolescence also.

Figure 1: Spinal, wrist and foot deformities in a child with rickets.

Adult patients with vitamin D deficiency may be asymptomatic or present with varying degrees of bony aches along with features of proximal muscle weakness. History of repeated fractures even on trivial trauma may be present. In severe cases, long bones may show bowing deformities (**Figure 2**). Seizures in adults due to hypocalcaemia caused by vitamin D deficiency are extremely rare. This is possibly due to PTH excess which prevents extreme decline in calcium levels and a relative metabolic alkalosis (PTH effect). Axial osteomalacia and resulting microfractures of the vertebrae may cause loss of the adult height. Rib involvement could result in a deformed chest. Enthesopathy and ligamentous calcification as occurs in X-linked hypophosphatemic osteomalacia or fluorosis could result in joint stiffness.

Figure 2: Photograph showing bowing of lower limbs.

Investigations

Routine investigations including haemogram, renal function tests, liver function tests and urine routine examination are important to rule out a systemic cause of metabolic bone disease. The basic investigation for a metabolic bone disease work-up includes calcium, phosphorus and alkaline phosphatase, 24-hour urinary calcium and fractional excretion of phosphorus as assessed by tubular reabsorption of phosphorus (TRP) and TmpGFR. Serum albumin is also needed to make appropriate corrections for the serum calcium level. A 24-hour urinary creatinine is also needed along with 24-hour urinary calcium to assess for adequacy of urine collection.

In osteomalacia, serum calcium levels are low to normal, phosphorus levels are low and alkaline phosphatase is high. In the initial stages, phosphorus levels may be low and normal calcium levels due to secondary hyperparathyroidism. A 24-hour urinary calcium level in patients with osteomalacia is low (normal calcium excretion is 2.5 to 4 mg/kg/day).This helps in distinguishing osteomalacia from other metabolic bone disorders like normocalcaemic hyperparathyroidism and renal tubular acidosis where the 24-hour urinary calcium levels are high. In osteomalacia, 25(OH)D levels are low and PTH levels are high. There is no utility of $1,25(OH)_2D$ in patients with nutritional osteomalacia since these levels are usually normal due to the enhanced 1-alpha hydroxylase activity, an action mediated by PTH. $1,25(OH)_2D$ levels are low in patients with osteomalacia due to renal causes, fluorosis or oncogenous osteomalacia. **Table 2** gives the differential biochemical parameters in patients with metabolic bone diseases due to different causes.

Table 2: Biochemical Parameters in Metabolic Bone Diseases

Calcium	Phosphorus	Alkaline Phosphatase	24-hour Urinary Calcium	Diagnosis
Normal	Decreased	Increased	Decreased	Osteomalacia
Decreased	Decreased	Increased	Decreased	Osteomalacia
Normal	Decreased	Normal	Decreased	Osteomalacia
Increased	Decreased	Increased	Increased	Hyperparathyroidism
Normal	Decreased	Increased	Increased	Normocalcaemic hyperparathyroidism, Renal tubular acidosis
Decreased	Increased	Normal	Decreased/normal	Hypoparathyroidism
Decreased	Increased	Increased	Decreased/normal	Renal failure, selective renal resistance to PTH action

Asymptomatic/Subclinical Osteomalacia

Some healthy Indian adults or some patients who report mild non-specific bony aches and pains have normal calcium, phosphorus and alkaline phosphatase vitamin D and PTH levels but low 25(OH)D levels. It is difficult to detect this subgroup since most of them have normal calcium, phosphorus and ALP levels. PTH levels are also within the normal range albeit high normal, a finding difficult to explain. A 24-hour urinary calcium in these patients is usually low.

A comprehensive evaluation of a patient with metabolic bone disease demands radiographs of the pelvis, skull, dorsolumbar spine (anteroposterior and lateral views), chest and bilateral forearms and hands. There is usually a generalised osteopaenia with coarsening of the trabeculae. Widening, fraying and cupping of the distal ends of the shaft and disappearance of the zone of provisional calcification is seen. Pseudofractures (thin cortical radiolucent lines at right angle to the shaft) may be present. The common sites of pseudofractures includes medial margins of the neck of femur, pubic rami (**Figures 3A and 3B**) borders of scapulae, ribs and rarely margins of forearm bones. Secondary hyper-parathyroidism manifests as diastasis of the pubic rami, though presence of cysts, pepper pot appearance of the skull, subperiosteal resorption and tufting of the phalanges points towards a diagnosis of primary hyperparathyroidism. Interosseous membrane calcification and calcification of the ligamentous joints is usually seen with fluorosis. Rarely, patients with fluorosis may masquerade as ankylosing spondylitis. **Figure 4** shows a female with florid osteomalacia and hypocalcaemic tetany in **Figure 5**.

Figure 3A: Radiograph of pelvis showing osteopaenia, pubic diastasis and pseudofractures of the pubic rami.

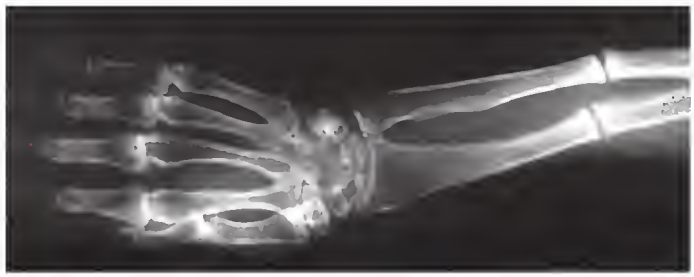

Figure 3B: Pseudofractures in forearm bones (looser zone).

Figure 4: Photograph shows a female with florid osteomalacia.

Management

Treatment of osteomalacia or rickets should be tailored to the underlying disorder. In almost all cases treatment with calcium 1 to 3 g daily is required. Patients with nutritional osteomalacia, where activation pathway is intact, could be supplemented with cholecalciferol instead of calcitriol which is more expensive. These patients could be given monthly cholecalciferol for 2 to 4 months. In more severe cases, where depleted vitamin D stores have to be replenished cholecalciferol 60,000 IU weekly for a month and then monthly for 3 to 6 months , sometimes per year are required. In patients with osteomalacia due to a renal cause or hypoparathyroidism or VDDR I where 1-alpha hydroxylation is defective, active metabolite, calcitriol in the dose of 0.25 to 0.5 mcg should be supplemented. In cases of malabsorption, vitamin D could be administered parenterally. In our practice, development of hypercalcaemia or nephrocalcinosis is extremely rare. This is possibly due to poor vitamin D stores which take a long time to normalise.

Figure 5: Photograph shows hypocalcaemic tetany.

In the initial stages of vitamin D therapy, bone pains may worsen and alkaline phosphatase levels may increase, thereby indicating active bone remodelling. There is a gradual increase in phosphorus levels as the PTH levels come down. The radiologic healing takes around 4 to 6 weeks. It is also important to reinforce the patients to ensure a healthy nutrition and a minimum exposure to sunlight (290-315 nm) for 30 minutes of unprotected skin per day.

It is advisable to check calcium, phosphorus and alkaline phosphatase levels of other unaffected family members, especially siblings. Similarly, dietary advice should be reinforced for the whole family.

8.4 Osteoporosis

SNA Rizvi

INTRODUCTION

Osteoporosis is the second most common metabolic bone disease in India. The term describes a group of bone disorders in which the absolute bone mass is less than normal. There is deterioration of micro-architecture of the skeleton leading to increased bone fragility and risk. The mineral-to-matrix ratio is reduced. Histologically, it is characterised by a decrease in the number and size of the trabeculae, with normal width of the osteoid seams. It is a silent underlying condition which often remains asymptomatic until a fracture occurs. The actual prevalence of osteoporosis remains unknown because of its asymptomatic nature. In India it has been presumed that 35% of post-menopausal women are at the risk of developing osteoporosis. Osteoporotic bone fractures commonly occur at the spine, hip and wrist. On an average a post-menopausal woman has 40% to 50% chance of developing a fracture including 15% chance of hip fracture in her lifetime. More than 10% of hip fracture victims die within one year from various complications and nearly 50% of the survivors are incapacitated, some of them permanently.

Clinically, osteoporosis has been classified into two categories (**Table 1**).

Bone mass is the result of the amount of bone achieved during growth and at maturity, and the subsequent rate of bone loss. The remodelling of bone (its formation and resorption) is a continuous process throughout life. In normal individuals, for many years after closure of the epiphyses, skeletal mass remains constant and the rates of bone formation and resorption (bone remodelling) are approximately equal. In osteoporosis the rate of bone resorption exceeds that of bone formation.

AGE-RELATED OSTEOPOROSIS (POSTMENOPAUSAL AND SENILE)

Normally, bone mass is lost gradually in both sexes, but in women, the rate of bone loss is accelerated at the time of menopause. The suggested aetiopathogenesis of age-related (involutional) osteoporosis is shown in **Figure 1**.

The differentiating features between types I and II involutional osteoporosis are summarised in **Table 2**.

Table 2: Types of Involutional Osteoporosis

	Postmenopausal (Type I)	Age-related senile (Type II)
Age (years)	51-70	>70
Sex ratio (F : M)	5:2	2:1
Type of bone loss	Mainly trabecular	Cortical and trabecular
Rate of bone loss	Accelerated	Not accelerated
Fracture sites	Vertebrae (crush), distal radius	Vertebrae (multiple wedging), hip (extracapsular)
Parathyroid function	Decreased	Increased
Calcium absorption	Decreased	Decreased
Renal conversion of 25(OH)D to $1,25(OH)_2D$	Decreased secondary to decreased PTH secretion	Decreased due to decreased 25(OH)D α activity
Main cause	Factors related to menopause	Factors related to to aging

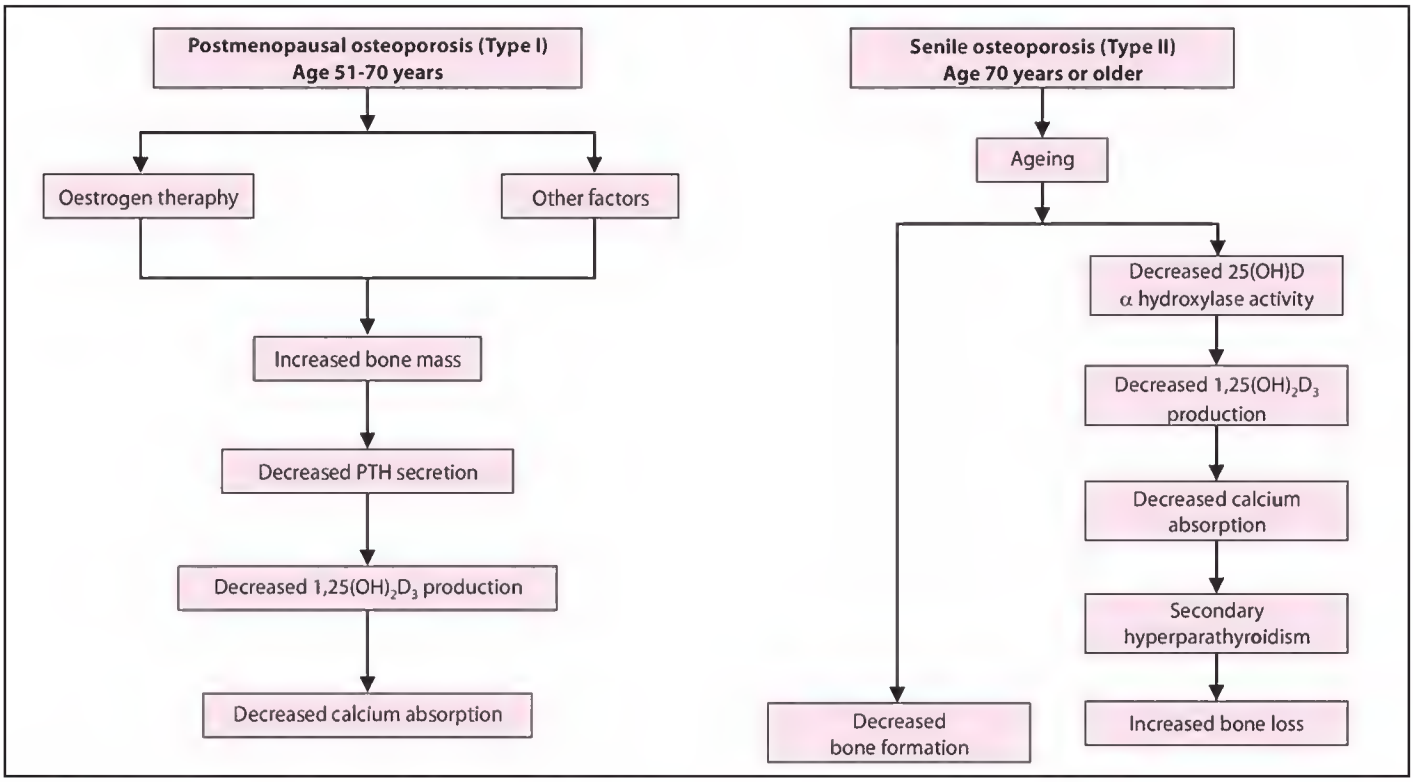

Figure 1: Mechanisms of bone loss in involutional osteoporosis.

CLINICAL FEATURES

Most patients are asymptomatic until they develop a complicating fracture which often occurs after minimal trauma. Fractures are most common in the hip, humerus, ribs and wrists. The most frequent symptoms are pain in the back, deformity of the spine (kyphosis) and loss of height. Pain usually results from collapse of the vertebral bodies, especially in the lower dorsal and upper lumbar regions; it is typically acute in onset. Generalised bone tenderness would suggest coexisting osteomalacia. Impaired movement of thoracic cage can produce cardiopulmonary embarrassment and exercise intolerance and disablility.

DIAGNOSIS

The calcium, phosphorus, and alkaline phosphatase levels in the blood are normal. In the past, osteoporosis used to be diagnosed after manifestation of fracture in old age but now can be achieved by *Bone Densitometry* which include dual energy X-ray absorptiometry (DEXA), quantitative computed tomography, quantitative ultrasound, radiographic absorptiometry and single energy X-ray absorptiometry. DEXA is being most preferred densitometry technique for diagnosis of osteoporosis. The results are interpreted in terms of T-Scores and Z-Scores. T-Scores represent the bone mass of the patient compared to the mean peak bone mass of the young adult reference population using standard deviations. Z-Scores compare the patients bone mineral density (BMD) with the mean BMD for the person of the same age. According to WHO osteoporosis is diagnosed using T-Scores as follows:

BMD within 1.0 SD	–	Normal
BMD between 1.0 and 2.5 SD	–	Osteopaenia
BMD below 2.5 SD or more	–	Osteoporosis
BMD beyond 2.5 SD with one or more fragility fractures	–	Severe osteoporosis

X-rays are the easiest but evident only after loss of 30% to 50% of bone mass. The radiological changes are more marked in the bones of the axial skeleton and consist of loss of bone density, reduction in the number and size of the trabeculae, and thinning of the cortex. The lumbar and thoracic vertebrae become biconcave, and later compression or collapse causes anterior wedging.

Some of the risk factors are shown in **Table 3**.

Table 3: Risk Factors for Osteoporosis

- Age (advanced : 50 years or more)
- Sex (female)
- Race (caucasian or oriental ethnic origin)
- Habitus (petite or thin)
- Menopause (premature, surgically induced)
- Positive family history for osteoporosis
- Reduced weight for height
- Diet
  - Calcium (low)
  - Caffeine (excess)
  - Alcohol (excess)
  - Protein (low)
  - Phosphate (low)
- Sedentary life-style
- Cigarette smoking
- Multiparity
- Other disorders affecting mineral metabolism
- Medications
  - Steroids
  - Anti-epileptics
  - Thyroid supplements
  - Anti-coagulants
- Hypogonadism

PREVENTION OF OSTEOPOROSIS

Prevention or early treatment of osteoporosis is still the most certain way to maintain a sound skeleton. The various elements for prevention are summarised in **Table 4**. It involves maintenance of normal oestrogen levels, high calcium intake, exercise, sensible weight and lifestyle modification (avoiding cigarette smoking, excess of alcohol and coffee).

Table 4: Elements of Osteoporosis Prevention

Calcium intake 1.0-1.5 g per day
Moderate phosphorus intake
Moderate vitamin D intake, 400-800 IU per day or calcitriol 0.25 µg/day
Appropriate exercise programme
Avoidance of alcohol and cigarette
Periodic assessment of skeletal status
Prophylactic agents when indicated, Alendronate 5 mg or Raloxifene 60 mg per day

Clinical deterioration due to further bone loss can generally be prevented by administration of oestrogens and anabolic steroids combined with calcium supplementation, small doses of vitamin D, and maintenance of physical activity. A typical programme consists of oral administration of 0.625 mg to 1.25 mg of conjugated oestrogen or the equivalent dosage of another natural oestrogen daily for the first 25 days of the month, with administration of medroxyprogesterone acetate 10 mg daily during the last 10 days of the month to complete shedding of the endometrium. The 19-nortestosterone derivatives (desogestrel, norgestinate) have negligible side-effects. Hormonal replacement therapy (HRT) slows down bone loss, helps to maintain bone mass and skeletal integrity and protects against osteoporosis.

Pelvic examination, vaginal smear for cytology and possibly endometrial biopsy, manual examination of breasts and mammography are indicated at frequent intervals for evidence of carcinoma. Any bleeding other than that associated with oestrogen withdrawal should be investigated. History of ischaemic heart disease or of venous thrombosis is a contraindication for hormone replacement therapy. Recently, a new agent Tibolone (2.5 mg) with oestrogenic and progestogenic activity has been launched as an alternative to traditional HRT.

TREATMENT OF ESTABLISHED OSTEOPOROSIS

The primary goals of treatment are:

1. Increasing bone mass
2. Reducing the incidence of osteoporotic fractures
3. Arresting and reversing bone loss by inhibiting bone resorption and stimulating bone formation
4. Symptom relief

Symptom relief from fracture pain is provided by analgesics. Calcitonin has an analgesic action mediated by endorphins. Salmon calcitonin, the most potent injectable form, is given in doses of 50 to 100 MRC unit daily two-three times a week. It is also available as nasal spray.

Various drugs used in the treatment of osteoporosis are outlined in **Table 5**.

Hormonal Replacement Therapy

Oestrogen alone or in combination of progesterone may be used. It inhibits osteoclasts and decreases the rate of bone resorption and promotes absorption of intestinal calcium and stimulates osteoblast function. Adverse affects of HRT include vaginal bleeding, breast tenderness and upper gastrointestinal symptoms. It also increases the risk of breast and endometrial malignancy. It is no longer first line of treatment for post-menopausal osteoporosis.

Table 5: Drug Treatment for Osteoporosis

Anti-resorptive agent
HRT/Oestrogen, progesterone
Bisphosphonates
Etidronate, alendronate, pamidronate, tiludronate, risedronate, zolendronate (transdermal formulation)
Calcitonin
Calcium
Tibolone
Stimulators of bone formation
Fluoride
Parathyroid hormone
Agents with unknown action
Vitamin-D and analogues
Anabolic steroids
Ipriflavone
Newer therapies
Selective oestrogen receptor modulators (SERMS)
raloxifene, idoxifene, tamoxifene, droloxifene.
Activator of non-genomic estrogen like signalling (ANGELS)
Growth factors (TGF-β , IGF-1 and 2)

Tibolone

It is a synthetic steroid with simultaneous weak oestrogenic, androgenic and progestational activity. It is given in the dose of 2.5 mg daily with its beneficial affect on the lumbar spine.

Bisphosphonates

They are synthetic analogues of pyrophosphate with potent anti-resorptive properties. First generation include etidronate and clodronate. Second generation agents are alendronate, pamidronate and tiludronate and third generation includes risedronate. It inhibits bone resorption by inhibiting osteoclasts. Alendronate is approved by US Food and Drug Administration (FDA). It reduces vertebral fracture rate by 50% at a daily dose of 10 mg. It is avoided in abnormalities of oesophagus such as stricture or achalasia, inability to stand or sit for at least 30 minutes and hypocalcaemia. An alternative to oral preparation is now available as transdermal formulation of zolendronate.

It has been shown that alendronate and risedronate have profound effects on reduction of vertebral fractures and non-vertebral fractures of hip.

Calcitonin

It is a peptide hormone which is an effective interesting antiresorptive agent with excellent safety profile. The principal side effects are nausea, nasal irritation, and dizziness. It is costly and should be reserved for treatment of osteoporosis when HRT or bisphosphonates are contraindicated or ineffective 50-100 MRC units daily to three times a week is used.

Calcium

Calcium supplementation has significant beneficial effect on bone mass irrespective of age. Dietary calcium derived mostly

from dairy products slows bone loss in post-menopausal women. Combining with oestrogen or calcitonin offers an even greater benefit. The recommended dose for calcium in post-menopausal women is 1500 mg/day and in men and women on HRT is 1000 mg/day.

Fluoride

It stimulates bone formation and substantially increases bone density. In view of potential toxicity and inconsistent anti-fracture effect, it is not approved for the treatment of osteoporosis even in USA.

Parathyroid Hormone (PTH)

It prevents bone loss upto 3.4% in lumbar spine with daily injection of 500 units of hPTH subcutaneously. The drug has to be administered parenterally and is costly too.

Teriparatide is given by subcutaneous injection. It acts on osteoblast cell and increases the bone density at spine and is given for 18 months and effect lasts another 18 months after stopping the therapy. It is given only in severe osteoporosis with spine fracture. It is contraindicated in hypercalcaemia, kidney disease, Paget's disease and radiation therapy.

Combination Therapy

PTH and bisphosphonate combination was tried but no substantial improvement in prevention of fractures and change in BMD was noted.

Strontium Ranelate

New modality for treatment of osteoporosis has dual action which increases bone formation and uncoupling of bone remodelling.

Vitamin D and its Analogues

It has been shown that vitamin D and its active metabolite calcitriol and its analogue alfacalcidol have beneficial effects on bone mass in osteoporosis. Calcitriol decreases rate of vertebral fracture and improves vitamin D deficiency which is not very uncommon in old age. Recommended dose for vitamin D supplementation is 400-800 IU / day or 0.25 μg calcitriol daily.

Phytoestrogens

These are plant derived molecules that have oestrogenic actions and obtained from dry soyabeans and all soya based products. Ipriflavone has been shown to increase bone mass in established osteoporosis, its safety is yet to be established.

Selective Oestrogen Receptor Modulators (SERMS)

Raloxifene, has recently been approved for the treatment of post-menopausal osteoporosis. It has mixed oestrogen agonist and antagonist activity. The usual dose is 60 mg orally once a day. Side effects are leg cramps and worsening of hot flushes. BMD of spine and hip increased by approximately 2% to 3%, but it does not increase the risk of breast cancer or endometrial cancer.

In recent years , a number of new agents have been devised with little effects on endometrium and breast. These include tamoxifen, droloxofen and idotoxifen. Their potential for treatment of osteoporosis remains to be assessed.

Clinical trials are on to see the potential application of GH and TGF-β and IGF-1 and 2 in the management of osteoporosis.

IDIOPATHIC OSTEOPOROSIS

This is the term used to describe the disorder in children, younger men or premenopausal women in whom no aetiological factor is detected. Juvenile osteoporosis is a rare disorder with onset usually between the ages of 8 and 14 years; it is characterised by abrupt appearance of bone pains and occurrence of fractures after minimal trauma. Investigations show malabsorption of calcium and/or a high urinary calcium loss. Bone resorption is generally high and vertebrae reveal regular biconcavity with large disc spaces. In many cases the disorder is self-limited. It differs from osteogenesis imperfecta which occurs since birth, lasts life-long and has associated connective tissue defects such as blue sclerae and abnormal teeth. It does not respond to treatment with vitamin D and calcium.

In idiopathic adult osteoporosis, present in a young man or a premenopausal woman, malabsorption of calcium is frequently present and symptomatic improvement often follows treatment with calcium and vitamin D.

STEROID-INDUCED OSTEOPOROSIS

Osteoporosis commonly accompanies Cushing's syndrome, both exogenous and endogenous, and in some instances is rapidly progressive, especially in children and women over the age of 50 years. Osteoporosis in conditions of glucocorticoid excess is accounted for by a combination of low rates of bone formation accompanied by high rates of bone resorption. This results partly from glucocorticoid-induced secondary hyperparathyroidism and alteration in the metabolism of vitamin D_3. Treatment consists of withdrawal of glucocorticoids or decrease in its dose, and treatment with vitamin D in doses of 1.25 mg three times a week with supplemental oral calcium 1 g per day. The use of vitamin D metabolites such as $25(OH)D_3$ or $1,25(OH)_2D_3$ may prove to be more effective. Alendronate can be prescribed in men with steroid induced osteoporosis. Testosterone may be given if testosterone level is low. Calcitonin can be prescribed if bisphosphonate is contraindicated.

OSTEOPOROSIS IN MEN

Primary osteoporosis is seen in 50% where no aetiological factor is detected (idiopathic) whereas secondary (50%) is commonly associated with glucocorticoid excess (15%), hypogonadism (10%), alcoholism (7%), hypercalciuria (2%), smoking, immobilisation and some gastrointestinal disorder.

Treatment in cases of secondary osteoporosis consists of treatment of the cause, androgen, limitation of corticosteroid therapy, alcohol or smoking and use of thiazides for hypercalciuria. Idiopathic osteoporosis is treated with most prescribed modalities, includes exercise and prevention of falls, calcium and vitamin-D supplements, PTH (teriparatide) and alendronate.

8.5 Developmental Disorders of Bone

Rakesh K Sahay

A wide variety of inherited disorders affect the skeletal development. They affect the bone growth and remodelling and may also produce derangements in mineral homeostasis. From a practical clinical standpoint these disorders can be classified as sclerosing and non-sclerosing bone dysplasias (**Table 1**). An overview of some of the common clinically relevant developmental bone disorders has been provided.

Table 1: Developmental Disorders of Bone

Sclerosing bone dysplasias
- Osteopetrosis
- Carbonic anhydrase II deficiency
- Pycnodystosis
- Engelmann's disease
- Endosteal hyperostosis
- Osteopoikilosis
- Osteopathia striata
- Melorheostosis

Non-sclerosing bone dysplasias
- Osteogenesis imperfecta
- Fibrous dysplasia

Osteochondrodysplasias
- Multiple epiphyseal dysplasia
- Spondylo-epiphyseal dysplasia
- Handigodu disease
- Achondrodysplasia
- Metaphyseal chondrodysplasia
- Enchondromatosis
- Osteochondromatosis

Mucopolysaccharidosis
- Dysostosis multiplex
- Morquio's syndrome
- Hurler's syndrome

SCLEROSING BONE DYSPLASIAS

Osteopetrosis

Osteopetrosis (Marble bone disease, Albers-Schonberg disease): These disorders are caused by severe impairment of osteoclast-mediated bone resorption. Mostly two types of osteopetrosis include type I which is malignant (severe, infantile, autosomal recessive) and type II osteopetrosis, which is benign (adult, autosomal dominant). A rare autosomal recessive has a more benign prognosis. This is also known as intermediate form.

Clinical Presentation

Type I osteopetrosis presents in early childhood, and untreated is often fatal before age of five year. As bone and cartilage fail to undergo modelling, paralysis of one or more cranial nerves may occur due to narrowing of the cranial foramina and patient can at times present with resultant sensorineural deafness and blindness as initial complaints. Failure of skeletal modelling also results in inadequate marrow space, leading to extramedullary haematopoiesis with hypersplenism and pancytopaenia. Hypocalcaemia due to lack of osteoclastic bone resorption may occur in infants and young children.

Adult (benign) osteopetrosis type II is an autosomal dominant disease that is usually diagnosed by the discovery of typical skeletal changes in young adults who undergo radiologic evaluation of a fracture. The fractures may be accompanied by loss of vision, deafness, psychomotor delay, mandibular osteomyelitis, and other complications usually associated with the juvenile form. The milder form of the disease does not usually require treatment.

Radiography

Generalised symmetric increases in bone mass with thickening of both cortical and trabecular bone. The diaphyses and metaphyses are broadened (Erlenmeyer deformity), and alternating sclerotic and lucent bands may be seen in the iliac crests, at the ends of long bones, and in vertebral bodies. The cranium is usually thickened, particularly at the base of the skull, and the paranasal and mastoid sinuses are underpneumatised. The thickened cranium along with the vertebral end plate sclerosis gives the appearance of Rugger-Jersey spine.

Laboratory Findings

Elevated serum levels of osteoclast-derived tartarate-resistant acid phosphatase (TRAP) and the brain isoenzyme of creatine kinase are characteristic. Serum calcium may be low in severe disease, and parathyroid hormone and 1,25-dihydroxy vitamin D levels may be elevated in response to hypocalcaemia.

Treatment

Allogenic HLA-identical bone marrow transplantation has been successful in some children. Following transplantation, the marrow contains progenitor cells and normally functioning osteoclasts. A cure is most likely when children are transplanted before age of four years. Marrow transplantation from non-identical HLA-matched donors has a much higher failure rate. Limited studies in small numbers of patients have suggested variable benefits following treatment with interferon gamma-1b, 1,25-dihydroxy vitamin D (which stimulates osteoclasts directly), methylprednisolone, and a low calcium/high-phosphate diet. Decompression of the optic or auditory nerve compression may be needed. Orthopaedic management is required for the surgical treatment of fractures and their complications including malunion and post-fracture deformity.

NON-SCLEROSING BONE DYSPLASIAS

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI), characterised by generalised osteopenia and brittle bones (hence called brittle bone disease) is the most common genetic bone disorder and its prevalence is estimated around 1 in 10,000-20,000 births. The disorder is frequently associated with blue sclerae, dental abnormalities (dentinogenesis imperfecta), progressive hearing loss, and a positive family history. The clinical manifestations based on the mode of inheritance of OI are summarised in **Table 2**.

Table 2: Clinical Features of Osteogenesis Imperfecta Based on Mode of Inheritance

OI Type	Major clinical features	Inheritance
I	Normal stature, blue sclerae, hearing loss in about 50% of patients	AD
II	Lethal in perinatal period, minimal calvarial mineralisation, long bone deformities, platyspondyly	AD (new mutation) AR (rare)
III	Short stature, bone deformities, variable hue in sclerae, Dentigerous imperfecta (DI) and hearing loss common	AD or AR
IV	Normal sclerae, bone deformity, DI common, short stature and hearing loss variable	AD

AD = Autosomal dominant; AR = Autosomal recessive.

Skeletal Changes

Radiographs of the skull in patients with mild disease may show a mottled appearance because of small islands of irregular ossification. In type II OI, bones and other connective tissues are so fragile that massive injuries can occur in utero or during delivery. Ossification of many bones is frequently incomplete. Continuously beaded or broken ribs and crumpled long bones (accordina femora) may be present. In types III and IV, multiple fractures from minor physical stress can produce severe deformities. Kyphoscoliosis can impair respiration, cause cor pulmonale, and predispose to pulmonary infections. On radiographs the appearance of "popcorn-like" deposits of mineral on the ends of long bones is an ominous sign. In all forms of OI, bone mineral density in unfractured bone is decreased. However, the degree of osteopenia may be difficult to evaluate because recurrent fractures limit exercise and thereby worsen already reduced bone mass. Surprisingly, fractures appear to heal normally.

Ocular Changes

The sclerae can be normal, slightly bluish, or bright blue. Thinning of the collagen layers of the sclerae allows the choroid layers to be seen. Blue sclerae may also be seen in other conditions.

Dentinogenesis Imperfecta

Improper deposition or deficiency of dentine leads to yellowish brown or translucent bluish grey colour of teeth. The enamel generally appears normal. The deciduous teeth are usually smaller than normal, whereas permanent teeth are frequently bell-shaped and restricted at the base. These discoloured teeth may also fracture and need to be extracted.

Hearing Loss

The middle ear usually exhibits maldevelopment, deficient ossification, persistence of cartilage in areas that are normally ossified, and abnormal calcium deposits. This usually presents as hearing loss beginning during the second decade of life and occurs in more than 50% of individuals over age 30. The loss can be conductive, sensorineural or mixed and varies in severity.

Associated Features

Thinning of skin that scars extensively, joint laxity, cardiovascular manifestations such as aortic regurgitation, floppy mitral valves, mitral incompetence, and fragility of large blood vessels can also be seen. Short stature is the most prevalent secondary feature of OI.

Cardiopulmonary complications of osteogenesis imperfecta are the major cause of mortality directly related to the disorder. There is a high frequency of basilar invagination (BI) in patients with severe osteogenesis imperfecta, which is an upward displacement of vertebral elements into the foramen magnum. It may lead to static or dynamic stenosis of the foramen magnum, and compression of the medulla oblongata. Children should be screened by CT every 2-3 years, and followed annually by MRI if radiographic signs of BI develop.

Pathogenesis

OI results from a qualitative or quantitative defect in the type 1 collagen, which is the most abundant protein in bone. This is generally caused by mutations in the genes encoding for type 1 procollagen.

Diagnosis

Diagnosis is usually made on the basis of clinical criteria. The presence of fractures together with blue sclerae, dentinogenesis imperfecta, or family history of the disease is usually sufficient to make the diagnosis. The characteristic radiological features are decreased bone density, modelling defects of long bones and deformities caused by recurrent fractures. Osteogenesis imperfecta is frequently associated with either relative or absolute macrocephaly. Individuals with OI frequently have relatively long arm span for length and a shortened lower segment (pubis to floor). Elevated serum alkaline phosphatase, hypercalciuria and increased urinary excretion of hydroxyproline have also been noted. The mutation in type I procollagen gene can also be identified and if done in an individual patient, a simple test based on the polymerase chain reaction (PCR) can be used to screen family members at risk and for prenatal diagnosis. A lateral view of the skull should also be obtained to detect wormian bones.

Treatment

The recurrent fractures require orthopaedic care including surgical management, and in some instances, physical and rehabilitative therapy.

Treatment with bisphosphonates to decrease bone loss has been found to be helpful although long-term effects are not completely understood. Systemic infusion of stromal cells from bone marrow that can differentiate into osteoblasts and bone marrow transplantation from a HLA compatible donor have been tried. Growth hormone therapy has been found to increase growth in a small number of children with OI. Management of pneumonia and cor pulmonale is done as in any other patient but more aggressively. For severe hearing loss with stapedectomy or replacement of the stapes with a prosthesis may be required.

Prenatal Diagnosis

It can be diagnosed by ultrasonography at 18 to 24 weeks' gestation. DNA sequencing on chorionic villus sample (CVS) biopsies is possible. Cultured CVS cells can be used for DNA or RNA extraction and detection by either PCR and restriction enzyme digestion or sequencing. Appropriate genetic counselling is then required.

Fibrous Dysplasia

It is discussed in Chapter on 'Miscellaneous Bone Disorders'.

Achondroplasia

Achondroplasia is the commonest form of short-limb dwarfism. It is characterised by the presence of short limbs (particularly the proximal portions), normal trunk, large head, frontal and parietal bossing and flattening of the occiput, saddle nose, and an exaggerated lumbar lordosis. The tip of the nose is fleshy, with upturned nostrils. All the bones are affected but abnormal configuration of the skull, lumbar spine and pelvis are hallmarks of the disease. Radial heads may be dislocated and posterior scalloping of the vertebral bodies and dorsolumbar kyphosis is seen. Severe spinal deformity may lead to cord compression.

The disease is caused by a mutation of the fibroblast growth factor receptor 3 (FGFR3) gene that results in a gain-of-function state. The primary defect is abnormal chondrocyte proliferation at the growth plate that causes development of short but proportionately thick long bones. Other regions of the long bones may be relatively unaffected. This disorder has an autosomal dominant inheritance, but sporadic mutations also may be seen. Pseudo-achondroplasia clinically resembles achondroplasia but has no skull abnormalities.

8.6 Miscellaneous Bone Disorders

CV Harinarayan

PAGET'S DISEASE (OSTEITIS DEFORMANS)

Paget's disease of bone is a chronic skeletal disorder which may result in enlarged and/or deformed bones in one or more regions of the skeleton. The disease is characterised by abnormal bone turnover, structure and architecture. It was first described by James Paget in 1877. This disorder is quite common in Europe, North America, Australia and New Zealand. There are occasional cases reported from India.

Definition

It is a focal disorder of accelerated (anarchic) skeletal remodelling due to increase in osteoclastic activity and bone resorption followed by excessive bone formation resulting in an abnormal highly vascularised bone that is structurally disorganised, with an excess of fibrous connective tissue. It is the second most common disease after osteoporosis in Western population. Raised alkaline phosphatase in the presence of classical radiological picture is diagnostic of Paget's disease and is further substantiated by bone scan and/or bone histology.

Aetiology

Genetic and environmental factors are implicated in the pathogenesis. Environmental factors may be due to viral pathogen belonging to paramyxovirus group, such as measles virus. This disease has a strong genetic predisposition and several genetic loci have been linked to familial Paget's disease. It has autosomal dominant transmission. Different predisposition loci have been identified on chromosome 18 and on chromosome 6. Recently, many susceptible loci (2q36, 5q31, 5q35, 10p13) have been described.

Pathogenesis

Little is known about its pathogenesis. Characteristic feature is increased resorption of bone accompanied by increased formation. In early phase, bone resorption predominates and bones are very vascular. Excessive bone resorption is followed closely by formation of new pagetic bone. With decline in disease activity, there is decrease in bone resorption relative to formation leading to development of hard, dense, less vascular bone.

Clinical Features

The disease affects both sexes with male predominance. Age at presentation is fourth and fifth decades of life. The clinical features include bone pains, joint pains, skeletal deformities, low backache, fractures, painless swellings, skull enlargement, headache, deafness, visual impairment, loss of facial sensation, difficulty in biting, ataxic gait, neurogenic claudications and renal stones. Paget bones are fragile and susceptible to fractures with trivial trauma. In patients with skull involvement increase in size of head as reflected by increase in hat size, increased sweating and warmth over skull due to increased vascularity are seen. Paget's disease can lead to wide pulmonary artery pressure and high output failure.

Biochemical Features

Calcium and phosphorus levels are within normal range with raised alkaline phosphatase levels. Markers of bone turnover such as urinary N-telopeptide, urinary hydroxyproline/creatinine and urinary and serum deoxypyridinoline, C-telopeptide are increased. Hyperuricaemia may be present.

Radiological Features

The most commonly affected bones are the pelvis, lumbar vertebrae, skull, femur and tibia. Small bones in the hands and feet are seldom affected. The disease may be uni- or multi-focal (mono-ostotic or poly-ostotic) in distribution. Radiologically, Paget's bone consists of focal area of osteolysis which has blade of grass or candle-flame appearance. Unique radiological features differentiate Paget's disease from other bone diseases. The radiological features follow the histological findings on light microscopy. The correlation of the different phases with the clinical, radiological and pathological features of Paget's disease allows accurate diagnosis and treatment. These features can be divided into three phases: initial phase, mid phase, and late phase.

In the initial or active phase (osteolytic), skull shows osteoporosis circumscripta, especially of the frontal and occipital bones. In the long bones, there is a well-defined, advancing radiolucency with a V-shaped margin which begins subarticularly. In the mid phase, there are osteolytic and sclerotic lesions of the skull, pelvis and long bones. In the late or inactive (osteosclerotic) phase, there are 'cotton wool' areas of sclerotic bone. The spine shows enlargement of the vertebrae. Cortical thickening produces the 'picture frame' vertebral body or the 'Ivory vertebra'. Affected vertebral bodies have an almost 'bone within bone' appearance. Pelvis shows widening and coarsened trabeculation of pelvic ring with splitting of iliopectineal line. In late phase, the long bones show sclerosis with coarse and thickened trabeculae. Cortical thickening gradually encroaches the medullary canal and the epiphysis is nearly always involved.

The unusual radiological presentations of Paget's disease include unusual disease progression, massive post-immobilisation lysis, metastatic spread to Pagetic bone, and vertebral end-plate destruction that mimics infection. The radiological picture of Paget's disease before and after treatment is shown in **Figure 1**. The bone involvement as seen in Indian population is given in **Table 1**.

Bone Scan Features Tc-99m (MDP)

The scintigraphic uptake pattern ranges from diffuse uptake in a relatively early mixed phase to a mottled uptake pattern of the late sclerotic phase (**Figure 2**). Bone lesions begin at metaphyseal region and extend into diaphysis towards the

other end. Intense uptake in long bones involving one end to mid-shaft or further suggests Paget's disease. The 'butterfly' pattern of vertebral involvement suggests Paget's disease, which affects the entire vertebral body rather than metastatic disease, which has predilection for the pedicles.

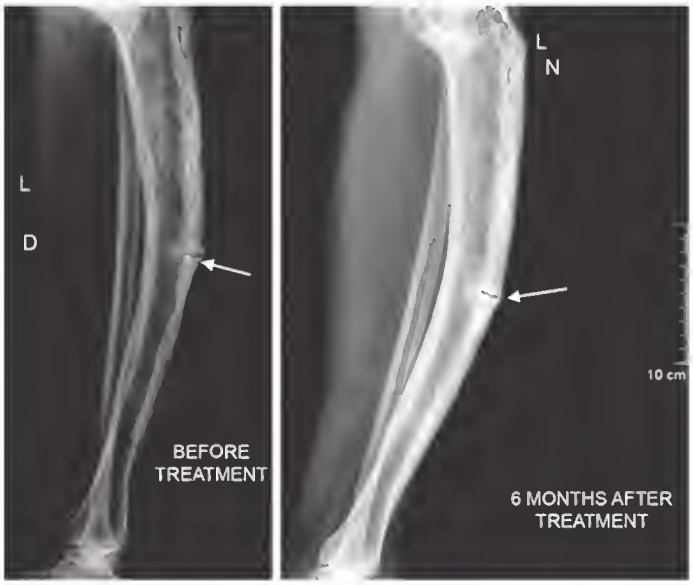

Figure 1: Radiological appearance in Paget's—pre- and post-therapy.

Table 1: Skeletal Site Involvement in Patients with Paget's Disease

Site of bone involvement	Cases (Percentage)
Skull	60
Spine	60
Pelvis	40
Femur	35
Tibia	18
Fibula	8-10
Ulna	9
Radius	10
Scapula	10
Sacrum	10
Clavicle	6

Complications

Hyperuricaemic gout and deafness are relatively common. An enlarged skull can lead to headaches or hearing loss. If the spine is involved, enlarged vertebrae may cause compression of the spinal cord or nerve roots. Secondary osteoarthritis, radiculopathy and renal stones are also seen. Bones can soften and lead on to bowed bones, basilar invagination and protrusio acetabuli. Transverse fractures with a predilection for the convex aspect of the bone, osteomyelitis and extra-medullary haematopoiesis are seen. Osteosarcomas or other types of sarcomas occur in less than 1% of patients with Paget's disease and carries a poor prognosis. High output cardiac failure can occur.

Treatment

Since the major defect is exaggerated bone remodelling, the treatment is based on the use of bisphosphonates. Bisphosphonates suppress or reduce bone resorption by osteoclasts. These include pamidronate given intravenously or

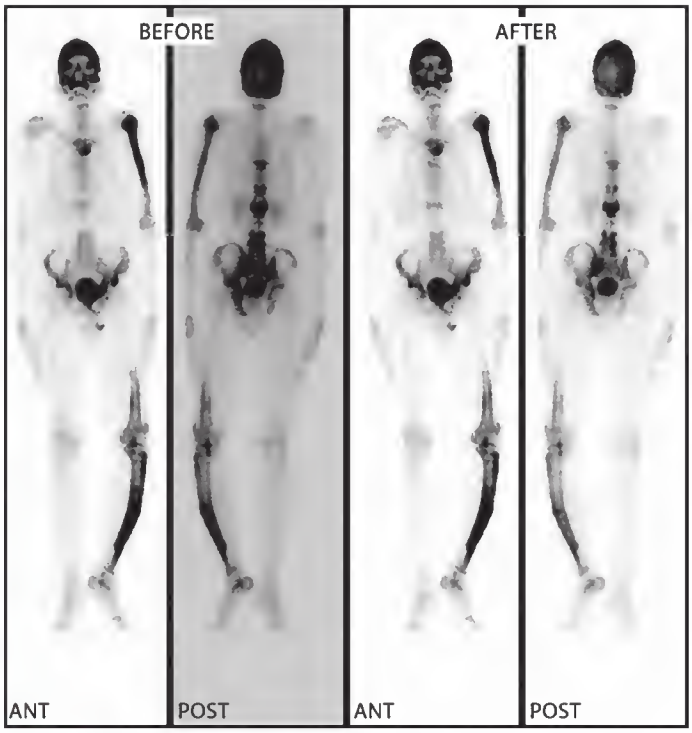

Figure 2: Nuclear scan of patient with Paget's disease before and 6 months after the treatment.

etidronate, tiludronate, alendronate and risedronate given orally. Zolendronic acid is said to produce more rapid, more complete and more sustained response. Calcitonin is now infrequently used. Non-pharmacological measures for pain management and surgery are used when indicated.

Prognosis

The disease is slowly progressive and the course can vary from stable to rapid progression. The outlook is good if the treatment is given early before major complications set in. The treatment can control the symptoms but not cure the disease and duration of the disease.

McCUNE-ALBRIGHT SYNDROME (FIBROUS DYSPLASIA)

McCune-Albright syndrome (MAS) is a triad of poly-ostotic fibrous dysplasia (FD), *Café-au-lait* skin pigmentation and endocrine disorder. The disease may present as mono-osototic, poly-ostotic or MAS and its variants or even panosteotic (entire skeleton). Mono-osototic form is the commonest.

Pathophysiology

It is mediated by activating mutation in the receptor associated heterotrimeric G protein $G_s\alpha$. The effect of $G_s\alpha$ results in hyperphosphaturic hypophosphataemia leading on to rickets and osteomalacia. The pathological effects of $G_s\alpha$ mutation in osteogenic cells are most pronounced during the rapid phase of growth. Thus, the disease is commonly present in childhood or adolescence.

The multiple endocrine hyperfunction and possibly fibrous dysplasia is due to defect in the G protein-cyclic AMP-protein kinase A-dependent pathway. Activating mutation in the G protein stimulates adenyl cyclase $G_s\alpha$. This signal transduction induces end-organ hyperfunction. It is of interest to note that the defect in Albright's hereditary osteodystrophy (pseudo-hypoparathyroidism) is converse to that found in MAS.

In Albright's hereditary osteodystrophy, the mutation in $G_s\alpha$ proteins results in deficient activity and decreases responsiveness to hormones mediated through cAMP-mediated signal transduction.

Clinical Picture

Clinical course is variable and depends on the skeleton involved. The disease is detected because of localised pain, deformities or fractures. The base of the skull and the proximal metaphysis of the femur are the sites commonly involved. Symptoms related to bone involvement include headache, seizures, hearing loss, narrowing of the external ear canal or even spontaneous scalp haemorrhages. Cutaneous pigmentation consisting of isolated dark-brown to light-brown macules on one side of the midline is seen. The borders are irregular or jagged (coast of Maine) in contrast to smooth borders of macules in neurofibromatosis (coast of California). The macules range from 1 cm to large areas, particularly the back, buttock or sacral region. When present in the scalp, the overlying hair may be more deeply pigmented than the remaining areas of the scalp.

Sexual precocity is common in females. Premature vaginal bleeding and development of breast, axillary and pubic hair are the main features. Hyperthyroidism is a common associated endocrine abnormality. Sexual precocity and adrenal and thyroid hyperfunctions associated with fibrous dysplasia are due to autonomous end-organ activity and not due to pituitary or hypothalamic dysfunction. Some subjects can have features of high cardiac output similar to Paget's disease.

Radiology

Radiographically, the lesion is limited to metaphysis or extends along the diaphysis for variable length. In children and adolescents, the picture consists of expansile, deforming medullary lesion with cortical thinning and an overall 'ground-glass' density. Femoral disease can present with fracture and deformity ranging from coxa vara to the classical 'Shepherd's crook deformity' of the femur, bowing of tibia, Harrison's grooves and protrusio acetabuli. Advanced skeletal age is correlated with skeletal precocity. Before puberty the lesion spares the epiphyseal region but involves the epiphysis in older individuals. Sclerosis in the lesion suggests less active disease. Involvement of facial bones usually with increased radiodensity may create leonine appearance (leontiasis ossea). The presentation in childhood may be with facial asymmetry or a 'bump' that persists, but symmetrical expansion of the malar prominences and/or frontal bosses may also be seen. Abnormal growth and deformity of the craniofacial bones may result in encroachment of cranial nerves. Involvement of temporal bones can cause progressive loss of hearing. Malignancy is very rare. Fibrous dysplasia and Paget's disease of the bone are two disorders that can cause a bone to become larger than normal.

Diagnosis and Management

Diagnosis is based on expert assessment of clinical, radiological and histopathological features. The extent of the disease must be assessed to predict the functional outcome. The metabolic derangements especially hypophosphataemia and growth hormone excess worsen the clinical outcome and should be assessed. Calcitonin may be effective in treatment of widespread disease associated with bone pain and high serum alkaline phosphatase.

OSTEONECROSIS OF THE JAW

Osteonecrosis of the jaw is an extremely painful condition, characterised by bone erosions and exposure of the bone which affects the mandible or maxillary bones. Inhibition of osteoclasts by bisphosphonates is hypothesised to disrupt the critical balance between the osteoclast and the osteoblast. In situations where healing of the bone is necessary, after chronic inflammation and infection associated with gum disease, disruption of the dynamic process of bone resorption and formation could contribute to the development of osteonecrosis of the jaw. In addition to chronic bisphosphonates therapy, it is associated with oral fungal infections, trauma, herpes zoster and radiation therapy.

BONE LOSS WITH CANCER THERAPIES

Chemotherapy, hormonal therapy and radiation have improved the survival rates in patients suffering from malignancies but they carry significant side effects.

Oestrogens play a key regulatory role in bone remodelling through oestrogen receptors (ER). Current breast cancer therapies decrease the circulating oestrogen levels by blocking or downregulating the receptor itself. Some agents do disrupt the oestrogen-skeleton axis leading to decreased bone mineral density, and increased risk of osteoporosis and fracture. There are two major classes of aromatase inhibitors; the non-steroidal reversible inhibitors, anastrozole and letrozole; and steroid irreversible inhibitors, exemestane. Both classes of aromatase inhibitors result in bone loss to some extent.

Prostate cancer patients with metastasis often receive palliative therapy in the form of androgen deprivation therapy (ADT) which includes surgical castration, pharmacological castration with LHRH agonists and antiandrogen therapy with agents like flutamide, nilutamide, bicalutamide or cyproterone. One of the potential complications with castration or LHRH agonist therapy is the decrease in bone mineral density.

Radiotherapy is also known to induce fractures. Rib-fracture after X-ray exposure is a potential complication of radiotherapy used for breast cancer. Brachytherapy (radiotherapy) for non-metastatic carcinoma prostate patients can lead to pelvic fracture.

9.1 Epidemiology and Basic Considerations of Diabetes

A Ramachandran, C Snehalatha

DEFINITION OF DIABETES MELLITUS

Diabetes mellitus is a metabolic disorder of multiple aetiology, characterised by chronic hyperglycaemia with disturbances of carbohydrate, fat and protein metabolism resulting from defects in insulin secretion, insulin action, or both. The long-term effects of diabetes include damage, dysfunction, and failure of various organs. The long-term effects include progressive development of retinopathy with potential blindness, nephropathy that may lead to renal failure, neuropathy with risk of foot ulcers, amputation, Charcot joints, and features of autonomic dysfunction, including sexual dysfunction. People with diabetes are at increased risk of cardiovascular, peripheral vascular, and cerebrovascular diseases.

DIAGNOSIS OF DIABETES

Clinical diagnosis of diabetes is made if a person has the symptoms, viz. polyuria, polydipsia, polyphagia, recurrent infections, unexplained weight loss and in severe cases drowsiness, coma and a casual plasma glucose concentration of ≥ 200 mg/dL or a fasting plasma glucose (FPG) of ≥ 126 mg/dL or a two hours post-glucose (2hPG) (75g load) of ≥ 200 mg/dL during an oral glucose tolerance test (OGTT). For clinical purposes, the diagnosis should always be confirmed by a repeat blood test on another day, unless there is unequivocal hyperglycaemia with acute decompensation or obvious symptoms.

Table 1 shows the diagnostic criteria for diabetes, impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) using capillary or venous plasma or whole blood. The diagnostic criteria are the same for adults or children. For children, a glucose load of 1.75 g per kg is used. For epidemiological studies, a single plasma glucose value measured after an overnight fast and/or 2hours after a glucose load can be used. In some populations, such as the Asians, the diagnostic sensitivity of the FPG is lower than that of the 2 hours PG. Pregnant women, who meet the WHO criteria for diabetes or IGT are classified as having gestational diabetes mellitus (GDM). After the pregnancy ends, the women should be tested with an OGTT, six weeks or more after delivery to reclassify the glucose tolerance.

CLASSIFICATION OF DIABETES MELLITUS

Type 1 Diabetes

Type 1 diabetes, formerly called juvenile diabetes, is usually diagnosed in children, teenagers, and young adults. Type 1 diabetes may develop in adults also. This is an autoimmune disease causing specific destruction of β-cells of pancreas which results in an absolute insulinopaenia.

Type 2 Diabetes

Type 2 diabetes, formerly called adult onset diabetes, is the most common form and has an insidious onset. It remains asymptomatic for many years. It is commonly seen in adults, but can occur even in childhood. Weight loss is uncommon unless hyperglycaemia is severe while ketosis is rare. Familial inheritance is very common. This form of diabetes usually begins with insulin resistance and initially there is a counter regulatory hyperinsulinaemia. With time, the pancreas loses its ability to secrete enough insulin in response to meals and clinical diabetes develops.

Table 1: Values for Diagnosis of Diabetes – (WHO 1999)

	Venous Plasma	Whole Blood Venous	Whole Blood Capillary
	Glucose Concentration in mg/dL		
Diabetes Mellitus:			
Fasting	≥126	≥110	≥110
2-hour PG	≥200	≥180	≥200
Impaired glucose tolerance (IGT):			
Fasting (if measured)	<126	<110	<110
2-hour PG	≥140 to <200	≥120 to <180	≥140 to <200
Impaired fasting glucose (IFG):			
Fasting	≥110 to <126	≥100 to <110	100 to <110
2-hour PG (if measured)	<140	<120	<140

To convert mg/dL to mmol/L, divide mg/dL by 18.

Gestational Diabetes

Gestational diabetes is carbohydrate intolerance resulting in hyperglycaemia of variable severity with onset or first recognition during pregnancy. It does not exclude the possibility that the glucose intolerance may antedate pregnancy but has not been previously recognised.

Other Types of Diabetes

A number of other types of diabetes exist which develop due to:

- Genetic defects of the β-cell,
- Genetic defects in insulin action,
- Diseases of the pancreas,
- Excess amounts of counter regulatory hormones,
- Infections,
- Rare autoimmune disorders, and
- Genetic syndromes associated with diabetes.

AETIOLOGY AND RISK FACTORS

Diabetes, either type 1 or type 2, has equally strong genetic and environmental risk factors, an interaction of which leads to the clinical expression of the disease. The genetic susceptibility for type 1 is associated with certain human leucocyte antigen (HLA) combinations (DR3+DR4) and the environmental insults are rather ill defined. Possibility of some aspects of diet and viral infections triggering an autoimmune exposure causing specific destruction of the β-cells of pancreas has been proposed.

Type 2 diabetes has a more complex aetiopathology. Though it has a strong genetic basis, as shown by its hereditary nature,

the major susceptibility genes have not yet been identified. Racial predisposition as seen in Asian populations, also is common. The environmental factors showing strong association with diabetes are increasing age, family history of diabetes, obesity, unhealthy diet, physical inactivity, insulin resistance, adverse intrauterine environment, and stress factors.

The pathophysiology of type 2 diabetes includes, impaired insulin secretion, impaired insulin action, insulin resistance and impaired incretin effect on the β-cell function and non-suppression of the action of α-cells, with rising blood glucose levels.

EPIDEMIOLOGY

Type 1 Diabetes

Type 1 diabetes is one of the most common metabolic disorders which occurs due to an absolute insulin deficiency. The disease shows an acute onset, with severe symptoms including weight loss. Positive family history of diabetes is rare and ketonuria is common. The patients are dependent on exogenous insulin for metabolic control and survival. The Diabetes Mondiale Study (DIAMOND) and the Europe and Diabetes Study have established population based national registries using standardised methods. There are wide geographic differences in the prevalence and incidence of type 1 diabetes. Finland has the highest number of patients with type 1 diabetes. The estimated global number of children (0 to 14 years) with type 1 diabetes is 4,80,000 and annually approximately 76,000 children develop the disease. Data from developing countries is sparse.

Type 2 Diabetes

The global burden due to diabetes is mostly contributed by type 2 diabetes which constitutes 80% to 95% of the total diabetic population. Diabetes mellitus is the most common metabolic disease which is prevalent in every part of the world and is a major public health challenge of the twenty-first century. The explosive increase in the prevalence of diabetes seen in the last three decades poses huge clinical and economic burden in many countries. The estimates by the International Diabetes Federation (IDF) show that 285 million adults (20 to 79 years) are affected by the disorder in 2010. Epidemiological trends indicate that without proper control and prevention, its prevalence will increase further to 438 million in 2030. This accounts for a global increase by 54%, i.e. a rise from a prevalence of 6.6% to 7.8% in 20 years. Nearly 70% of the people with diabetes live in developing countries; the largest numbers are in the Indian subcontinent and China. Nauru has the highest prevalence of diabetes (30.9%) and will continue to be so in 2030 (33.4%). Many Arab countries, Tonga, and Malaysia are among the top ten countries having high percentages of people with diabetes. There is little gender difference in the distribution in the number affected with diabetes. The largest numbers with diabetes are in the 40 to 59 age groups (132 million, in 2010) which is expected to rise further. By 2030, there will be more diabetic people in the 60 to 79 age groups (196 millions).

Children with Type 2 Diabetes

Type 2 diabetes in children is becoming common in many countries, especially so among Asian populations. There is little data about the onset and progress of complications in these children. Occurrence of cardiovascular diseases (CVD) is dependent on the duration and hence, there are no data available in children. Data from Japanese and Pima Indian children indicate presence of microvascular diabetic complications even at the time of diagnosis and with a short period of follow-up.

Gestational Diabetes

Gestational diabetes mellitus (GDM) is common in many populations, including Asian Indians. Pregnant women should be tested for GDM, in 24 to 28 weeks of gestation. GDM is a pre-diabetic state with an increased risk of development of the disorder in the subsequent pregnancies, in 60% to 90%. It is also known that women with GDM have a high-risk (up to 30%) of developing diabetes within 7 to 10 years after the index pregnancy.

Asian Scenario

The rising trend in prevalence of diabetes is evident globally. The changes are marked in developing countries, particularly in the Asian continent. Increasing levels of urbanisation, industrialisation and economic advancements adversely affect the biological, and environmental risk factors for diabetes and other non-communicable diseases. Unhealthy diet, physical inactivity and stress factors cause overweight/obesity and insulin resistance. Asian populations, particularly people of the Indian subcontinent have a strong genetic predisposition for diabetes. They also have high levels of insulin resistance and also have a low threshold for risk factors such as age, body mass index, and upper body adiposity. Both thrifty genotype and thrifty phenotype appear to operate in them. Clustering of cardiovascular risk factors, the metabolic syndrome is common in these populations, at a young age itself.

PREVALENCE OF DIABETES IN INDIA

The prevalence of diabetes in India in 1970's was 2.3% in urban and 1.5% in rural areas, as shown by the multi-centric study by the Indian Council of Medical Research (ICMR). In 2000s, the prevalence has risen to 12% to 19% in urban areas and to 4% to 9% in rural areas. A study from rural Andhra Pradesh reported a prevalence of 13.2%. Though, the studies are not strictly comparable due to methodological differences (**Table 2**) the rising trend in prevalence of diabetes in urban and rural areas in India, is evident. The narrowing of urban, rural divide in the prevalence is due to the rapid urbanisation and socio-economic transitions occurring in rural areas also.

India which has a large pool of pre-diabetic subjects (IGT and IFG) shows a rapid conversion of these high-risk subjects to diabetes. The Indian Diabetes Prevention Programme-1 (IDPP-1) has shown an annual incidence of approximately 18% among subjects with IGT.

National studies or population based studies on diabetic complications are sparse in India. A few population based studies indicate the prevalence of retinopathy to be 18% to 27.0% and overt nephropathy to be about 2.2% with a large percentage (27%) having microalbuminuria. Peripheral vascular disease is prevalent in 6.3%, peripheral neuropathy in 26%, and coronary artery disease (CAD) is detected in 21%.

The major contributory factors for the high prevalence of the complications are; delayed diagnosis of diabetes, inadequate control of glycaemia, hypertension, and lack of awareness about the disease among majority of the public.

ECONOMIC BURDEN DUE TO DIABETES

The cost of diabetes care is high and is escalating world wide. It is estimated by the WHO that the global expenditure for diabetes care would increase from 234 billions in 2007 to 411 billions in the next 20 years. The WHO estimate is based on lost productivity due to diabetes, heart diseases, and stroke together show that over the next 10 years, lost national income in billions of USD will amount to 555.7 in China, 303.2 in Russian Federation, 336.6 in India, 49.2 in Brazil, and 2.5 in Tanzania.

A study by us in India showed that the median expenditure had risen from INR 4,200 (USD 95) to INR 9,000 (USD 203) between 1998 to 2005. The indirect cost is more difficult to assess and is much higher than the direct cost. The proportion of annual income spent on health care is about 25% to 30% by the poor people. The cost increases many fold when diabetic complications are present.

PRE-DIABETES

Type 2 diabetes is a lifestyle disorder and an interaction of genetic and environmental factors precipitates the metabolic abnormalities existing in pre-diabetic subjects to the clinical stage of diabetes. There is a long asymptomatic pre-diabetic stage(s) before the development of diabetes. These stages are easily identifiable by OGTT. For the development of diabetes, both the basic pathophysiological defects, i.e. insulin resistance and β-cell secretory defect have to co-exist.

The definition of IGT has been stable. The American Diabetes Association (ADA) recommends that the normal cut-off for FPG of < 100 mg/dL. Both IGT and IFG have heterogeneous pathogenesis and hence may have different rates of progression to diabetes. People with combined IFG and IGT have approximately double the rate of conversion to diabetes than those with any one of the abnormalities. Both the states are associated with insulin resistance and other cardiovascular risk factors such as dyslipidaemia and hypertension. IGT is shown to be a stronger risk predictor than IFG.

PREVENTION OF DIABETES

Several systematic long-term prospective studies from different parts of the world have shown that type 2 diabetes is largely preventable. Although the genetic factors cannot be modified, its interaction with the diabetogenic environmental factors can be prevented by modifying obesity, diet, and physical activity. Indian Diabetes Prevention Programmes (IDPP-1 and IDPP-2) have shown that by improving physical activity and by using healthy diet, incidence of diabetes can be significantly reduced with a relative risk reduction of ~ 30%, in persons with IGT. Metformin in small doses was also found to be effective in primary prevention of diabetes.

Lifestyle changes due to urbanisation and modernisation have caused unhealthy diet habits, lack of physical activity, and increased stress leading to overweight or obesity with higher levels of insulin resistance. India and many other developing countries are going through this scenario and as a result, we notice more of chronic metabolic disorders than communicable diseases posing increasing challenge to the national health.

9.2 Pathogenesis of Type 1 Diabetes Mellitus

V Mohan, Rakesh Parikh

Understanding the pathogenesis of type 1 diabetes mellitus (type 1 DM) is crucial for developing preventive strategies. However, despite much research, it still remains largely unclear. As per current understanding, type 1 DM develops in people who are genetically predisposed. In addition, certain environmental triggers start the process of autoimmune destruction leading to complete β cell destruction and insulinopaenia that is characteristic of type 1 DM.

It is estimated that 50% to 90% of type 1 DM patients have evidence of auto-antibodies and they are labelled as type 1A DM or autoimmune type 1 DM while the remaining are called type 1B DM or idiopathic type 1 DM. The prevalence of type 1B DM is reported to be 5% to 10% in Caucasian populations. Though limited data is available on type 1 DM from India, in one study as much as 45% of recently diagnosed subjects were found to have idiopathic or type 1B DM. Though the exact pathophysiology is unknown for this subtype, various factors like viral infection, toxins, subclinical pancreatitis or some unidentified genetic defects might be responsible.

The pathogenesis of type 1 DM will be discussed here under the subheadings of genetic factors, environmental triggers and autoimmune destruction. As per the current understanding most of the type 1 diabetic subjects have some or the other genetic predisposition, though alone it is not sufficient to cause type 1 DM. In such genetically predisposed subjects, one or the other environmental trigger sets the process of insulitis. Its only after the β-cells are destroyed critically enough to cause insulinopaenia, that the subject might present with classical symptoms of type 1 DM. As the environmental triggers are highly unpredictable, routine screening in genetically predisposed subjects (first degree relatives of type 1 DM patients) have not been shown to be cost effective.

GENETIC FACTORS

Several studies have shown familial clustering of type 1 DM with siblings of type 1 diabetic subjects having a risk of 5% to 6%, while the risk of transmission of type 1 DM from parents is about 10%. The greatest risk is provided by an identical (monozygotic) twin with type 1 DM. The concordance rate even for monozygotic twins is only in the range of 25% to 50% while that of dizygotic twins is much lower. This suggests that in addition to genetic factors, there is a strong role for environmental factors in the development of type 1 DM.

The inheritance pattern of type 1 DM is complex and polygenic. Ongoing research over the last few decades has identified at least 20 candidate genes associated with type 1 DM. Different candidate loci are named with a prefix of IDDM, viz. IDDM 1, IDDM 2 and so on (**Table 1**). Among these, two chromosomal regions have emerged consistently across multiple studies. These are the human leucocyte antigen (HLA) region located on chromosome 6p21.3, and the Insulin gene region on chromosome 11p15 and these are labelled as IDDM 1 and IDDM 2, respectively.

Table 1: Genetic Loci Associated with Type 1 Diabetes Mellitus

HLA MOLECULE AND IDDM1 GENE

IDDM 1 (genes encoded within HLA region) remains the most powerful determinant of type 1 DM accounting for approximately 40% of familial inheritance of the disorder.

HLA Molecules

HLA are glycoproteins found on the surface of cells. They are comprised of class I and class II, both being encoded by different genes within the HLA region of chromosome 6. Class I molecules are found on surface of all nucleated cells and are involved in the 'restriction' of cytotoxic T lymphocyte activity. The antigen

peptides are recognised by CD8+ T lymphocytes only when they are presented along with HLA molecule. Class II molecules are normally confined to antigen presenting cells such as macrophages, B lymphocytes and activated T lymphocytes. Class II molecules are comprised of α and β chains which bind to foreign and self antigens in a cleft on the surface of molecule to be presented to CD4+ helper T lymphocytes.

Owing to the crucial role played by HLA molecules in immune response, any alterations in their structure might influence the predisposition to autoimmune disorders. The genes for class I HLA are encoded in HLA, A, B and C loci while that for class II are located on HLA, DP, DQ and DR regions.

The first evidence of allelic association between the HLA complex and type 1 DM was reported for the HLA-B15 allele and was based on serology. In subsequent studies, a positive association of type 1 DM with HLA-B8 and a negative association with HLA-B7 were established. Higher risks were shown to be associated with HLA class II specificities, namely DR3 and DR4, whereas DR2 (now renamed DR15) was shown to be protective. More than 90% of white Caucasian patients with type 1 DM have DR3 and/or DR4 as compared with 40% to 50% of controls. The greatest risk of type 1 DM is conferred by the simultaneous presence of DR3 and DR4, which are found together in 30% to 50% of patients but in only 1% to 6% of controls.

Recent molecular studies indicated that the primary susceptibility genes are situated in the HLA-DQ rather than the DR region. In white Caucasians, the DQA1*0301, DQB1*0302 (DQ8) allele (associated with DR4) and DQA1*0501-DQB1*0201 (DQ2) allele (associated with DR3) have the strongest association with type 1 DM. In contrast, DR2 and DQ6 (DQA1*0102-DQB1*0602) provide protection against the development of type 1 DM.

North Indian data suggests the strongest association is with DR3 unlike in south Indians where both DR3 and DR4 are associated with type 1 DM. Data from Orissa shows that DRB1*03 and DQ2 (DQA1*501, DQB1*0201), but not DR4 and DQ8, was significantly increased in patients with type 1 DM.

IDDM2

IDDM2 has been mapped to 5' end of insulin gene with variable number of tandem repeats (VNTR). IDDM2 contributes to 10% of familial inheritance. The class I allele of IDDM2 is associated with development of type 1 DM while class III is protective.

As shown in **Table 1**, there are several other genes associated with type 1 DM but these play a relatively minor role.

ENVIRONMENTAL FACTORS

Identification of the exact environmental trigger in any given case of type 1 DM is difficult owing to the larger number of environmental triggers. Epidemiological studies have suggested differences in incidence rates even among countries with similar genetic make-up, like Finland and Estonia or Norway and Iceland. Pointing to the role of environmental factors, it is of interest that children of Asian origin who moved to UK (traditionally having a low risk of type 1 DM) now have incidence rates approaching that of local white population strongly suggesting that environmental factors modulate the risk of developing type 1 DM. The incidence of type 1 DM is increasing in many countries, e.g. in Europe there has been an overall increase of 3.4% per year and even higher increase (6.3% per year) in children below 5 years of age. This sharp rise in incidence rates over a short period of time suggests the role of changing environmental factors operating in early life. Finally, seasonal variations in occurrence of new onset type 1 DM also suggest the role of environmental triggers for type 1 DM. Among the various environmental factors studied viruses and dietary factors have been reported and these are discussed below.

Viruses

Recently diagnosed type 1 DM patients may show serological or other evidence of viral infection. There are a few case reports of type 1 DM being diagnosed during or soon after viral infection. Viruses can damage β-cells either directly by cytolytic effects or indirectly by an autoimmune response that is initiated or enhanced by a viral infection. In certain patients in whom β-cell destruction is going on, viral infection can act as a terminal insult destroying a critical number of residual β-cells. A few of the viruses implicated in development of type 1 DM are described below.

Mumps virus

This was one of the first viruses implicated in the development of type 1 DM. Some children with mumps parotitis develop islet cell antibodies suggesting an autoimmune basis.

Coxsackievirus B

Coxsackievirus B is the virus implicated more often. It has been shown to have cytolytic activity on β-cells in animal experiments. Autoimmune mechanisms have also been suggested through cross reactivity of the virus with specific β-cell antigens. An alternative hypothesis of the virus acting as a 'bystander' activating autoreactive T cells against islet antigens has also been suggested.

Other viruses, like rubella, cytomegalovirus, retroviruses, Epstein-Barr virus, echoviruses, hepatitis A virus, varicella zoster, measles, polio, influenza and rotavirus have also been suggested to be associated with type 1 DM based on circumstantial evidence. Some viruses, such as lymphocytic choriomeningitis virus (LCMV) and mouse hepatitis virus also have been shown to be protective against type 1 DM in animal experiments.

Overall, the role of viruses causing type 1 DM is less recognised nowadays.

Dietary Factors

Nitrites and nitrates are common components in food and can react with amines and amides to produce nitrosamines and nitrosamides. The high incidence of type 1 DM in Sicily and Finland has been reported to be due to these compounds in drinking water. An increased incidence of type 1 DM in Icelandic boys was observed and linked to the consumption of smoked and cured mutton.

Exposure to cow milk early in life has been linked to the development of type 1 DM in humans particularly in Scandinavia. Some studies have suggested milk powder based diets to be diabetogenic.

Five to ten per cent patients with type 1 DM have coeliac disease. Wheat gluten has been found to be diabetogenic in BB rats.

In a Finnish study dietary supplementation of children with vitamin D was found to be protective against type 1 DM. Cod liver oil which is a good source of vitamin D, when taken during pregnancy has also been shown to be beneficial.

Other Factors

Bafilomycin A1 produced by *Streptomyces* (which are ubiquitous bacteria found in soil and tubers) could be a source of β-cell toxins. Other bacteria may also act as adjuvant to food antigens. It has been observed that heat killed bacteria or microbial products can act as an adjuvant.

AUTOIMMUNE DESTRUCTION

The strongest evidence to support autoimmunity as the ultimate pathogenesis comes from the presence of insulitis (presence of inflammatory cells consisting of T lymphocytes, B lymphocytes, and macrophages) around the islets in recently diagnosed patients of type 1 DM. Fifty per cent to ninety per cent of type 1 DM patients have presence of antibodies against, islet cells (ICA), glutamic acid decarboxylase (GAD) 65, and IA2. Moreover type 1 DM has a strong association with other autoimmune disorders, like Hashimoto's thyroiditis, Grave's disease, pernicious anaemia, coeliac disease, etc. Subjects with genetic predisposition to type 1 DM, if exposed to certain environmental trigger, autoimmune destruction of β-cells starts. If the β-cells are destroyed to such an extent that the patient becomes insulinopaenic, he or she would develop hyperglycaemia and present with classical features of type 1 DM.

Cellular Immune Response

Type 1 DM is a T cell mediated disease. β-cells can become the target of CD8 T cells due to their close resemblance with other foreign antigens (e.g. virus), the immune response being directed towards the foreign antigen. Alternatively some virus may infect β cells and the viral proteins may get expressed over the β cells. In this case, the CD8 T cells directed against the virus, would attack the β-cells.

Humoral Response

Humoral response does not cause type 1 DM *per se* but is considered to be the result of insulitis. In the process of insulitis, islet cell antigens leak out of the damaged β-cells and initiate a humoral immune response. Islet cell antibodies (ICA), GAD 65 antibodies, IA-2 antibodies, and insulin autoantibodies (IAA) are produced. These antibodies can be detected in the subject long before development of type 1 DM as insulitis is slowly progressive disease. However, all subjects with ICA or GAD – Ab do not necessarily develop type 1 DM. Insulin antibodies carry a very small risk of type 1 DM, but its presence along with ICA increases the 5-year risk of type 1 DM to 50% to 70% particularly in childhood type 1 DM below 5 years of age. Presence of two or more antibodies suggests a greater risk of type 1 DM. Approximately 80% of patients with type 1 DM express two or more autoantibodies. Although around 3% of normal subjects might express one or more antibodies, the chances of having two or more antibodies being present in a normal subject, is less than 0.3%. Indians have a high prevalence of type 1B DM and hence absence of these antibodies does not rule out type 1 DM.

CONCLUSION

In subjects who are genetically predisposed to type 1 DM, certain, as yet, poorly defined environmental triggers initiate T-cell mediated immune response. With the development of insulitis, autoantibodies are produced, which can be detected long before the development of clinical type 1 DM. Insulitis is a slowly progressive disease and over a period of months or years, may cause complete destruction of β-cells (insulinopaenia) leading to clinical manifestation of type 1 DM (**Figure 1**).

9.3 Pathogenesis of Type 2 Diabetes Mellitus

Hemraj B Chandalia

INTRODUCTION

Simply stated, type 2 diabetes is caused by the interaction of certain genetic abnormalities with adverse environmental factors. To further identify the genetic and environmental factors and unravel the pathogenetic mechanisms is a daunting task. A clear picture is emerging in certain areas, while it is blurred in others. However, elucidation of these mechanisms holds the key to vast opportunities for therapeutic interventions.

GENETIC FACTORS

Type 2 diabetes is a polygenic disorder, caused by a cluster of susceptibility genes. It is very difficult to pinpoint these genes, as they may be present without the phenotypic manifestations or the disease may be seen at times in the absence of these genes. It is also possible that these genes vary in various ethnic groups. The classic method of candidate gene identification has been unsuccessful in unravelling these genes. The problem has also been approached by studying the functional candidate genes, tracing back the functional or biochemical abnormality to the genetic abnormality. Further, linkage analysis and micro satellite genotyping technique followed by positional cloning has been tried with limited success.

The genetic aetiology is clear in a group of monogenic type 2 diabetes (**Table 1**). Here the gene is clearly identifiable and the phenotypic presentation and treatment approaches well elucidated. Some of these genes operate by producing insulin resistance while others do so by producing a β-cell secretory defect. These forms of diabetes show an autosomal dominant inheritance, identified by a vertical transmission. Mitochondrial diabetes is maternally transmitted diabetes, caused by an A to G transition in the mitochondrial tRNA Leu (UUR) gene at base pair 3,243. The disease is associated with sensorineural hearing loss. The same genetic anomaly at times produces a syndrome of Mitochondrial myopathy, encephalopathy, lactic acidosis and strokes (MELAS), the different phenotypic expression of the same genetic anomaly is not yet well understood. Although the prevalence of these varieties of diabetes would vary in various ethnic groups, it is estimated that they do not make more than about 5% to 10% of young-age diabetes. Some rare genetic abnormalities described are insulin gene abnormality which produces an abnormal insulin or a convertase deficiency which impairs the conversion of proinsulin to insulin.

Abnormalities of insulin receptor are rare. They produce syndromes of extreme insulin resistance (type A insulin resistance, Leprechaunism, Rabson-Mendenhall syndrome; **Table 1**). If all these anomalies are put together, they may not make more than 1% of all type 2 diabetes.

The search for genetic abnormalities in the common form of type 2 diabetes has been very intense but not very fruitful. Most susceptibility genes described increased the hazard ratio in diabetics versus the normal population only marginally.

Of a variety of candidate genes, calpain-10, Kir 6.2, peroxisome proliferator activated receptor-γ, hepatocyte nuclear factor-4α gene and transcription factor 7-like 2 gene are important. Many of these genes predispose to obesity, thus leading to diabetes. However, an interesting gene, ENPP-1 K121Q causes insulin resistance in the non-obese Asian Indians and is one of the susceptibility genes in this population.

Table 1: Monogenic Forms of Type 2 Diabetes

Phenotype characterised by defective insulin secretion

Mutations in the insulin or proinsulin genes
Mitochondrial gene mutations
Phenotype characterised by insulin resistance
Mutations in the insulin receptor gene
Type A insulin resistance
Leprechaunism
Rabson-Mendenhall syndrome
Lipoatrophic diabetes
Mutations in the PPAR-γ gene

ENVIRONMENTAL FACTORS

Physical inactivity and excessive caloric intake are well recognised environmental factors producing type 2 diabetes. These factors can produce the disease independently in a genetically susceptible person, but usually work via production of obesity.

Obesity and type 2 diabetes are inextricably interrelated. They further coexist in the form of metabolic syndrome, together with other anomalies like hypertension, high triglycerides, and low HDL-cholesterol. It is estimated that 25% to 30% of the population in India and elsewhere suffers from the metabolic syndrome. In the shadow of a global spurt of obesity, type 2 diabetes is emerging as an epidemic.

Obesity results from the interaction of multiple susceptibility genes with environmental factors. By various estimates, aetiologically hereditary factors account for 50% to 70% of the obesity. Obesity is characterised by insulin resistance, an important feature of type 2 diabetes.

GENE-ENVIRONMENT INTERACTIONS

The mechanism of interaction of gene and environment is a very complex issue. The environmental factors interact by altering the expression of genes. There is also a gene-gene

interaction. Intrauterine environment also may influence the subsequent development of many non-communicable diseases like diabetes, obesity, and hypertension. Low birth weight, presumably due to poor maternal nutrition leads to development of insulin resistance in childhood and adult life. This is further exacerbated by over-nutrition in the post-natal period.

Epigenetic phenomenon, where unchanged DNA sequence can lead to altered phenotype, probably due to enhanced or suppressed expression of certain genes that may be responsible for obesity and diabetes Environmental factors may operate through epigenesis.

BIOCHEMICAL PERTURBATIONS

The biochemical perturbations in type 2 diabetes were described earlier than the genetic factors. Of these, the most well known abnormalities are of peripheral and hepatic insulin resistance, and impaired β-cell function.

Peripheral and Hepatic Insulin Resistance

With the advent of radioimmunoassay, massive data on serum insulin levels in obesity and diabetes became available. Hyperinsulinaemia was described first in obesity and later in type 2 diabetes, including type 2 normal weight diabetic. Thus, the concept of insulin resistance emerged. In spite of high insulin levels, there is poor glucose utilisation and insulin inaction in the muscle, adipose tissue, and liver.

In type 2 diabetes, adipose tissue in general and visceral fat in particular, exhibits a decreased inhibition of lipolysis and increased lipoprotein lipase activity, both resulting in a heightened flux of fatty acids in the liver and other tissues. High fatty acids levels are known to inhibit glucose utilisation, as demonstrated by Randle (glucose-fatty acid cycle). In type 2 diabetes and obesity, the adipose tissue also expresses increased amounts of 11β-hydroxysteroid dehydrogenase type 1 (11 β HSD-1), leading to increased cortisol levels and increased lipolysis locally. Adipose tissue is known to cause insulin resistance by secreting TNF-α and interleukins. Of the multiple adipose tissue hormones, resistin is responsible for insulin resistance, while adiponectin and leptin ameliorate insulin resistance. Although leptin levels are high in type 2 diabetes, there is also a state of leptin resistance. These biochemical abnormalities are accentuated in the abdominal adipose tissue, which is known to be abundant in type 2 diabetes. Interestingly, Asian Indians have increased adiposity even at a relatively low BMI, which may be one of the reasons for the increased type 2 diabetes. For this reason, the BMI above 23 kg/m^2 is also considered overweight in the Asian Indians, unlike the cut-off point of 25 kg/m^2 in the Caucasians.

The skeletal muscle glucose utilisation is impaired to a greater degree than adipose tissue in type 2 diabetes (**Figure 1**). In the post-prandial state, the glucose is primarily deposited as glycogen in the muscle. Hyperinsulinaemic-euglycaemic clamp studies have shown that the non-oxidative glucose disposal, like that in hexose monophosphate (HMP) shunt is severely impaired in type 2 diabetes and other insulin resistant states. The cause of this resistance is a high free fatty acid (FFA) concentration in the myocytes, as demonstrated in several studies by using a nuclear-magnetic resonance imaging. This would limit the glycogen synthesis through the HMP shunt. Recently, a defect in glucose transport has been described in the milieu of high fatty acids. In insulin resistant state, fatty acid oxidation or re-esterification leading to triglyceride synthesis is also impaired, thus leading to high levels of intra-myocellular FFA. On exercise, many of the abnormalities, including the diminished amount of glycogen synthase gets corrected, thus improving insulin sensitivity. Exercise increases glucose transporter activity, improves capillary density, increases mitochondrial mass, and increases type 2 A muscle fibres which are involved in the glycolytic process.

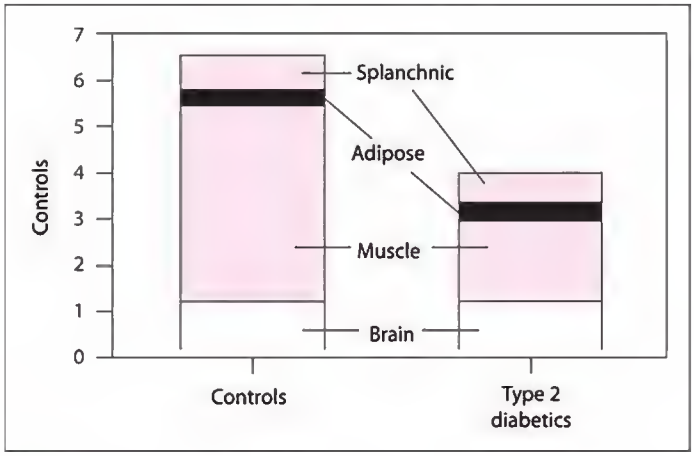

Figure 1: Diminished glucose utilisation in type 2 diabetics, primarily in the skeletal muscle.
Courtesy: DeFronzo RA. Lilly Lecture 1987: The triumvirate: beta cell, muscle, liver. A collusion responsible for NIDDM. Diabetes 1988; 37: 667-87.

The hepatic insulin resistance leads to enhanced gluconeogenesis and glycogenolysis. Thus, increased hepatic glucose production is a hallmark of uncontrolled diabetes. Type 2 diabetes is often associated with a fatty liver, with or without elevated liver enzymes and evidence of hepatic necrosis. It is also a manifestation of hepatic insulin resistance and is often reversed by weight loss and the use of insulin sensitisers.

The molecular mechanism of insulin resistance has been a subject of intensive studies (**Figure 2**). The resistance is very rarely due to an abnormal insulin or insulin receptor. Sustained hyperglycaemia produces glucotoxicity, probably by a failure to enhance hexosamine pathway, leading to increased glucosamine levels. Increased glucosamine levels can produce insulin resistance in adipose tissue and skeletal muscle. Sustained hyperinsulinaemia also down-regulates the insulin receptor and further aggravates insulin resistance. The main locus of the resistance appears to reside at the post-receptor level. Insulin signalling is initiated by the binding of insulin to alpha subunits of the receptors. This initiates a cascade of auto-phosphorylation and dephosphorylation through the intra-cellular tyrosine kinase, insulin receptor substrates (IRS-1, 2, 3, 4) and other signal regulatory protein family (Gab-1, Cb-1, CAP, APS).

The β subunit of insulin receptor has been shown to undergo besides tyrosine auto-phosphorylation, a serine-threonine phosphorylation. The latter type of phosphorylation increases insulin resistance and impairs insulin signal transduction. The insulin signal is terminated by dephosphorylation of the β subunit of receptor by tyrosine phosphatases, the activities of which is increased in insulin resistant states.

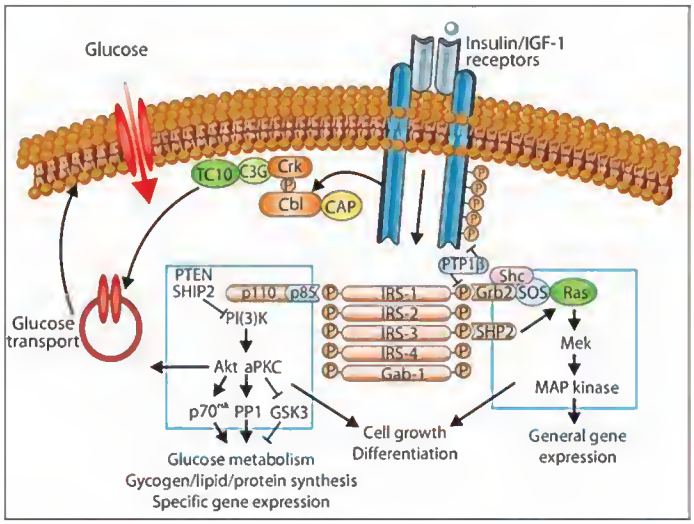

Figure 2: Molecular mechanisms of insulin resistance. Altered post-receptor events, tyrosine kinase phosphorylation, IRS and other signal regulatory proteins are responsible for the resistance.

Source: Saltiel AR, Kahn CR. Insulin signalling and the regulation of glucose and lipid metabolism. Nature 2001; 414: 799-806.

aPKC = Atypical protein kinase C; GSK3 = Glycogen synthase kinase 3; IGF= Insulin-like growth factor; MAP = Mitogen activated protein; PI (3)K = Phosphatidyl inositol 3 kinase; PPI = Protein phosphatase 1; PTEN = Phosphatase and tensin homologue deleted on chromosome 10; SH1P2 = SH2-domain-containing inositol-5-phosphatase

Following the insulin receptor phosphorylation a number of down stream events, including an increase in phosphatidyl inositol-3 kinase (PI-3 kinase) leads to the translocation of GLUT-4. In insulin resistant state, the GLUT-4 is not depleted, but its translocation is hampered. The glucocorticoid-induced insulin resistance is also associated with a reduced insulin stimulated IRS-1 associated PI-3 kinase.

Insulin Secretory Defects in Type 2 Diabetes

In a non-diabetic individual, besides the meal-related insulin secretion, there are rapid oscillations in insulin secretion every 8 to 15 min, without any glycaemic stimulus. There is also a circadian rhythm occurring every 80 to 150 min. Overall, about 18 to 32 units of insulin are secreted daily and about 50% is extracted by the liver for local action during its first passage.

In type 2 diabetes, the rapid meal-related insulin secretion, which primarily occurs in about 30 min post-meal and mostly represents the preformed insulin, is attenuated. The post-meal response for the 2-hour period post-meal appears to be exaggerated but in relation to the high glycaemic levels is indeed also impaired. In obesity and impaired glucose tolerance group, absolute amounts of insulin secreted may be excessive. The molecular mechanism of this phenomenon is probably an overexpression of hexokinase gene as compared to the glucokinase gene. As the former has a low Michaelis constant (K_m) for glucose, hypersecretion is produced. The circadian rhythm of both types of non-meal related insulin responses is also altered or attenuated.

The β-cell mass appears to be slightly reduced at the time of diagnosis of diabetes; however, the functional capacity is impaired out of proportion to its mass and hence in many studies, a 50 % reduced insulin response has been described at the onset of type 2 diabetes. Subsequently, the β cell mass declines further in a relentless fashion with increasing insulinopaenia. This is at time correlated to fibrillary amylin deposition in the β-cells.

The genetic factors that determine β cell differentiation, growth and apoptosis are being intensively studied at present. The growth factors and their biology is yet to be elucidated. It obviously holds the key to a fruitful avenue for intervention. However, it is characterised by an early apoptosis of β cells. The insulin resistance and β cell failure exist and progress pari passu. In early phases there is predominately a resistant state. Subsequently, β cell failure dominates the scene. The β-cell is able to compensate by increased insulin secretion in the face of rising blood glucose, but at about 140 mg/dL of blood glucose the insulin secretion levels off and a further rise in blood glucose results in diminishing insulin secretion (**Figure 3**).

In about 10% of type 1 diabetics, the β cell failure may be due to auto immunity. This is called latent autoimmune diabetes of adults (LADA) and aetiologically represents a forme fruste of type 1 diabetes.

OTHER PATHOGENETIC MECHANISMS

Besides the role of β cell, skeletal muscle, adipose tissue, and liver in the genesis of type 2 diabetes, a few other important pathogenetic mechanisms have been described. The gastro-intestinal tract secretes a group of important hormones, collectively labelled as incretins. This includes two extremely well-known members: glucagon like peptide (GLP-1) and glucose-dependent insulinotropic peptide (GIP). The former is secreted from the L-cells of the ileum and the latter from the K-cells located in the proximal small intestine. These hormones account for the enhanced insulin secretory response upon ingestion of glucose orally, as compared to that obtained by intravenous glucose administration. This has been termed the incretin effect. In type 2 diabetes, the incretin effect is blunted, which can be corrected by injecting GLP-1 or its longer acting analogue, like exenatide or liraglutide. GLP-1 is normally destroyed by a group of enzymes called dipeptyl peptidases, of which dipeptyl peptidase-IV (DPP-IV) is the predominant one. Compounds inhibiting DPP-IV inhibitors prolong the effect of endogenous GLP-1 and are being used therapeutically at present.

Although non-suppressibility of glucagon following a meal was described in type 2 diabetes almost 4 to 5 decades ago, it gained further relevance recently, with the availability of therapeutic tools to correct this anomaly. GLP-1 analogues and DPP-IV inhibitors described above correct this defect by suppressing glucagon levels post-prandially. Tachy-alimentation has also been described to aggravate diabetes by exposing the body to sudden surge of nutrients. GLP-1 analogues and DPP-IV inhibitors are known to retard gastric emptying, thus offering an additional mechanism of action.

The hypothalamic neurons and neurotransmitters have been considered in the pathogenesis of type 2 diabetes. There are numerous changes described in the neurotransmitter secretion in obesity and type 2 diabetes. The rapid first phase insulin response is mediated through these pathways. It has been demonstrated that the hypothalamic nuclei regulating appetite are also insulin resistant. After the ingestion of glucose, the elevated plasma insulin levels are unable to exert the inhibitory response in these nuclei in obese, insulin resistant individuals. Hence, pharmacological manipulation of these neurons by promoting satiety can be utilised in type 2 diabetes. More recently, dopamine agonists, like bromocriptine have been shown to improve hyperglycaemia in type 2 diabetes.

Another new pathogenetic mechanism described shows involvement of kidney in the pathogenesis of type 2 diabetes. Normally about 160 g of glucose is filtered in the glomerular filtrate; 90% of it is absorbed in the proximal convoluted tubule by a high capacity glucose transporter called SGLT2. Remaining 10% of the filtered glucose is absorbed in the straight descending part of the proximal tubule by another glucose transporter SGLT-1. It has been demonstrated that in type 1 diabetes the tubular maximum for the glucose absorption is increased. Although it is not clear whether the same holds true of type 2 diabetes, the levels of SGLT-2 mRNA is four-fold increased in the proximal tubular renal cells. This may account for increased glucose resorption and hence, hyperglycaemia. Inhibition of SGLT has provided another avenue to treat type 2 diabetes.

In summary, type 2 diabetes originates from a complex interaction of genetic and environmental factors, which express themselves in the form of myriad biochemical abnormalities.

9.4 Clinical Features and Diagnosis of Diabetes Mellitus

D Maji

Diabetes mellitus is a group of metabolic disorder involving carbohydrate, lipid and protein metabolism, characterised by chronic hyperglycaemia, as a result of defects in insulin secretion from the β-cells of pancreas or peripheral action of insulin (insulin resistance) or both. During the course of the disease the diabetic subjects are at risk of development of microvascular (retinopathy, nephropathy, neuropathy) and macrovascular (coronary artery, cerebrovascular and peripheral vascular disease) complications later in the course of the disease. The features of long term complications then become a part of the diabetic phenotype.

CLINICAL FEATURES

Clinical features of diabetes mellitus are variable and depend upon the type of diabetes and the stages of the natural history of diabetes at which it is seen (**Figure 1**).

In the earlier part of development of diabetes, the patient may remain asymptomatic for a long period of time; on the other hand in the later part of the disease the features of long-term complications of diabetes may manifest and become part of the diabetic syndrome. There are four major types of diabetes—type 1 diabetes, type 2 diabetes, other specific types of diabetes and gestational diabetes (**Figure 2**).

As the clinical manifestations of these types of diabetes may be different, they will be considered separately.

TYPE 1 DIABETES

Type 1 diabetes constitutes less than 2% of total diabetic population in India. In majority of type 1 diabetes patients; there is rapid destruction of β-cells of pancreas; in a susceptible subject due to viral mediated autoimmune process. A typical type 1 diabetes patient is below 30 years, is underweight and present with frank symptoms, e.g. polyuria, polydipsia, polyphagia, weakness, weight loss, restlessness and if continued for some period, may lead to diabetic ketoacidosis with altered sensorium and severe dehydration. Occasionally a child with similar clinical presentation in a remote area may die before the diagnosis is made. Any comatose child presenting with severe dehydration without diarrhoea; a diagnosis of type 1 diabetes should be in the list of diagnostic consideration. In some type 1 diabetic subjects; β-cell destruction is slower and may mimic a type 2 diabetes in clinical presentation (latent autoimmune diabetes in adult; (LADA). After initial treatment with insulin, a type 1 diabetic may recover some residual β-cell function (the so-called 'honeymoon phase') when they can be maintained with a small daily dose of insulin; rarely, they do not even need insulin for some period of time. However, this phase of recovery of residual β-cell function is temporary and the autoimmune process ultimately destroys the remaining β-cells and the subject becomes completely insulin deficient and require insulin for survival.

TYPE 2 DIABETES

Type 2 diabetes constitutes almost 98% of diabetic population in India. Age, obesity, lack of physical activity, and family history of diabetes are the predisposing factors for type 2 diabetes. Other risk factors are – hypertension, dyslipidaemia, and past history of gestational diabetes mellitus (GDM). Some may

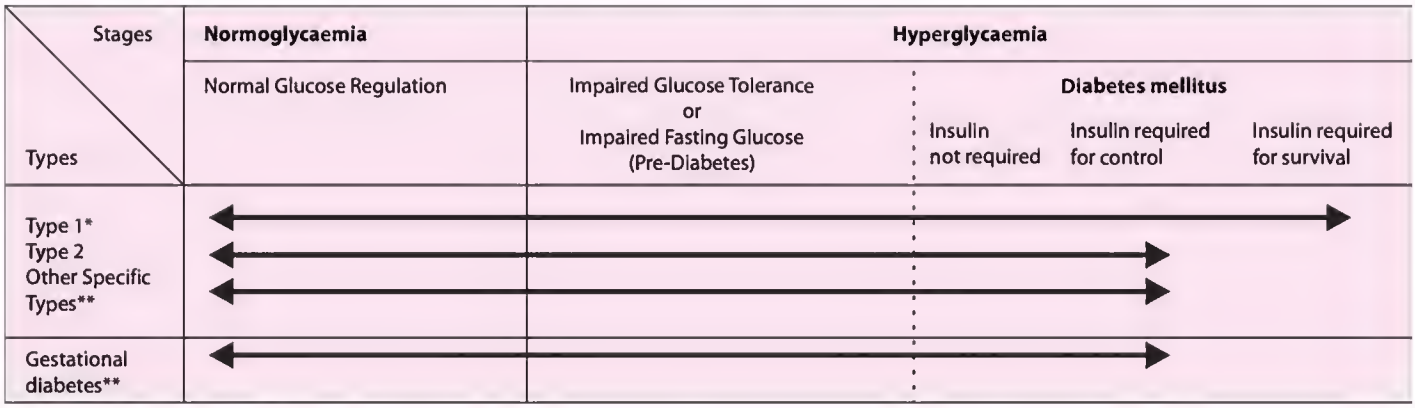

Figure 2: Four major types of diabetes.

Disorders of glycaemia: aetiologic types and stages.
** Even after presenting in ketoacidosis, these patients can briefly return to normoglycaemia without requiring continuous therapy (i.e.'honeymoon remission').*
*** In rare instances patients in these categories (e.g. Vacor toxicity, type 1 diabetes presenting in pregnancy) may require insulin for survival.*

present with the characteristic symptoms of polyuria, polydipsia and polyphagia with weakness and weight loss, many type 2 diabetics are asymptomatic and remain silent for many years and at diagnosis may have features of long-term complications like neuropathy (tingling, numbness, paraesthesia of lower limbs), retinopathy or even nephropathy. A middle-aged female often consult gynaecologist for pruritus vulva, a male subject may consult physician for balanitis; because chronic hyperglycaemia makes a subject prone to several type of bacterial or fungal infections. Asymptomatic patients are diagnosed during routine health check-up for LIC policy, or job recruitment or before surgery. In spite of this, about half of the type 2 diabetic population in India remain undiagnosed.

LATENT AUTOIMMUNE DIABETES IN ADULTS (LADA)

LADA includes a heterogeneous group of conditions that are phenotypically similar to type 2 diabetes, but patients have autoantibodies that are common to type 1 diabetes (**Table 1**).

Table 1: Characteristic of Special Tests for the Diagnosis of Diabetes Mellitus

	Type of Diabetes		
Test	**Type 1**	**Type 2**	**LADA**
C-peptide	<1.51 ng per mL (0.5 nmol per L): PPV of 96% for diagnosis in adults and children	<1.51 ng per mL: NPV for diagnosis in adults and children	
GADA	60% prevalence in adults and children	7% to 43% prevalence in adults and children	Presence: PPV of 92% for requiring insulin at 3 years
	73% prevalence in children	NPV of 94% for requiring insulin at 6 yrs in adults	Absence: NPV of 49% for requiring insulin at 3 years
IA-2α and IA-2β	40% prevalence in adults and children	2.2% prevalence in adults	PPV of 75% for requiring insulin at 3 years in persons 15 to 34 years of age
ICA	75% to 85% prevalence in adults and children	4% to 21% prevalence in adults	PPV of 86% for requiring insulin at 3% in persons 15 to 34 years of age

GADA = Glutamic acid decarboxylase antibody; ICA = Islet cell antibody; LADA = Latent autoimmune diabetes in adults; NPV = Negative predictive value; PPV = Positive predictive value

Diagnostic criteria includes age of 30 years or older, no insulin treatment required for six months after diagnosis and the presence of antibodies to glutamic acid decarboxylase (GAD), islet cells (ICA), tyrosine phosphate (IA 2α and IA 2β), or insulin (IAA).

OTHER SPECIFIC TYPES

These group of diabetes refers to glucose intolerance that develops in association with other disorders other than those currently defined as type 1 or type 2 diabetes.

Genetic Defect of the β-Cell

Several forms of diabetes are associated with monogenic defects in β-cell. They are characterised by early onset in young age before 25, inheritance is autosomal dominant and they have impaired insulin secretion from β-cell with minimal insulin resistance, they are called maturity onset of diabetes in young, (MODY). Six different chromosomal locations have been identified (**Table 2**).

Table 2: Classification of Currently Recognised Genetic Defects of β-cell Function: Maturity-Onset Diabetes of the Young (MODY)

MODY Type	Chromosome	Defective Gene Product	Molecular Defect	Most Common Therapy
1	20q	HNF-4α	β-cell mass, insulin secretion	Oral hypoglycaemic agent, Insulin
2	7p	Glucokinase	Glucose phosphorylation	Diet and exercise
3	12q	HNF-1α	β-cell mass, insulin secretion	Oral hypoglycaemic agent, Insulin
4	13q	IPF-1 (PDX-1)	β-cell development and function	Oral hypoglycaemic agent, Insulin
5	17 cen-q	HNF-β	β-cell mass, insulin secretion	Insulin
6	2q	Neuro D1/ β-2	β-cell development and function	Insulin

Endocrinopathy

Hormone like growth hormone, cortisol, glucagon and epinephrine are diabetogenic. Syndromes associated with the excess of these hormones are associated with hyperglycaemia leading to secondary diabetes, e.g. Cushing, syndrome,

acromegaly glucagonoma, phaeochromocytoma. Apart from symptoms of hyperglycaemia, they will have clinical features related to respective endocrine disorder.

Drugs

Some drugs affect β-cell functions, e.g. Vacor (a rat poison), pentamidine, glucocorticoids (quite often used in pharmacologic doses), can cause or precipitate diabetes. Some of the anti-psychotic drugs also have diabetogenic effect, e.g. clozapine, olanzapine, risperidone, quetiapine, ziprasidone, aripiprazole.

Other syndromes

Many genetic syndromes, are associated with increased incidence of hyperglycaemia; chromosomal disorders like Klinefelter's syndrome, Turner's syndrome, and Down's syndrome. Wolfram's syndrome, an autosomal recessive disorder, is associated with insulin deficient diabetes and absence of β-cells seen at autopsy.

Chronic Pancreatic Disease

Chronic calcific pancreatitis develop hyperglycaemia, along with defects of exocrine function of pancreas. Fibrocalcific pancreatic disease (FCPD) which was earlier considered as a separate type, are now put in this category of secondary diabetes.

Haemochromatosis

Abnormal glucose intolerance occurs in 75% to 80% of haemochromatosis patients where iron deposition is found in different tissues of the body including liver and pancreas. The severity of cirrhosis and iron load is correlated with the degree of glucose intolerance. Characteristic bronze colour skin and hepatospl-enomegally are prominent clinical features in this condition.

DIAGNOSIS

Diagnosis of diabetes should be made in the early stage of development of the hyperglycaemic state, as several reports including that of Diabetes Control and Complication Trial (DCCT), United Kingdom Prospective Diabetes Study (UKPDS) and Steno 2 trial, clearly suggest that long-term complications of diabetes can be prevented or delayed if treatment is started early. In clinical practice, however, diabetes is diagnosed late.

A plethora of diagnostic criteria existed before the publication of National Diabetes Data Group (NDDG) in 1979 and WHO Expert Committee Report, 1980. WHO has published several technical reports relating to diabetes in 1965, 1980, 1985, 1994, and 1999. The diagnostic criteria used over this period are not accepted any more. Today there is wide acceptance of the fact that there is a continuous spectrum of glucose levels between those considered normal and those to be considered as diabetic.

ORAL GLUCOSE TOLERANCE TEST

Oral glucose tolerance test (OGTT) should be done in the morning after fasting for 10 to 16 hours before the test; having unrestricted carbohydrate diet for 72 hours. No smoking should be done during the test. Any concomitant medication or illness should be noted. The test should be performed with 75 g of anhydrous glucose in 150 to 300 mL of water taken over 5 minutes time. Children to be given 1.75 gm/kg body weight, up to total of 75 gm of glucose. It is recommended in asymptomatic individuals to reconfirm the results on another occasion. Interpretation of OGTT is described in **Table 3**.

Table 3: WHO Diabetes Criteria-Interpretation of OGTT

Glucose levels	Normal		Impaired fasting glycaemia (IFG)		Impaired glucose tolerance (IGT)		Diabetes Mellitus	
Venous Plasma	Fasting	2 hrs	Fasting	2 hrs	Fastin;g	2 hrs	Fasting	2 hrs
(mmol/L)	<6.1	<7.8	≥6.1 & <7.8	<7.8	<7.0	≥7.8	≥7.0	≥11.1
(mg/dL)	<110	<140	≥110 & <126	<140	<126	≥140	≥126	≥200

To convert mmol/L to mg multiply by 18

HbA1c AND DIAGNOSIS OF DIABETES MELLITUS

HbA1c is an index of mean blood glucose in fasting and post-prandial state and is well established, and widely used as a clinical measure of chronic glycaemia, in the follow-up monitoring of diabetes. Several studies indicate that HbA1c may show a glycaemic threshold with microvascular complications, suggesting it may additionally be useful as a diagnostic test for diabetes (**Table 4**). The main factors in support of using HbA1c as a screening and diagnostic test include: (1) HbA1c does not require patient to remain fasting, (2) HbA1c reflects longer-term glycaemia than does plasma glucose, (3) HbA1c laboratory methods are now well standardised and reliable, and (4) errors caused by non-glycaemic factors affecting HbA1c such as haemoglibinopathies are not frequent and can be minimised by confirming the diagnosis of diabetes with a plasma glucose specific test.

Table 4: Interpretation of HbA1c Test in Hyperglycaemic States as Proposed by Experts

Normal	<5.7%
Pre-diabetes	5.7% to 6.4%
Diabetes	6.5% or more

Gestational Diabetes Mellitus (GDM)

When hyperglycaemia is just recognised during pregnancy, it is defined as gestational diabetes. Majority of GDM are asymptomatic and diagnosed on routine check-up in the obstetric clinic. In general glucose intolerance resolves after the pregnancy is over, but in those who continue to have hyperglycaemia after delivery might have had unrecognised diabetes before pregnancy.

Table 5: Interpretation of OGTT for GDM Plasma Sugar Value Given Below in mg/dL

	100 gm 3 hours OGTT	100 gm 3 hours OGTT	100 gm 3 hours OGTT	75 gm 2 hours OGTT	75 gm 2 hours OGTT
	O'Sullivan and Mahan 1973	NDDG 1979	Carpenter and Couston' 82 ADA 1997	ADA 1998	WHO 1999
Fasting	90	105	95	95	126
1 hours	165	190	180	180	—
2 hours	145	165	155	155	140
3 hours	125	145	140	—	—
	Any two	Any two	Any two	Any two	

DIAGNOSIS OF GESTATIONAL DIABETES

Diversity of opinion exists for the diagnosis of gestational diabetes. O'Sullivan was the first to use the term Gestational Diabetes in 1961. In 1964 O'Sullivan and Mahan suggested the 100 gm 3 hours OGTT in the 2nd and 3rd trimester of pregnancy to diagnose GDM.

In 1979, the NDDG recommended a 15% upward adjustment of the diagnostic threshold using the venous plasma glucose in place of whole blood glucose. In 1982, Carpenter and Loustan modified the O'Sullivan and Mahan criteria using new enzymatic glucose oxidase method. The present American Diabetes Association (ADA) criteria recommends both 100 gm and 75 gm OGTT done between 24 and 28 weeks of gestation.

The WHO criteria is based on the 75 gm OGTT. The International Association of Diabetes and Pregnancy Study Group also recommends that all women with no prior history of diabetes undergo a 75 gm 2 hours OGTT between 24 and 28 weeks.

SCREENING FOR DIABETES

Diabetes is a common disease and associated with significant morbidity and mortality. It has an asymptomatic phase that may be up to 7 to 10 years before the diagnosis is made. If treated early, the long-term complications may be preventable, so testing is rationale for screening diabetes. Both fasting plasma glucose (FPG) and 2 hours post-glucose values (after 75 gm glucose) are now used widely in clinical practice as well as in epidemiological studies. Though a casual plasma glucose more commonly called random plasma glucose (RPG) 200 mg/dL or greater with symptoms is an established diagnostic criteria for diabetes; but as a screening test for diabetes it is insensitive specially when the value is on the lower side (**Tables 6 and 7**).

Table 6: Sensitivity and Specificity of Achieved in Screening for Diabetes Based on Random Plasma Glucose of Various Levels

Random Plasma Glucose (mg/dL)	Sensitivity (%)	Specificity (%)
≥110	84	65
≥120	76	77
≥130	63	87
≥140	55	92
≥150	50	95
≥160	44	96
≥170	42	97
≥180	39	98

The following ADA guidelines are widely accepted for screening of diabetes.

Additional Risk Factors for Diabetes

- Physical inactivity
- Hypertension
- HDL cholesterol <35 mg/dL
- Triglyceride >250 mg/dL
- History of cardiovascular disease
- Previous IFG or IGT
- First degree relative is diabetic
- History of GDM
- Member of high-risk ethnic group
- Delivery of baby >9 lb
- History of PCOD

Table 7: Criteria for Screening and Diagnosis of Diabetes at a Glance

Screening	Diagnosis
FPG ≥100 mg/dL	FPG ≥126 mg/dL
A1c >6.0%	A1c ≥6.5%
RPG ≥130 mg/dL	RPG ≥200 mg/dL
If screening result is negative, screen again in 3 years	2-hour OGTT ≥200 mg/dL
If screening result is positive but below the diagnostic threshold, do another test for diagnosis, using a different method	Diagnosis requires confirmation unless unequivocal symptoms of hyperglycaemia are present
If screening result is above the diagnostic threshold but a second test does not reach the threshold, test again in 1 year	Diagnosis based on HbA1c requires confirmation using a glucose dependent test (FPG or OGTT) or, if first HbA1c is ≥7.0%, by a second HbA1c ≥6.5%
	In asymptomatic persons with Hba1c ≥6.5%, if FPG ≥126 mg/dL or RPG ≥200 mg/dl, diagnosis is confirmed
	If screening is positive but less than the diagnostic threshold, two tests are required to reach the diagnostic threshold

Testing to detect type 2 diabetes should be considered in asymptomatic adults with BMI of 25 or greater and one or more additional risk factors for diabetes.

Screening for Gestational Diabetes (GDM)

Risk assessment at the 1st prenatal visit: High-risk GDM

- Marked obesity
- Previous GDM
- F/H/O diabetes
- Glycosuria

If testing is negative, re-testing should be done at 24 to 28 weeks of gestation.

Women with GDM should be screened for diabetes 6 to 12 weeks post-partum and subsequent screening for the development of diabetes.

CONCLUSIONS

In summary, diabetes is a heterogeneous metabolic disorder with varied manifestation. Prevention, timely diagnosis, and early initiation of treatment are important in patients with diabetes mellitus. Many of the complications associated with diabetes such as nephropathy, retinopathy, neuropathy, cardiovascular disease, stroke, and death can be delayed or prevented with early and appropriate treatment of elevated blood sugar, blood pressure, and blood lipids. Based on aetiology, diabetes is presently classified as type 1 diabetes, type 2 diabetes, diabetes due to other illness and gestational diabetes. At present there has been wide acceptance of the WHO criteria (1997) for the diagnosis of diabetes on the basis of fasting plasma glucose and modified oral glucose tolerance test. Of late; estimation of HbA1c has been proposed by experts to diagnose and screen diabetes. The lack of availability of HbA1c testing in more remote or underserved areas, the cost of the test and lack of standardisation of the test are of legitimate concern. There is uniform agreement that earlier the diabetes is diagnosed and measures taken, the greater is the benefit of the patient.

9.5 Lifestyle Modifications in Management of Diabetes

BK Sahay

INTRODUCTION

Lifestyle measures which combines increased physical activity and dietary modifications are an important component in the management of both type 1 and type 2 diabetes mellitus (DM). The role of exercise in the control of DM has been known since ages. Our ancient ayurvedic physicians Sushruta and Charaka stressed on the role of exercise in the treatment of DM. Even after the advent of insulin, Joslin emphasised the importance of exercise as one of the basic principles of management of diabetic patients. All major guidelines for diabetes management recommend lifestyle changes as part of the standard treatment in all patients of DM.

DIETARY THERAPY

The goal of dietary therapy is to provide a nutritionally balanced diet to maintain the ideal body weight (IBW) of the patient to achieve good glycaemic control along with correction of the dyslipidaemia. The dietary planning is based on the type of diabetes, weight of the patient, activity profile, and presence of co-morbid conditions.

Dietary macronutrient composition is one of the important consideration for the dietary therapy in diabetes. Studies have shown that higher intakes of saturated and trans-fats are associated with an increased risk of diabetes, whereas higher intake of mono-unsaturated and poly-unsaturated fats is associated with decreased risk of diabetes. The importance of consuming minimally processed foods with low glycaemic index and glycaemic load is recommended in the management of diabetes. Whole grain products such as whole wheat breads, brown unpolished rice, oats, and barley tend to produce lower glycaemic and insulinaemic responses than highly processed refined grains. Such unprocessed whole grains are also rich in fibre, antioxidants, vitamins, and phytochemicals.

The calorie requirements are calculated for each individual (**Table 1**) based on his weight and physical activity. These are distributed into three principal meals and two snacks. The calories are derived mainly from carbohydrates 50% to 60%, 20% from proteins and 20% from fats. The carbohydrates should be of low glycaemic index and should be rich in fibre, the source of fat should be 7% each of saturated mono- and poly-unsaturated fats. Three percent of total energy should be derived from essential fatty acids. Cholesterol intake should be less than 300 mg per day. With regard to fat in the diet, one should take into account the invisible fat in the diet derived from cereals and legumes and milk products which nearly contributes to 50% of the required fat. As per the choice of oils in the diet, none of the available oils are ideal, however the choice of cooking oil should be as follows: (a) use an oil which has moderate quantity of linoleic acid like groundnut oil, rice bran or sesame, (b) use an oil which has high amounts of linoleic acid like safflower oil, sunflower oil, cotton seed or corn oil along with an oil which has relatively low levels of linoleic acid like palm oil (mix equal quantities or use equal quantities separately), (c) use any of the above oils with alpha-linoleic acid containing oil like mustard oil or soyabean oil. Roughly the oil intake should be half a litre per person per month. The salt intake should be between 5 to 6 g per day. Dietary guidelines are summarised in **Table 2**.

Table 1: Calorie Requirements Based on Activity and Ideal Body Weight (IBW)

Category	Sedentary	Moderately Active	Strenuous Physical Activity
Overweight/Obese	20	25	30
Ideal weight	25	30	35
Underweight	30	35	40

IBW is calculated as (Height in cm -100) x 0.9
Grid for calculating the recommended caloric intake (Kcal/kg/day) based on physical activity and weight of the individual

Table 2: General Guidelines for Diet in Diabetes Mellitus

Energy (Calories)	25 to 30 calories/kg IBW, reduce calories in obese and increase in underweight individuals
Protein	0.8 g/kg body weight, supplement provided for pregnancy, lactation and growth. A small quota of animal proteins—fish, chicken, milk and yoghurt and appropriate food intake recommended, avoid cattle meat and eggs
Fats	20% to 25% of total calories
Saturated	6% to 7% of total calories
PUFA total	6% to 7% of total calories
N6/N3 ratio	1:1 to 4:1
MUFA	6% to 7% of total calories
Cooking oil	0.5 kg/month/person Total fat intake, with cholesterol 300 mg per day
Carbohydrates	55% to 60% of total calories To encourage complex carbohydrates, i.e. mainly whole grain cereals, pulses, beans, vegetables, and salads. Avoid simple and refined carbohydrates like bakery products or deep fried items
Fruits	Fresh fruits up to 400 g per day. Avoid juices
Dietary fibre	30 to 40 g per day preferably from natural sources; avoid loss from refining and processing. Indian diet is rich in fibre and generally does not require addition of fibre supplements
Common salt	Up to 5 to 6 g per day. Reduced intake to 4 g per day in the presence of hypertension, renal failure and hearing problems
Condiments and spices	Provides anti-oxidants, trace elements, minerals, and n-3 fatty acids
Artificial sweetners	Use of saccharin and aspartame in limited quantity is acceptable. Avoid in pregnancy and lactation
Alcohol	Avoid if possible. If not, drastically restrict. It is utilised as fats. 1 g = 7 calories (2 small drinks/one glass of wine/ pint of beer (preferably avoided)
Tobacco	Avoid smoking or its use in any form

Fresh fruits up to 400 grams per day are advisable. Consuming the whole fruit is better than the fruit juice which needs to be avoided. Ideal fruits are citrus fruits, orange sweat lime, guava, apple, papaya and pomegranate. They provide vitamins and fibre. Each one portion contains 40 to 50 calories.

Indian diets traditionally are high in carbohydrate content. There have been concerns expressed regarding difficulty in achieving glycaemic control and an increase in the risk of development of complications with such diets. However, studies from India and Japan have shown that even with diet high in carbohydrate content, good glycaemic control can be achieved without increasing the risk for complications.

EXERCISE THERAPY

Adequate physical activity helps in correcting obesity which is a major modifiable risk factor in type 2 DM. In addition, physical activity may independently enhance insulin sensitivity and glucose tolerance. Exercise increases the skeletal glucose transporter protein GLUT4 which is responsible for insulin independent glucose transport into the skeletal muscle.

Regular physical exercise is associated with changes in body composition with a reduction in body fat and increase in muscle mass, a reduction in triglycerides, increase of high density lipoprotein 2 fraction. Exercise causes a reduction in blood pressure, corrects the endothelial dysfunction and brings about improvement in the fibrinolytic activity. Exercise also induces weight loss and subsequently helps in maintenance of the weight.

To be effective, exercise should be performed regularly. An exercise schedule that is enjoyable and suits the needs of an individual should be chosen. Daily exercise of 30 to 45 minutes is preferable. It should be done on an empty stomach either in the morning or evening. An exercise session should have a warning up and cooling down. Following a session of exercise, there is an increase in insulin sensitivity which returns to baseline after 72 hours of cessation of exercise. This underlies the importance of persistent and regular exercise. Apart from the aerobic exercises (isotonic exercises), resistance training exercises (isometric exercises) are also useful since they increase the muscle mass, particularly in the elderly patients.

Before an exercise programme is initiated a thorough clinical evaluation of the patient should be made particularly in regard to cardiovascular disease, neuropathy, autonomic neuropathy, nephropathy and retinopathy. If any of these is present, suitable precautions and modification should be made in the exercise schedule. Treadmill exercise test should also be performed in all cases in order to detect myocardial ischaemia. A fair degree of glycaemic control has also to be achieved before initiating the exercise programme particularly in patients with type 1 diabetes, wherein exercise done in the background of a poor glycaemic control can precipitate diabetic ketoacidosis (**Table 3**).

Presence of autonomic neuropathy may limit an individual's exercise capacity and increase the risk of adverse cardiovascular events. Hypotension and hypertension are more likely to develop in patients with autonomic neuropathy. These patients have difficulties in thermoregulation and should be advised to avoid exercises in extremely hot or cold environments and to be careful about their hydration.

Hitherto it was thought that exercise should not be recommended for type 1 DM, currently there is enough evidence that regular physical exercise helps in improving the insulin sensitivity as well as cardiovascular risk factors.

Table 3: Summary of Exercise Recommendations for Patients with Type 2 Diabetes Mellitus

Screening	Search for vascular and neurological complications including silent ischaemic heart disease Stress electrocardiogram in patients >35 years of age or >10 years of diabetes
Exercise programme and type	Aerobic Resistance Yogic practices
Intensity	50% to 70% of maximum aerobic capacity
Duration	20 to 60 minutes with warm up and cool down
Frequency	Ideally daily or at least 5 times a week
Avoid complications	Careful selection of exercise type and intensity Patient education Monitoring of blood glucose by patient and overall programme by medical personnel
Compliance	Make exercise enjoyable Convenient location

Many of the elderly patients tend to avoid physical exercise. However, with increasing age there is a progressive decline in insulin sensitivity, muscle mass and strength and loss of mineral from bones. Regular physical exercise can prevent and reverse these changes. Exercise also improves the quality of life in the elderly diabetics.

Upper body exercises should be routinely recommended for diabetic subjects with arthritis. Pregnant women with diabetes should also be advised walking and if this is not possible they should be advised upper body exercises.

For cardiovascular conditioning, the exercise intensity in healthy adults should be such that 75% to 90% of the target heart rate (THR) is achieved for at least 15 minutes (THR = 220-Age). However, for the diabetic subjects, the intensity of the exercise should achieve 50% to 70% of THR.

Missing exercise for more than 72 hours may increase the blood glucose by 80 to 100 mg in subjects on oral hypoglycaemic agents (**Table 4**).

Table 4: Caloric Expenditure in a 60 kg Individual Performing Various Forms of Exercise for 60 Minutes

Type of Exercise	Caloric Expenditure
Aerobics	450+
Cycling, moderate	450+
Jogging (5 m per hour)	500
Gardening, digging	500
Skipping with rope	700+
Running	700+
Swimming, active	500+
Walking (3 m per hour)	280
Table Tennis	290
Gardening	350
Tennis	350+

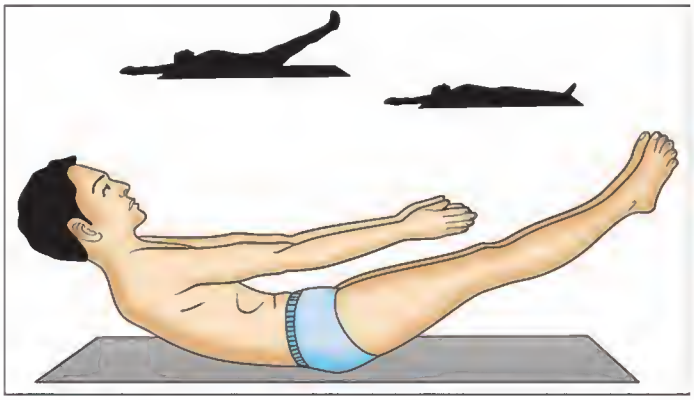

Figure 3: *Naukasana.*

ROLE OF YOGIC PRACTICES

Several recent studies have documented the beneficial effect of yogic practices in both type 2 and type 1 DM yogic practices improve glycaemic control, reduce blood pressure, correct dyslipidaemia, reduce insulin resistance and eliminate stress leading to effective control of diabetes and prevention of its long-term complications. Some of the common yogic exercises are shown in (**Figures 1 to 6**).

9.6 Oral Anti-Diabetic Drugs

Anil Bhansali, Viral Shah

INTRODUCTION

Oral anti-diabetic drugs (OADs) have been used for more than five decades in the management of type 2 diabetes mellitus (T2DM). T2DM is characterised by insulin resistance and insulin deficiency. Therefore, there are two main classes of drugs, one which decreases insulin resistance and the other which increase insulin secretion. The basic mechanism and target organs have been illustrated in **Figure 1**. This chapter gives an overview of different OADs and their brief details.

HISTORICAL PERSPECTIVE

The quest for oral anti-diabetic agent began in the backdrop of the discovery of insulin. Lacklustre introduced guanidine derivative, synthalin A, in 1926 that marked the journey of OADs. It was serendipity when chemist Marcel Janbon and co-workers, who were studying sulphonamide antibiotics, discovered that the compound sulphonylurea can induce hypoglycaemia in animals. Sulphonylurea was first discovered by Frank and Fuchs but later on withdrawn from market due to bone marrow suppression. Subsequently, number of drugs came in the market. First synthesis of dimethylbiguanide (metformin) is attributed to Werner and Bell in 1922 and it was Sterne's work that studied mechanism of metformin in great detail and popularised it. Thiazolidinediones were discovered in late 1970s when lipid lowering drug ciglitazone was found to possess hypoglycaemic effects. Acarbose was isolated in 1975 from the strains of actinoplanes species and synthesised in laboratory in 1988 and found to be the inhibitor of alpha-glucosidase.

CLASSIFICATION OF ORAL ANTI-DIABETIC DRUGS

1. Agents stimulating insulin release (secretagogues)
   - A. Sulphonylureas
     - (a) First generation: chlorpropamide and tolbutamide
     - (b) Second generation: glibenclamide, glipizide and gliclazide
     - (c) Third generation: glimepiride
   - B. Non-sulphonylureas
     - Meglitinides: repaglinide and nateglinide
   - C. GLP-1 analogues
     - Exenatide and liraglutide
   - D. DPP-IV inhibitors
     - Sitagliptin, vildagliptin and saxagliptin
2. Agents lowering insulin resistance (sensitisers)
   - A. Biguanides: phenformin and metformin
   - B. Thiazolidinediones: pioglitazone and rosiglitazone
3. Agents reducing carbohydrate absorption
   - A. Alpha-glucosidase inhibitors: acarbose, voglibose and miglitol
4. Agents decreasing renal reabsorption of glucose
   SGLT-2 inhibitors

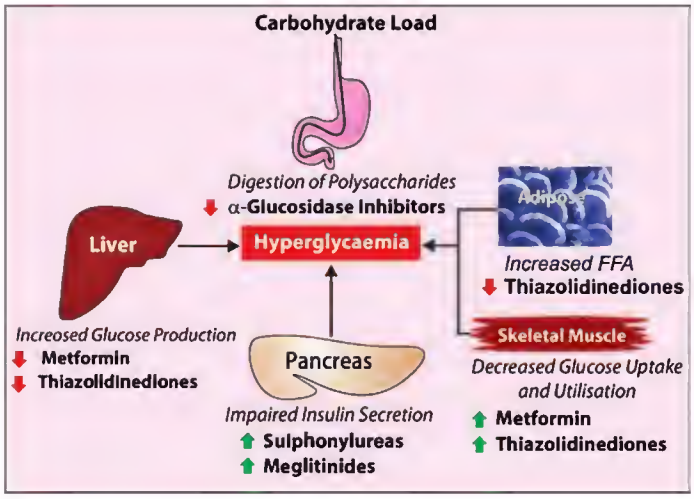

Figure 1: Site of action of different OADs.

SULPHONYLUREA

Structure

Basically sulphonylureas have a benzene ring plus sulphonyl group plus urea. Differences in the para position of the benzene ring and in addition of a group to the urea results in different sulphonylurea compounds.

Mechanism of Action

Insulin secretion is regulated by an ATP dependent K^+ channel located in the plasma membrane of the β cell. Under fasting conditions, most of the channels are open, and K^+ is actively extruded from the β-cell. When the plasma glucose rises, glucose is transported into the β-cell through GLUT receptor and phosphorylated by glucokinase enzyme. This results in the formation of ATP from ADP. Increase ATP/ADP ratio cause ATP dependent K^+ to close resulting into depolarisation of cell. Voltage dependent Ca^{2+} channel opens and calcium moves from extracellular space to β-cell cytosome causes the insulin granule to migrate to cell surface whereas its contents are released by exocytosis. ATP dependent K^+ channel consists of two subunits named SUR which is the binding site for various sulphonylurea drugs, other is KIR channel. The potency of sulphonylurea is a function of its binding affinity to the SUR receptor (**Figure 2**).

Indications

Sulphonylureas are drugs of choice after lifestyle modification and metformin fails to achieve glycaemic target. However, when A1c is more than 9%, sulphonylureas are usually to be started in combination with metformin. Good responders to sulphonylureas include: (a) short duration of diabetes, (b) normal weight subjects, (c) fasting plasma glucose less than 200 mg/dL, and (d) preserved β-cell mass.

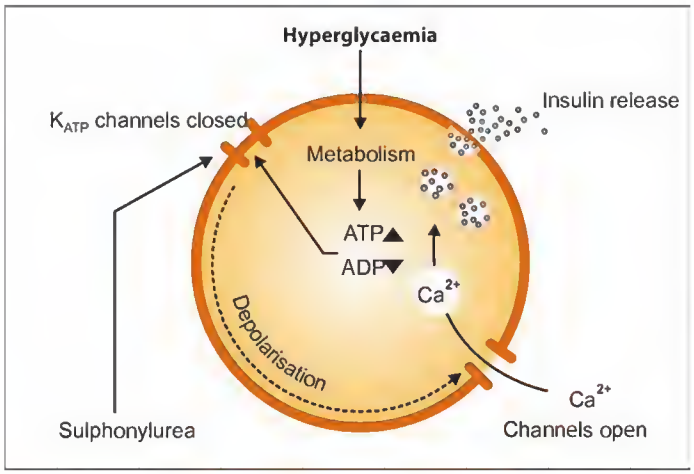

Figure 2: Mechanism of action of sulphonylureas.

secondary failure are dietary indiscretion, lack of physical activity, intercurrent illness and declining β-cell function.

NON-SULPHONYLUREA SECRETAGOGUES

Structure

The meglitinide analogues are non-sulphonylurea compounds derived from the benzimido non-sulphonylurea portion of glibenclamide. **Table 2** shows the differences between sulphonylureas and non-sulphonylureas.

Mechanism of Action

Mechanism of these agents are similar to that of sulfonylureas but they bind to a site on the SUR 1 sub unit of the β-cell ATP dependent K^+ channel that is different from the binding site for sulfonylureas.

Characteristic of Each Agent

Repaglinide is a carbamoylmethyl benzoic acid derivative, which can be safely used in patients with renal failure. Nateglinide is a derivative of phenylalanine and very rapid acting insulin secretagogue. Its rate of association and dissociation are much more rapid. It has very low binding affinity for cardiovascular ATP dependent K^+ channels.

These agents are generally indicated for the control of post-prandial hyperglycaemia alone or as an adjuvant treatment with other anti-diabetic agents. Their use is contraindicated in hepatic insufficiency and pregnancy.

Table 1: Characteristics of Different Oral Anti-Diabetic Agents

Drug	Dose Range (mg)	Peak Level (hours)	Half-life (hours)	Duration of Action (hours)	Route of Excretion	Reduction in A1c
Sulphonylureas						
Tolbutamide	500 to 3,000	3 to 4	4.5 to 6.5	6 to 12	Kidney	1% to 2% with almost all agents
Chlorpropamide	100 to 500	2 to 4	36	Up to 60	Kidney	
Tolazamide	100 to 1,000	3 to 4	7	10 to 14	Kidney	
Glipizide	2.5 to 40	1 to 3	2 to 4	8 to 10	Kidney 80%, faeces 20%	
Glyburide (Glibenclamide)	1.25 to 20	~4	10	10 to 24	Kidney 50%, faeces 50%	
Gliclazide	40 to 240	3 to 4	6 to 15	Up to 20	Kidney 70%, bile 30%	
Glimepiride	1 to 8	2 to 3	9	12 to 24	Kidney 60%, faeces 40%

Pharmacokinetic properties of different OADs are given in **Table 1**. Adverse effects, contraindications and drug interactions of different OADs are listed in **Table 3**. Commonly used drugs which can enhance the effect of OADs are listed in **Table 4**.

Primary Sulphonylurea Failure

For unknown reasons, not all T2DM patients respond to the anti-diabetic action of sulphonylureas and this is known as primary sulphonylurea failure.

Secondary Sulphonylurea Failure

Most patients of T2DM who respond very well initially may have a loss of effective anti-diabetic response after several years of treatment and this is known as secondary sulphonylurea failure. In the United Kingdom Prospective Diabetes Study (UKPDS), treatment with sulphonylureas achieved an A1c less than 7% in 50% of patients at three years, 34% at six years and 24% at nine years. Six and nine year data from the UKPDS showed that this secondary failure is a characteristic of all anti-diabetic treatments and not just sulphonylureas. Still, the term secondary sulphonylurea failure remains in clinical practice. Secondary failure is usually considered as a good initial response to the oral glycaemic agents for at least 1 month. The causes of this

Table 2: How Non-Sulphonylureas Differ from Sulphonylureas?

Sulphonylureas	Non-Sulphonylureas
Act on SUR1 K^+ channel	Act on different channel
Intermediate or long acting	Short acting
To be taken before meal	Taken along with meal
Major effect to decrease FPG and modestly PPG	Mainly reduce PPG
Hypoglycaemia is common	Hypoglycaemia is rare
A1c reduction is good (1% to 2%)	Modest A1c reduction (0.5% to 1%)
Weight gain is a problem	Less weight gain

Table 3: Contraindication, Adverse-events and Drug Interactions of Different OADs

Drug	Contraindications	Adverse Effects	Drug Interactions
Sulphonylureas	(a) T1DM Pregnancy Major surgery Severe infections	Hypoglycaemia Weight gain Hypersensitivity reaction (rare) ? Concern about cardiovascular ill-effects	Drugs increase hypoglycaemic response: aspirin, fibrates, alcohol, H2 blockers, allopurinol, probenecid Drugs decrease hypoglycaemic effects: barbiturate, rifampicin, steroid, oestrogen, phenytoin, β-blockers
	(b) Hypersensitivity to sulpha compounds Significant liver or kidney disease	Chlorpropamide causes hyponatraemia	—
Non-sulphonylurea secretagogues	Renal and liver disease	Hypoglycaemia and weight gain less common than sulphonylureas	Drugs increase repaglinide metabolism: rifampicin, barbiturate, carbamazepine Drugs decrease metabolism: antifungal, erythromycin NSAIDs, and sulphonamides may increase its action
Biguanide	Serum creatinine >1.5 mg/dL in males and >1.4 mg/dL in females. Hepatic dysfunction Congestive heart failure (CHF) class- III, IV Alcohol abuse/binge drinking. Acute or chronic metabolic acidosis Relative contraindications are acute myocardial infarction, pregnancy, and severe infections. It should be withheld 24 hours prior to radiological procedure requiring contrast agent and surgery	Nausea, vomiting, dysgeusia, occasional diarrhoea, lactic acidosis and B12 deficiency are rare	Cimetidine increases the metformin level Nifedipine enhances absorption
Thiazolidinediones	Liver disease (AST >3 times), CHF requiring treatment (class III and IV)	Weight gain, oedema, precipitation of CHF, hepatotoxicity (rare), anaemia decrease bone mineral density	Rosiglitazone metabolised by CYP2C8 and pioglitazone by CYP3A4, hence, drugs metabolised by this pathway may interfere with its level
Alpha-glucosidase inhibitors	Inflammatory bowel disease, gastroparesis, serum creatinine >2 mg/dL	Flatulence, diarrhoea, abdominal discomfort, and distension	May increase level of sulphonylureas Resin and antacid decrease the effect

Table 4: Drugs which Enhance the Effect of OADs Causing Hypoglycaemia

Drugs with Moderate-Quality Evidence	Drugs with Low-Quality Evidence
Gatifloxacin	Artesunate/artemisinin/artemether
Glucagon	Chloroquine, oxaline, sulphonamide
Indomethacin	IGF-I
Pentamidine	Lithium
Quinine	Propoxyphene and dextropropoxyphene

BIGUANIDES

Structure

Metformin is chemically 1,1-dimethylbiguanide, derived from herb *Galega officinalis*.

Mechanism of Action

Metformin decreases hepatic glucose production, principally due to reduced gluconeogenesis and also through reduced glycogenolysis, and thus, its main effect is reduction in fasting plasma glucose. At therapeutic concentrations, metformin suppresses hepatic gluconeogenesis by potentiating the effect of insulin and increasing the activity of activated protein kinase (AMP). It can also reduce hepatic extraction of lactate. The rate of glycogenolysis is decreased by reducing the effect of glucagon and impeding the activity of hepatic glucose 6-phosphatase. Insulin-mediated glucose uptake is also enhanced by metformin. Metformin increases the translocation of insulin sensitive GLUT4 into the cell membrane. It also suppresses fatty acid oxidation and reduces triglycerides. It also increases glucose turnover particularly in the splanchnic bed which may benefit both glucose lowering and weight stabilising effect.

Indication of metformin as per American Diabetes Association (ADA) guideline is 'it is to be given in all T2DM patients in absence of contraindications'.

THIAZOLIDINEDIONES

Mechanism of Action

The thiazolidinediones were found to be ligands for an orphan receptor known as peroxisome proliferator-activated receptor

gamma (PPAR-γ). This receptor is a member of the nuclear receptor superfamily of ligand-activated transcription factors. The specific genes that are PPAR-γ responsive are lipoprotein lipase, fatty acid-binding proteins and, PEPCK which regulates lipid metabolism, insulin action, and adipose tissue differentiation. The major pharmacological action includes; increased insulin mediated glucose uptake in muscle and to increase adipogenesis. The beauty of this class of drugs is that it increases subcutaneous fat and not the visceral, and hence, despite increase in adipogenesis it increase insulin sensitivity. It converts the larger adipocyte into smaller one. These convert small dense LDL into large LDL, increases HDL, decreases TG, decrease plasma free fatty acids. Their vascular actions include; improve endothelial dysfunction, reduce peripheral resistance, decrease plasma fibrinogen and PAI-1, and thus, improve procoagulant state, decrease carotid intima media thickness. These are also shown to have inhibitory effect on neo-intimal proliferation after coronary stent. These also have shown to reduce β-cell loss.

Rosiglitazone is surrounded with recent controversies. This drug is found to increase cardiovascular mortality and also increase in incidence of atypical bone fracture due to decrease in bone mineral content.

Indication

These can be used as mono-therapy or in combination with other drugs in type 2 DM patients. These are more useful in patients with insulin resistance.

ALPHA-GLUCOSIDASE INHIBITORS

Mechanism of Action

Alpha-glucosidase inhibitors are competitive suppressants of small intestine brush border α-glucosidases, which are essential to hydrolyse disaccharides, oligosaccharides, and polysaccharides to monosaccharides. Therefore, carbohydrate absorption and digestion is delayed and prolonged resulting in lowering of postprandial hyperglycaemia. These agents do not interfere in absorption of lactose as they require β-glucosidase (lactase) for their digestion. Furthermore, these increase the secretion of GLP-1 and decrease secretion of GIP, significance of which still remains elusive.

Indication

These can be used in both type 1 DM and type 2 DM. However, their main use is to treat postprandial hyperglycaemia. It can delay the progression of IGT to diabetes, and hence, can be used to treat IGT. These can be used in combination with other drugs to achieve glycaemic control.

ADVERSE EVENTS

The side effects, contraindications and drug interactions are summarised in **Table 3. Table 4** gives a list of drugs which potentiates effect of OAD and induce hypoglycaemia.

Cardiovascular Safety of OADs

Cardiovascular safety has become hot issue after a meta-analysis by Nissen in May 2007. He showed increased risk of myocardial infarction with rosiglitazone. Since then FDA warned that it is mandatory for all anti-diabetic drugs to establish their cardiovascular safety. Among thiazolidinediones, rosiglitazone but not the pioglitazone is associated with high cardiovascular risk. The large, pro active study clearly demonstrated the cardiovascular safety of pioglitazone. Older studies, beginning in the 1970s with the University Group Diabetes Programme trial have suggested that diabetic patients receiving sulphonylureas were at increased cardiovascular risk compared with diabetic patients who did not receive such medications. Therefore, it was believed that sulphonylureas particularly glibenclamide through SUR1 receptor on cardiac myocyte can adversely affect the ischaemic preconditioning. However, in the United Kingdom Prospective Diabetes Study (UKPDS), treatment with sulphonylureas was not associated with increased risk of cardiovascular morbidity and mortality. Furthermore, a number of studies did not show any adverse cardiovascular effect of newer sulphonylureas. Metformin is the only drug shown to reduce cardiovascular morbidity and mortality. A meta-analysis of eight different trials showed no increase in cardiovascular mortality with the use of acarbose.

9.7 Insulin Therapy

Rama Walia

Insulin is one of the oldest, best studied and most effective treatment for diabetes. Insulin therapy is a must and life saving for patients with type 1 diabetes while many patients with advanced duration of type 2 diabetes also require insulin therapy for optimal glycaemic control. Insulin was discovered by an orthopaedic surgeon, Frederick G. Banting (**Figure 1**) who was assisted by a medical student Charles H. Best (**Figure 2**). The first clinical trial took place on January 1922 on a patient, Leonard Thompson. The rest is history of success of insulin.

PHYSIOLOGY OF INSULIN SECRETION

Insulin is a two chain polypeptide having 51 amino acids (**Figure 3**). A-chain has 21 amino acids while B-chain has 30 amino acids. Insulin is secreted in a pulsatile manner. There are rapid oscillations occurring every 8 to 15 minutes that are superimposed on slower oscillations occurring at a rate of once per 80 to 150 minutes. Fifty per cent of total insulin secreted by pancreas is secreted under basal conditions and the remainder is secreted in response to meals as postprandial bursts.

Under basal conditions insulin secretion rate is 0.5 to 1 U/h. After food intake insulin is released in two phases. First phase is transient (2 to 5 minutes) followed by a second phase in which there is progressive increase in insulin secretion for 5 to 52 minutes.

INSULIN PREPARATIONS

Initially commercial preparations of insulin were derived from beef and pork pancreas. In 1980s, human insulins were produced by recombinant deoxyribonucleic acid (DNA) technology in *Escherichia coli* and yeast. In 1990s, insulin was genetically engineered to produce various insulin analogues.

Conventional Insulin

Regular insulin is short-acting soluble crystalline zinc insulin. Regular insulin been modified by adding zinc with or without protamine to retard its absorption and prolong the duration of action, e.g. neutral protamine Hagedorn (NPH) or isophane insulin which is an intermediate acting insulin.

Insulin Analogues

The self association of insulin molecules in a hexamer leads to slow absorption with a lag period of 30 to 60 minutes. With recombinant DNA technology, rapid acting insulin analogues have been synthesised which remain in monomeric form and are, therefore, rapidly absorbed, e.g. insulin lispro, insulin aspart, and insulin glulisine. The action profile and structural change of various insulin preparations are shown in **Table 1**. The use of rapid acting insulin analogues allows more flexibility and convenience as these are to be injected only 5 to 15 minutes prior to meals, although overall glycaemic control may not improve as assessed by HbA1c. Because of the shorter duration of action than regular insulin (**Table 1**), the incidence of post-absorptive hypoglycaemia is decreased by almost 25% thereby reducing the requirement for inter-prandial snacking.

Currently available long-acting insulin analogues include insulin glargine and insulin detemir (**Table 1**). Insulin glargine has a pH of 4 and it makes microprecipitates in subcutaneous tissue from which insulin is slowly released. Insulin detemir is designed to bind albumin in plasma after absorption (**Table 1**). These alterations result in prolonged duration of action with little peak activity thereby reducing the incidence of hypoglycaemia. Additionally, weight gain associated with insulin therapy may be avoided particularly with insulin detemir. This probably

Figure 2: Dr. Charles H. Best.

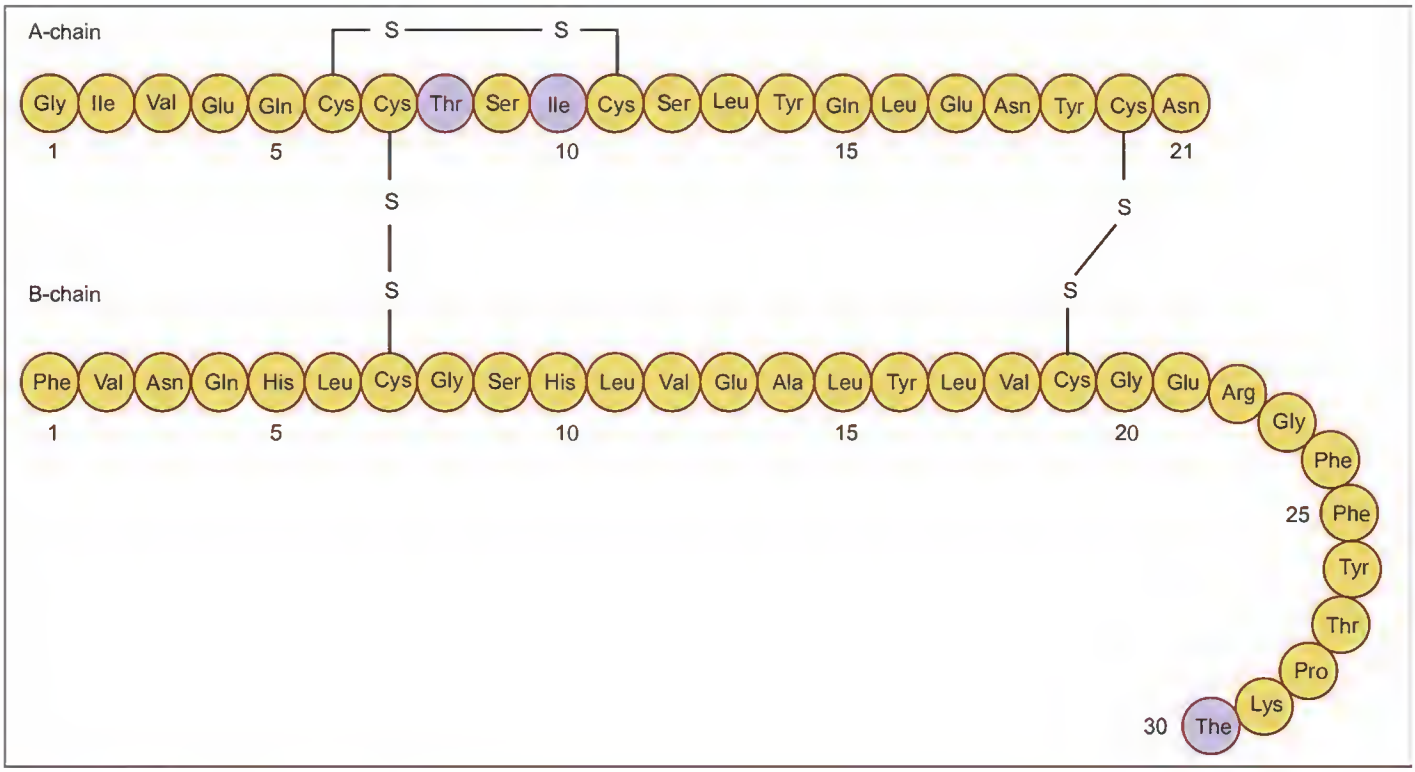

Figure 3: Amino acid sequence of human insulin.

Table 1: Action Profile of Various Insulin Preparations

Insulin Preparations	Structural Change	pH	Onset (h)	Peak (h)	Duration (h)
	Conventional insulin				
Short-acting insulin					
Regular insulin(human)	—	N	0.5 to 1	2 to 3	6 to 8
Intermediate-acting insulin					
Neutral protamine Hagedorn, NPH (human)	Addition of protamine	N	1.5	4 to 10	16 to 24
	Insulin analogues				
Rapid-acting insulin					
Lispro	Lysine-proline conversion in B-chain	N	0.2 to 0.5	0.5 to 2	3 to 4
Aspart	Aspartic acid for proline substitution in B-chain	N	0.2 to 0.5	0.5 to 2	3 to 5
Glulisine	Lysine for asparagine substitution in B-chain	N	0.2 to 0.5	1	4
Long-acting insulin					
Glargine	Glycine for asparagine substitution in A-chain and a prolonged B-chain	4	2 to 4	none	20 to 30
Detemir	Acylation of lysine in B-chain with saturated fatty acid	N	1 to 2	none	20

N= Neutral

happens due to less snacking as hypoglycaemias are reduced and secondarily due to a selective appetite modulating effect of insulin detemir.

Insulin lispro and insulin aspart are approved for use during pregnancy and marginally reduce glycosylated haemoglobin (HbA1c) as well as incidence of hypoglycaemia with no differences in gestational outcome when compared with human regular insulin. Insulin detemir and insulin glargine are still not approved for their use during pregnancy. Patients having significant hyperglycaemia require higher proportion of short/ rapid acting insulin.

Indications for Insulin Therapy

Insulin therapy is a must and life saving in patients with type 1 diabetes. Therefore, omission of insulin in these patient is suicidal. Insulin therapy is also treatment of choice for gestational diabetes mellitus. Indications for insulin therapy in patients with type 2 diabetes at diagnosis include fasting plasma glucose >250 mg/dL, HbA1C >10%, patients having severe osmotic symptoms, and weight loss and/or ketosis. During follow-up, insulin is to be initiated if patient has inadequate glycaemic control (HbA1c >7%) on maximal doses of two or more oral anti-diabetic drugs. Insulin also

needs to be started during inter-current illness and patients undergoing surgery.

TIMINGS AND DOSAGES OF INSULIN THERAPY

Short-acting regular human insulin needs to be injected 30 to 60 minutes prior to meals while rapid acting insulin analogues can be injected 5 to 15 minutes prior to meals. However, if pre-prandial plasma glucose is higher, then short-acting analogues are to be injected 30 minutes prior to meal to achieve adequate glycaemic control. If required, in case of children and in patients with gastroparesis these can be injected even after meals.

Insulin NPH is to be injected once or twice a day usually with regular insulin 30 minutes prior to meals. In basal bolus regimen, it can be drawn in the same syringe containing regular insulin with out change in efficacy or pharmacokinetics reducing the number of injection. In this way, peak action of NPH insulin takes care of post-lunch hyperglycaemia. Similarly, the night dose of NPH insulin can be injected before dinner along with regular insulin. However, if the total dose of insulin being injected at one time exceeds 30 units, then regular and NPH insulins need to be injected at separate sites. If a patient develops nocturnal hypoglycaemia, then along with reducing the night dose of insulin, the timing of the NPH insulin can also be shifted to 10 p.m. so that the peak activity of the NPH insulin overlaps with the early morning surge of counter-regulatory hormones thereby avoiding hypoglycaemia.

Insulin glargine can be given once a day at fixed time, usually at 8 pm or 8 am Insulin detemir needs to be injected twice a day at fixed timings, e.g. 8 am and 8 pm, as its duration of action is around 20 hours. Long-acting analogues cannot be mixed with rapid/short-acting insulins.

In patient having mainly fasting hyperglycaemia, intermediate or long-acting insulin can be injected at 10 pm It is convenient and improves glycaemic control with lesser weight gain. The dose can be modified according to fasting plasma glucose (FPG) every third day. If post-prandial glycaemic control remains inadequate, short/rapid acting insulin is to be added either in form of pre-mixed preparation insulin or as basal bolus regimen. At this time insulin secretagogues should be stopped. Patients with FPG less than 200 mg/dL can be managed with pre-mixed insulin injected twice a day before meals. The usual preparation used is 30:70 or 25:75 ratio of short/rapid acting insulin to intermediate acting insulin. Higher percentage of short/rapid acting insulin (50%) is sometimes required to control post-prandial hyperglycaemia. Usually 50% to 70% of the required daily dose is injected before breakfast and 30% to 50% is injected before dinner. If required short/rapid acting insulin can be injected prior to lunch to control post-lunch hyperglycaemia. If FPG is more than 200 mg/dL, then the patient needs to be started on basal bolus regimen which means short/rapid acting insulin being injected prior to meals while intermediate/long-acting insulin injected separately at timings as described before. In this each component of insulin therapy can be manipulated separately according to individual requirement but at the cost of increased number of insulin injections. Insulin dose can be modified according to the rough 1,500 rule. 1,500/total insulin dose per day is equal to the effect of 1 unit of insulin on blood glucose in mg/dL. Insulin dosage needs to be individualised in each patient to achieve satisfactory glycaemic control. The reader is referred to chapter 7 Insulin Therapy in management diabetic ketoacidosis.

Site and Technique of Injection

Conventionally, insulin is injected with syringe subcutaneously in anterior abdominal wall. Other sites like arms and thighs are not preferred because of erratic absorption, especially if patient undertakes any physical activity leading to increased blood flow to the limb and hence rapid absorption of the insulin. After raising a skin fold the injection must be given perpendicular to the skin in obese individuals and at 45 degrees in thin patients. The site of injection must be rotated to avoid lipodystrophy.

Insulin vials are available in two strengths, namely 40 and 100 units per mL. One should be careful that the 'number' of units/mL on insulin vial must match the 'number' of units/mL on insulin syringe. Insulin pen devices are certainly user-friendly and convenient to carry. Insulin needs to be stored in refrigerator at 2 to 8 degree Celsius.

GLYCAEMIC TARGETS

The targets for fasting and post-prandial plasma glucose are 70 to 130 mg/dL and <180 mg/dL, respectively for adult population according to American Diabetes Association (ADA). The HbA1c needs to be targeted <6.5% to 7%. Glycaemic targets for children are described in **Table 2**. The goals need to be individualised, depending on the age of the patient, associated co-morbidities, and the risk of hypoglycaemia.

Table 2: Glycaemic Targets in Paediatric Age Group

Age (year)	Plasma Glucose (mg/dL)		HbA1c
	Before Meals	Bedtime	
<6	100 to 180	110 to 200	<8.5% but >7.5%
6 to 12	90 to 180	100 to180	<8%
13 to 19	90 to 130	90 to 150	<7.5%

Self Monitoring of Blood Glucose on Insulin Therapy

Patients on insulin therapy need to monitor blood glucose three or more times daily as recommended by ADA. The blood glucose is monitored pre-prandially to adjust insulin dosage. If HbA1c still remains high then post-prandial blood glucose needs to be targeted to achieve desired HbA1c.

INSULIN DELIVERY DEVICES

Conventionally, insulin is injected subcutaneously with the help of syringe. Pen devices have the advantage of hidden needles and convenience. Continuous subcutaneous insulin infusion (CSII) with insulin pump is another option. In this, rapid-acting insulin provides basal as well as prandial cover. This improves glycaemic control with decreased incidence of hypoglycaemia while reducing the number of pricks. Non-invasive insulin delivery includes use of inhaled insulin, buccal spray, and in form of tablets. The absorption of inhaled insulin starts immediately as that of rapid-acting insulin analogues but its duration of action is similar to regular insulin. In smokers, the bronchial tumour rate under inhaled insulin seems to be increased. With buccal spray device, insulin

particles get deposited in buccal cavity while oral insulin is in tablet form and delivers insulin to gastro-intestinal tract. The bioavailability of these preparations is approximately 10% and these mimic rapid-acting insulin in onset and duration of action. Other investigational routes of delivery include transdermal iontophoretic transport, powdered insulin delivery though skin using helium gas, liposome based formulation for insulin delivery, etc.

Adverse Effects of Insulin Therapy

The commonest problem with insulin therapy is hypoglycaemia (blood glucose <70 mg/dL) and weight gain. Risk factors for hypoglycaemia include-mismatched insulin syringe, mismatched meal timings, unusually vigorous exercise, impaired ability to defend against hypoglycaemia and hypoglycaemia unawareness in patients with autonomic neuropathy. Weight gain happens partly due to improved glycaemic control and partly due to inter-prandial snacking to avoid hypoglycaemia. These can be reduced by carefully titrating insulin therapy and educating the patient about it. Lipoatrophy, lipohypertrophy, and insulin allergy is rare now-a-days because of the availability of purified insulins.

Although there were some reports of association of increased risk of malignancies with insulin glargine but other studies have refuted it. This can be due to its higher affinity to IGF-1 receptor which determines the mitogenicity of insulin. However, insulin glargine is still not approved for pregnant patients and children less than six years of age.

9.8 Newer Modalities of Treatment in Type 2 Diabetes Mellitus

Anil Bhansali, G Shanmugasundar

INTRODUCTION

Type 2 diabetes mellitus is characterised by multiple metabolic abnormalities that result in hyperglycaemia. These include obesity, insulin resistance in skeletal muscle, adipose tissue and liver, increased hepatic production of glucose, and dysfunction of the islet cells of the pancreas. Islet cell abnormalities include qualitative and quantitative defects of insulin secretion from β-cells and dysregulated glucagon secretion from α-cells. It has also been shown that patients with type 2 diabetes have an impaired incretin effect. These multiple metabolic abnormalities lead to persistent hyperglycaemia unless intervened, results in the long-term complications of type 2 diabetes including micro- and macrovascular diseases. These long-term complications, in turn, cause considerable morbidity, and are associated with reduced life expectancy and increased health care costs.

Current treatment options have different mechanisms of action and are variably effective at lowering blood glucose levels. This includes biguanides, insulin secretagogues, thiazolidinediones, alpha-glucosidase inhibitors, and insulin.

Challenges in Achieving Good Glycaemic Control in Type 2 Diabetes

Clinical and observational studies clearly link glycaemic control to diabetes complications. However, while the beneficial effects of glucose-lowering interventions are established for microvascular disease, the data for macrovascular disease are less convincing, with recent trials suggesting that very intensive glucose-lowering may even result in an increase in cardiovascular events if implemented late in the course of the disease. However, the long-term follow-up of UK Prospective Diabetes Study Group (UKPDS) patients suggests persistent effects of good control if implemented early. The main limitations and unwelcome effects of most commonly used drug therapies are hypoglycaemia, fluid retention and weight gain, all of which may theoretically increase the risk of cardiac events (**Table 1**).

NEWLY AVAILABLE THERAPIES

New therapies are emerging, some of them address the unwanted side-effects and limitations of older therapies (**Table 2**).

INCRETIN-BASED THERAPIES

Incretins are intestinal hormones that increase insulin release from the pancreas and inhibit glucagon release. They are released after the ingestion of food from the L and K cells of the gastrointestinal tract. The main incretin that has found therapeutic use is glucagon-like peptide-1 (GLP-1). GLP-1 improves β-cell responsiveness to glucose and, unlike GIP, inhibits gastric emptying and has a central nervous system effect, resulting in reduced food intake and a decrease in body weight. Endogenous incretin peptides are short-lived due to their degradation by the enzyme dipeptidyl-peptidase-4 (DPP-4). The discovery of the incretin-DPP-4 pathways led to the development of GLP-1 analogues, which are resistant to the actions of DPP-4 and DPP-4 inhibitors, which protect the natural incretin hormones from deactivation.

Table 1: Adverse Effects of Commonly Used Oral Hypoglycaemic Agents

Type	Prototype	Hypoglycaemia	Fluid Retention	Weight Homeostasis	Typical Problems
Biguanide	Metformin, Metformin SR	No	No	Weight neutral or modest weight loss	Lactic acidosis; thus C.I in renal failure. Do not use in CKD 4, caution in CKD 3, liver and heart failure, GI intolerance
Sulphonylureas + other insulin secretagogues	Gliclazide, Glimeperide, Glipizide Glibenclamide, Repaglinide	Particularly in the elderly	No	Weight gain	No β- cell preservation
Thiazolidenediones/ Glitazones	Rosiglitazone, Pioglitazone	Uncommon	Frequent, especially in combination with insulin	Weight gain	CI in heart failure; avoid rosiglitazone in IHD, increased fracture risk in women
Insulin	Soluble, basal and biphasic insulin preparations	Frequent	Occasional	Weight gain	Other drawbacks: injection. First inhaled insulin withdrawn for economic reasons; also concerns regarding lung function and cancer risk
	Detemir			Weight neutral	

Table 2: Summary of Newer Glucose Lowering Therapies

Drug	Examples	Mechanism of Action	Dose Range	HbA1c Reduction	Advantages	Adverse Effects/ Disadvantages
Incretin mimetics	Exenatide Liraglutide	↑ Insulin, ↓ Glucagon, slow gastric emptying	5 or 10 µg BD 1.2 or 1.8 mg OD	0.5% to 1.0%	Weight loss	Injection—nausea, pancreatitis
Incretin enhancers	Sitagliptin Vildagliptin	Prolong endogenous GLP-1 action	100 mg OD 50 mg BD	0.4% to 0.9%	Weight neutral, no hypoglycaemia	Nausea, pancreatitis, dose reduction in renal failure
	Saxagliptin	Care while using in renal failure	5 mg OD			
SGLT-2 inhibitors	Dapagliflozin	Inhibits glucose re-absorption	5 to 10 mg OD	0.5% to 0.9%	Weight loss	Polyuria, genital infections
Amylin agonist	Pramlintide	Slow gastric emptying, ↓ glucagon	60 to 120 µg TDS	0.3% to 0.5%	Reduce postprandial glycaemia, weight loss	Injection, nausea Hypoglycaemia with insulin use

BD = Twice daily; OD = Once daily; TDS = Thrice daily; SGLT-2 = Sodium glucose transporters-2

INCRETIN MIMETICS

Exenatide

It is the synthetic version of exendin-4, a specific agonist of the GLP-1 receptor originally isolated from the salivary secretions of the lizard *Heloderma suspectum*, otherwise known as the gila monster. Its duration of action is longer compared with GLP-1, largely due to its resistance to degradation by DPP-4. It is a DPP-4 resistant peptide with a half-life of more than 2 hours, giving a therapeutic effect for 4 to 6 hours, it is administered twice daily by subcutaneous injection (5 or 10 µg) before main meals. It typically decreases HbA1c by 0.8% to 1.0% over 6 to 12 months, with substantially decreased postprandial glycaemic excursion, modestly decreased basal glycaemia and weight loss of 2 to 5 kg.

The improvement in glycaemic control is due to enhanced glucose-dependent insulin secretion, the suppression of postprandial glucagon secretion and slower gastric emptying. In addition, GLP-1 analogues reduce food intake, with subsequent weight reduction, and therefore, higher insulin sensitivity. Because their effect on insulin secretion is dependent on the prevailing glucose concentration, incretin analogues have a low risk of hypoglycaemia when used alone or in combination with metformin or thiazolidinediones but can increase the risk of hypoglycaemia when used with sulphonylureas.

Nausea is the most commonly reported side-effect, affecting up to 44% of patients in clinical trials. This, however, tends to reduce with time, and only 4% of patients in clinical trials withdrew from treatment as a result of nausea. There are case reports of acute pancreatitis in association with exenatide use, but it is currently unclear whether this is a true side-effect or a chance association. Meanwhile, it seems wise to avoid the use of this drug in patients with a history of pancreatitis or those at high risk (e.g. with severe hypertriglyceridemia).

Liraglutide

Liraglutide is another GLP-1 agonist which is now available. It is nearly identical to human GLP-1; consequently, the rate of antibody formation is low. Liraglutide has a significantly longer half-life (12 to 14 hours) than exenatide and can be dosed once daily. Like exenatide, liraglutide appears to reduce HbA1c levels (0.7 to 1.2) in patients poorly controlled on oral anti-diabetic medications, reduces fasting and postprandial plasma glucose levels, and results in progressive weight loss (4 to 6 kg). Improvements in glycaemic control appear to be better with liraglutide than with exenatide, probably because the former has a better effect on fasting plasma glucose levels. Risk of hypoglycaemia is low.

Incretin Enhancers

Gliptins acts as inhibitors of the enzyme DPP-4, which is responsible for the very rapid inactivation of the circulating incretin GLP-1 and GIP. Thus, DPP-4 inhibitors have been developed to prolong the circulating half-life of incretins, and thus, enhance the biological effects of endogenous incretins particularly GLP-1. Currently available gliptins include sitagliptin, vildagliptin and saxagliptin, which almost completely inhibit DPP-4 activity for about 12 to 18 hours causing increased endogenous incretin concentration to two-to-three-folds.

Sitagliptin

The usual recommended dose of sitagliptin is 100 mg per day, but 25 mg and 50 mg tablets are available for dosing in patients with moderate-to-severe renal impairment. The recommended doses for patients with renal impairment are 50 mg per day if the creatinine clearance is between 30 and 50 mL/min, and 25 mg per day if the creatinine clearance is <30 mL/min. Sitagliptin can be taken with or without food. It has been shown to be safe and efficacious in clinical trials, producing A1c reductions of 0.65% to 0.94%, with patients who had higher A1c levels (>9.0%) receiving the most benefit. No severe hypoglycaemia was reported with its use.

Vildagliptin

Clinical trials show that vildagliptin is similar to sitagliptin for dosing, efficacy, and safety profiles. A recent Cochrane review 19 compared the efficacy and safety of vildagliptin and sitagliptin in multiple studies, and concluded the following: 'Compared with placebo, A1c reductions of ~0.7% (sitagliptin) and 0.6% (vildagliptin) were noted; there were improvements in metabolic control when compared with other hypoglycaemic agents; neither medication produced weight gain, both were well tolerated, and there was no severe hypoglycaemia; and no definite conclusion could be drawn from published data about their effects on β-cell function'.

Saxagliptin

This drug is also available. Dose is 5.0 mg OD. It has similar action profile and effectiveness in glucose reduction. Other important

side-effects are pertaining to gastrointestinal tract like nausea, flatulence and diarrhoea.

Pramlintide

Pramlintide is an analogue of amylin, a small peptide hormone that is released into the blood stream by the β-cells of the pancreas along with insulin, after a meal. Like insulin, amylin is deficient in individuals with diabetes. By augmenting endogenous amylin, pramlintide aids in the absorption of glucose by slowing gastric emptying, promoting satiety via hypothalamic receptors (different receptors than for GLP-1), and inhibiting inappropriate secretion of glucagon, a catabolic hormone that opposes the effects of insulin and amylin.

It is used as an adjunct to insulin therapy for type 1 and type 2 diabetes. Although it has received only minor use, possibly due to the need for multiple daily subcutaneous injections separately from insulin, it has been shown to benefit glycaemic control while enabling a reduced insulin dose and a decrease in body weight.

SGLT-2 Inhibitor

The sodium glucose co-transporter-2 is located predominantly in the first segment of the proximal tubules of the kidney, where it acts as the conduit to re-absorb most of the filtered glucose. Dapagliflozin is a potent and highly selective SGLT-2 inhibitor. It causes urinary energy loss of up to 200 to 300 Kcal per day and can lower HbA1c up to 0.5% to 0.9% over 3 months with weight loss of 2.5 to 3 kg. Potential side-effects include polyuria and an increased risk of urinary and genital fungal infections. Other drugs in this group are sergliflozin and remogliflozin.

Glucokinase Activators

Glucokinase is the main 'glucose sensor' in the pancreas and liver. Defects in the glucokinase gene cause one form of maturity onset diabetes of the young, MODY 2. Glucokinase activators increase the sensitivity of glucokinase to high levels of glucose, leading to increased insulin secretion, increased liver glycogen synthesis and a decrease in liver glucose output. Potential concerns include hypoglycaemia due to increased insulin secretion. However, 'liver-selective' glucokinase activators with lower potential for hypoglycaemia have also been developed and tested in pre-clinical models.

Glucagon-Receptor Antagonists

The abnormal increase of liver-derived gluconeogenesis in type 2 diabetes mellitus is targeted by glucagon-receptor antagonists, which are currently being tested in humans.

Sirtuins

Sirtuin deacetylases have been discovered with the study of calorie restriction and resulting prolonged lifespan. SIRT1-activators do not only increase mitochondrial activity but also improve insulin secretion and glycaemia. Human studies in diabetic patients are in progress.

Other agents are expected to emerge from targeting gut hormones and appetite regulators, e.g. PYY3-36, ghrelin-antagonists, melanocortin-4 (MC4)-antagonists and MTP-antagonist (which limit gut absorption of fat) and various combinations of the above.

Insulin Pumps

Rather than receiving multiple daily subcutaneous injections of short- and either long- or intermediate-acting insulin, patients using an insulin pump receive a continuous subcutaneous infusion of short-acting insulin. These devices hold insulin reservoir and supply insulin via a plastic tube into subcutaneous tissue. Pumps are able to more precisely dose insulin compared to insulin syringes or pens. Pumps are also programmable to provide different doses of basal insulin throughout the day. This feature allows patients to increase their basal insulin, for example, to counteract the 'dawn phenomenon' or to decrease their basal rate to compensate for increased physical activity.

Insulin pumps in some, but not all, studies have been associated with improved metabolic control and lower risk of mild and severe hypoglycaemia in patients with type 1 diabetes. Most studies also show that the A1C improvement is modest, usually less than one percentage point. Some of the newest insulin pumps are also available with integrated continuous glucose monitoring devices mimicking pancreas.

CONCLUSIONS

Control of blood glucose in type 2 diabetes mellitus is important to improve outcomes, but achieving long-term control is challenging and all existing agents have limitations, particularly as most of the older agents and insulin cause an increase in body weight and hypoglycaemia. Newer agents, especially those that target body weight, have significant potential, but their place in the therapeutic algorithm is not yet determined possibly because of lack of data on cardiovascular safety profile.

9.9 In-Hospital Management of Diabetes Mellitus

Nihal Thomas, Rahul Ramnik Baxi

INTRODUCTION

A study has shown that India has spent a mind-boggling Rs.1.5 trillions on diabetes care in 2010. A significant proportion of inpatients with hyperglycaemia have undiagnosed diabetes and stress hyperglycaemia. Hospitalisation should be resorted to in diabetes patients only when absolutely necessary to cut down on costs.

EVIDENCE OF HARM FROM IN-HOSPITAL HYPERGLYCAEMIA AND BENEFITS OF GLUCOSE LOWERING

There is compelling evidence that poorly-controlled glucose levels are associated with a higher in-hospital morbidity and mortality, prolonged length of stay, unfavourable post-discharge outcomes and significant increase in healthcare costs. We have tried to stratify the impact of inpatient diabetes management, relying on evidence-based norms.

Which Patient Requires Hospitalisation?

Hospitalisation for a patient for reasons related to diabetes may be indicated in specific situations.

1. Acute metabolic complications like diabetic ketoacidosis, hyperglycaemic hyperosmolar state and hypoglycaemia with neuroglycopaenia.
2. Newly diagnosed diabetes in children and adolescents when unstable or brittle, for the purpose of dose adjustment or monitoring (when not possible on outpatient basis).
3. Chronic poor metabolic control that necessitates close monitoring to determine the aetiology and modify therapy as in hypoglycaemia unawareness.
4. Severe chronic complications requiring intensive treatment or other conditions unrelated to diabetes that significantly affect its control, particularly wherein ambulation may be a problem.
5. Uncontrolled insulin-requiring diabetes during pregnancy for rapid control.
6. The institution of insulin pump therapy or other intensive insulin regimens.

Diabetes In-Hospital Team

The patient

The patient forms the core of the team and is encouraged to participate in the formulation and conduct of their own care plan while admitted in the hospital.

Consultant physician/diabetologist/endocrinologist

The primary role of the consultant is as a leader of the multi-disciplinary team. They work closely to provide clinical support to diabetes specialist nurses and diabetes educators. The practical knowledge of 'on the spur of the moment' innovation is vital towards patient care, and over-rides theoretical knowledge.

Diabetes educator or diabetes specialist nurses

They play a key role in patient and staff education and implementation of glycaemic control strategies and are able to facilitate a smooth patient pathway from hospital to home. The diabetes educator could also be the leader of the team.

Diabetes specialist dietician

They play a pivotal role in those with complex nutritional needs —those unable to swallow, those with renal failure, pregnancy, cystic fibrosis, and the elderly.

Targets to be Achieved

1. Initiate glucose monitoring in any patient not known to have diabetes, but who receives therapy associated with high-risk for hyperglycaemia, including high-dose glucocorticoid therapy and initiation of enteral or parenteral nutrition. If hyperglycaemia is documented and persistent, treatment is necessary. Such patients should be treated to the same glycaemic goals as patients with known diabetes.
2. A plan for treating hypoglycaemia should be established for each patient. Episodes of hypoglycaemia in the hospital should be tracked.
3. All patients with diabetes admitted to the hospital should have their glycosylated haemoglobin (HbA1c) obtained if the result of testing in the previous 3 months is unavailable.
4. Patients with hyperglycaemia in the hospital should have appropriate plans for follow-up testing and care documented at discharge.

GOALS FOR BLOOD GLUCOSE LEVELS

Critically-Ill Patients

Insulin therapy should be initiated for treatment of persistent hyperglycaemia starting at a threshold of 180 mg/dL (10 mmol/L). Once insulin therapy is initiated, a glucose range of 140 to 180 mg/dL (7.8 to 10 mmol/L) is recommended for the majority of critically-ill patients.

Non-Critically-Ill Patients

There is no clear evidence for specific blood glucose goals. If treated with insulin, the pre-meal blood glucose target should generally be less than 140 mg/dL (7.8 mmol/L) and random blood glucose less than 180 mg/dL (10.0 mmol/L), provided these targets can be safely achieved. More stringent targets may be appropriate in stable patients with previous tight glycaemic control and less stringent targets in those with severe co-morbidities.

Hospital Barriers to Glucose Control

This may seem to be a paradox. However, hospitalisation may in fact hamper the efforts to achieve glycaemic control in some situations. Indeed, it may be more prudent to have good educational facilities on an out-patient basis to enable patient self-emancipation.

1. Majority of diabetes patients are hospitalised for reasons other than diabetes, e.g. vascular complications. The care of diabetes *per se* becomes subordinate to care for the primary diagnosis.
2. Infection, fever, glucocorticoid therapy, surgical trauma and general medical stress exacerbate hyperglycaemia due to release of counter regulatory hormones.
3. Decreased physical activity (in previously active patients) also exacerbates hyperglycaemia.
4. Strict diet and supervised compliance with drugs may result in hypoglycaemia in patients who were not compliant earlier.

COMMON ERRORS IN MANAGEMENT

Admission Orders and Lack of Therapeutic Adjustment

The out-patient treatment regimen is often continued unchanged or withdrawn entirely upon admission. Although either of these choices may occasionally be indicated, patients more commonly will require some modification of their out-patient regimen. A patient may be treated with regular insulin alone during the entire hospital stay, which will deprive the treating physician of an opportunity to observe the patient's response to regimens that can be transferred home.

High glycaemic targets

Blood glucose levels are commonly allowed to be more than 200 mg/dL. In-patient care is sometimes taken for granted to be superior; however, infrastructural limitations and nursing staff inadequately trained in diabetes could work contrary.

Overutilisation of 'sliding scales'

There are opinions that sliding scales are illogical, as they are designed to correct the therapeutic inadequacies of the previous 4- to 6-hour period rather than anticipating future requirements. Sliding scale is used frequently as the only means of insulin dosage, rather than concurrently with intermediate-acting insulins, which may lead to fluctuations of insulin supply and erratic glucose control. Sliding scale may be used in certain situations outlined in **Table 1**.

Table 1: Situations in which Sliding Scales may be Useful

To adjust pre-prandial insulin based on the pre-meal capillary glucose level and the anticipated carbohydrate consumption
With basal insulin analogues, such as insulin glargine
To evaluate patient's initial response to insulin
In patients receiving parenteral nutrition, in whom each 6-hour period is similar to the last

Underutilisation of insulin infusions

Intravenous insulin is recommended for patients with hyperglycaemic emergencies and also in the peri-operative setting or when glucose control has deteriorated with conventional subcutaneous insulin. The intravenous route provides predictable insulin delivery and enables quick control of glucose levels. Adequate nurse training, staffing and supervision is required for their safe implementation.

Blood Glucose Monitoring

In patients on enteral or parenteral nutrition, glucose monitoring is optimally performed every 4 to 6 hours. Glucose testing should be performed every 1 to 2 hours in patients on intravenous insulin infusions. In patients eating usual meals, glucose levels should be monitored as fasting and 2 hours post-prandial after three major meals. The common error in SMBC monitoring have to be kept in mind and taken care (**Table 2**).

Table 2: Sources of Errors in Bedside Blood Glucose Results

Sources of analytical error	Sources of use error
False high	Inadequate metre calibration
Low haematocrit	Inadequate quality-control
Hyperbilirubinaemia	Poor technique in finger prick
Severe lipaemia	Poor technique of applying blood drop on test strip
False low	Test strip with unmatched meter code or that has passed the expiration date
High haematocrit	
Either false high or false low	
Hypoxia	
Shock and dehydration	
Drugs: acetaminophen overdose, dopamine, mannitol, salicylate	

GLUCOSE CONTROL

General Recommendations

A key component of providing effective insulin therapy in the hospital setting is to determine whether a patient has the ability to produce endogenous insulin or not (**Table 3**).

Table 3: Characteristics of Patients with Insulin Deficiency

Known type 1 diabetes
History of pancreatectomy or pancreatic dysfunction
History of wide fluctuations in blood glucose levels
History of diabetic ketoacidosis
History of insulin use for >5 years and/or diabetes for >10 years

Patients with type 1 diabetes will require some insulin at all times to prevent ketosis, even when not eating. The insulin regimen should be revised frequently based on the values of glucose monitoring. Intermediate-acting insulin added once or twice daily, even at small doses, will stabilise the control. Glucose levels should be maintained as close to the normal range as possible in the post-operative, post-myocardial infarction, and intensive care settings. Conservative targets should be set in patients prone to hypoglycaemia (e.g. brittle diabetes, hypoglycaemia unawareness), in very elderly or in those with short life expectancy due to co-morbid conditions and with inadequate nursing or monitoring support.

Patient Specific Recommendations

Patient on oral agents and not consuming food

In patients on sulphonylurea or other secretagogues, the drugs should be withheld and a short-acting insulin sliding scale should be used temporarily. Addition of intermediate-acting insulin should be considered, if insulin is needed for more than 24 hours. Metformin may be withheld owing to concerns about altered renal function in the acutely ill. Avoid α-glucosidase inhibitors as these are effective only when taken with food. Thiazolidinediones are discontinued in patients with abnormal hepatic or cardiac function.

Patient on oral agents and consuming food

In patients on oral agents with controlled sugars, continue the medication but consider a dosage adjustment of 25% to 50%, due to the likelihood of better dietary adherence. Metformin should

be withheld in peri-operative patients (general anaesthesia), in those with standard contraindications, or when dehydration is suspected or anticipated and if radio-contrast studies are planned. α-glucosidase inhibitors and thiazolidinediones may be continued. Insulin should be started if sugars are uncontrolled.

Patient on insulin and not consuming food

Intravenous insulin infusion should be strongly considered in type 1 diabetes patients. Alternatively, half to two-thirds of the patient's usual dose of intermediate-acting insulin may be given along with a short-acting insulin sliding scale.

Some patients with type 2 diabetes on insulin may have improved control with diet restriction and require only short-acting insulin. A 5% dextrose solution intravenously at 75 to 125 mL per hour should be provided.

Patient on insulin and consuming food

Continue insulin, although consider dosage reduction (10% to 50%) in well-controlled patients because of the likelihood of more rigid dietary adherence.

Patient Scheduled for Surgery

Peri-operative instructions

In general, patient's treatment programme is least affected if surgeries are scheduled for early morning. Blood glucose levels should be monitored every 1 to 2 hours before, during and after the procedure.

Type 1 diabetes

Insulin infusion should be given at a maintenance rate (1 to 2 units per hour) with a 5% dextrose solution at 75 to 125 mL per hour, adjusted to maintain glucose levels between 100 and 150 mg/dL. Alternatively, give one-half to two-thirds of the usual dose of intermediate-acting insulin on the morning of procedure.

Type 2 diabetes

If the patient is taking an oral anti-diabetic agent, hold the medication on the day of procedure and resume when tolerating a normal diet.

If the patient is treated with insulin, give one-half of intermediate-acting insulin on the morning of procedure. Do not give short-acting insulin unless the blood glucose level is >200 mg/dL. Alternatively, an insulin infusion can be used.

SPECIFIC CLINICAL SITUATIONS

Insulin Pumps

Patients who use continuous subcutaneous insulin infusion (CSII) therapy in an out-patient setting can continue using it in the hospital, provided they are mentally and physically fit to do so. The availability of hospital personnel with expertise and experience in CSII therapy is essential.

Enteral Nutrition

For intermittent enteral feedings, intermediate-acting insulin with a small dose of regular insulin is adequate. For continuous feeding, once or twice daily insulin glargine (or NPH) can be used. Start with a small basal dose and use correction-dose insulin as needed while the glargine dose is being increased.

Parenteral Nutrition

The high glucose loads in standard parenteral nutrition frequently results in hyperglycaemia. Insulin therapy is recommended with glucose targets according to severity of illness.

Glucocorticoid Therapy

The best predictors of glucocorticoid-induced diabetes are family history of diabetes, increasing age and glucocorticoid dose and duration. For patients receiving high-dose intravenous glucocorticoids, an intravenous insulin infusion may be appropriate. During steroid tapers, insulin dosing should be proactively adjusted to avoid hypoglycaemia.

Switching from Intravenous to Subcutaneous Insulin

It is important to administer short-acting insulin subcutaneously 1 to 2 hours before discontinuation of the intravenous insulin infusion. Intermediate or long-acting insulin must be injected 2 to 3 hours before discontinuing the insulin infusion.

Prevention of Hypoglycaemia

Hypoglycaemia is the most important limiting factor in the management of diabetes, more so in patients on insulin. Institutions are more likely to have protocols for the treatment of hypoglycaemia than for its prevention. Tracking such episodes and analysing their causes are important quality improvement activities (**Table 4**).

Table 4: Causes of Hypoglycaemia in Patients on Insulin

Sudden reduction in oral intake or nil per oral status
Discontinuation of enteral feeding/TPN/IV dextrose
Pre-meal insulin given and meal not ingested
Unexpected transport from nursing unit after rapid acting insulin given
Reduction/omission of corticosteroid dose

Medical Nutrition Therapy in the Hospital

Current nutrition recommendations advise individualisation based on treatment goals, physiologic parameters, medication usage and other co-morbid conditions, such as obesity, dyslipidaemia, hypertension and renal failure. A registered dietician, skilled in diabetic MNT, should serve as an in-patient team member.

DISCHARGE PLANNING

Patients (and their families) should be familiar with their glucose targets and drug regimens after discharge from hospital and should understand any changes made in their treatment (**Table 5**).

Table 5: Issues to be Addressed Prior to Hospital Discharge

Level of understanding related to the diagnosis of diabetes
Self monitoring of blood glucose and explanation of home blood glucose goals
Recognition, treatment and prevention of hyperglycaemia and hypoglycaemia
Identification of health care provider who will provide diabetes care after discharge
Information on consistent eating patterns
When and how to take oral medications and insulin administration
Sick-day management
Proper use and disposal of needles/lancets/syringes

9.10 Hypoglycaemia

Siddharth N Shah

INTRODUCTION

Hypoglycaemia occurring several hours after meals was described for the first time in 1922. In 1927, hyperinsulinism as a cause was recognised in a patient with malignant pancreatic islet cell tumour who had episodes of severe hypoglycaemia. Hypoglycaemia is the major hazard of insulin treatment and to a lesser extent with OAD, while trying to achieve tight control. The patient may experience symptoms of hypoglycaemia when the blood glucose concentration is less than 50 mg/dL but individual susceptibility varies considerably. At its mildest it is no more than a slight inconvenience, but at its severest unconsciousness, it is both a hazard and an embarrassment. Hypoglycaemia occurs commonly in patients on sulphonylureas especially elderly patients on long-acting drugs like chlorpropamide and glibenclamide. Neonatal hypoglycaemia of infants born to diabetic mothers is well known.

DEFINITION

Hypoglycaemia or low blood glucose is a clinical state associated with low (less than 50 mg/dL) or relatively low plasma glucose concentration usually associated with signs and symptoms of autonomic hyperactivity and neuroglycopaenia. The Diabetes Control and Complications Trial (DCCT) has defined hypoglycaemia as an event resulting in seizure, coma, confusion, irrational or other prodromal symptoms consistent with hypoglycaemia (e.g. sweating, palpitations, hunger or blurred vision) in conjunction with a laboratory-determined or finger stick blood glucose less than 50 mg% and amelioration by treatment that raises blood glucose. Prodromal symptoms of hypoglycaemia remembered by the subject as occurring shortly before the event. Severe hypoglycaemic coma or seizure requires hospitalisation or intravenous glucose or glucagon.

AETIOLOGY

The most common cause of hypoglycaemia is iatrogenic, i.e. drug-induced oral hypoglycaemic agents or insulin. Hypoglycaemia secondary to alcohol, insulinoma, kidney and liver disease and that associated with endocrine dysfunction and neonatal hypoglycaemia are among the other causes of hypoglycaemia.

PHYSIOLOGY OF GLUCOSE COUNTER-REGULATION

Energy requirements are made from the substrate derived from food and excess substrates stored as fat, protein and glycogen. Insulin is the primary hormone mediating the anabolic phase of metabolism when the counter-regulatory hormone levels are suppressed. The metabolic adjustment during the catabolic phase includes the activation of liver for glycogenolysis and gluconeogenesis and use of free fatty acid from triglycerides stored in adipose tissue.

HYPOGLYCAEMIA AND THE BRAIN

Glucose is an obligate oxidative fuel for the brain under physiological conditions. The brain accounts for > 50% of whole-body glucose utilisation. The brain can oxidize alternative fuels, such as ketones, if their circulating levels are high enough to enter the brain in a substantial quantity, but that is seldom the case. Because it cannot synthesise glucose, it utilises physiological levels of circulating non-glucose fuels effectively, or store more than a few minutes supply of glucose as glycogen. The brain requires virtually continuous supply of glucose from the arterial plasma glucose concentration. This supply is required for maintenance of neural function and integrity. At some level of hypo-glycaemia (perhaps 50 to 55 mg/dL) (2.8 to 3.1 mmol/L) since symptoms normally occur at that level, blood-to-brain glucose transport becomes limited to brain glucose metabolism and therefore, function is impaired.

Maintenance of Systemic Glucose Balance

Falling plasma glucose concentrations elicit a sequence of responses that normally prevent or rapidly correct hypoglycaemia. Because obligatory glucose utilisation by the brain is fixed and exogenous glucose delivery from food is intermittent, systemic glucose balance is maintained and hypoglycaemia (as well as hyperglycaemia) is prevented by dynamic regulation of endogenous glucose production by the liver (and the kidneys) and of glucose utilisation by non-neural tissues such as muscle.

The physiological defence against declining plasma glucose concentrations include: (1) a decrease in insulin secretion; (2) an increase in glucagon secretion, in absence of the latter, an increase in epinephrine secretion. The behavioural defence is the ingestion of carbohydrates prompted by awareness of hypoglycaemia. The first physiological defence against hypoglycaemia is a decrease in pancreatic islet β-cell insulin secretion. That occurs as plasma glucose concentration decline and within the physiological range and increase hepatic (and renal) glucose production with virtual cessation of glucose utilisation by insulin-sensitive non-neural tissues. The second physiological defence is an increase in pancreatic islet α-cell glucagon secretion that occurs as plasma glucose concentrations fall just below the physiological range and increases hepatic glucose production (largely by stimulating glycogenolysis). Increased glucagon secretion is signalled by a decrease in intra-islet insulin, perhaps among other β-cell secretory products, in the setting of low plasma glucose concentration. The third physiological defence, which becomes critical when glucagon secretion is deficient, is an increase in adrenomedullary epinephrine secretion that too occurs as plasma glucose concentration through an array of mechanisms which include direct stimulation of hepatic (and renal) glucose production, limitation of glucose clearance by insulin-sensitive tissues, mobilisation of gluconeogenic substrates such as lactate

and amino acids from muscle and glycerol from fat, and limitation of insulin secretion. Unlike insulin and glucagon secretion, which are regulated primarily by changes in glucose concentrations within the pancreatic islets and only secondarily by central nervous system-mediate autonomic inputs, sympathoadrenal activity, including epinephrine secretion, is regulated with the central nervous system.

Hypoglycaemia-Associated Autonomic Failure in Diabetes

The concept of hypoglycaemia-associated autonomic failure (HAAF) in diabetes (**Table 1**) postulates that recent antecedent hypoglycaemia as well as prior exercise or sleep, causes both defective glucose counter-regulation (by reducing increments in epinephrine in the setting of absent decrements in insulin and absent increments in glucagon during subsequent hypoglycaemia) and hypoglycaemia unawareness (by reducing sympathoadrenal and the resulting neurogenic symptom response during subsequent hypoglycaemia) and, therefore, a vicious cycle of recurrent iatrogenic hypoglycaemia. Perhaps the most compelling support for the concept of HAAF is the finding, in three independent laboratories, that as little as 2 to 3 weeks of scrupulous avoidance of hypoglycaemia reverses hypoglycaemia unawareness and improves the attenuated epinephrine component of defective glucose counter-regulation in most affected patients. While HAAF is largely a functional, dynamic disorder that can induce and reverse, there may also be a structural (neuropathic) contribution to the attenuated sympathoadrenal response.

Table 1: HAAF (Hypoglycaemia-Associated Autonomic Failure)

Absolute endogenous insulin deficiency
A history of severe hypoglycaemia, hypoglycaemia unawareness, or both as well as recent antecedent hypoglycaemia, prior exercise, and sleep
Aggressive glycaemic therapy *per se* (lower AIC levels, lower glycaemic goals)

The first defence against falling plasma glucose concentration is decreased insulin secretion and the glucose counter regulatory hormones are activated. Glucagon plays a primary role in the glucose counter-regulatory process. Epinephrine becomes important when glucagon is deficient. Other factors such as cortisol and growth hormone are involved in prolonged hypoglycaemia; other hormonal neuro-transmitters and normal physiological response to falling blood glucose concentration is the decline in insulin secretion and it occurs at a glycaemic threshold of 83 mg/dL. The symptoms of hypoglycaemia are felt at blood glucose of 54 mg/dL and those of cognitive dysfunction at 49 mg/dL.

PATHOGENESIS

Hypoglycaemia is most commonly encountered due to over dosage with insulin or oral hypoglycaemic drugs. This may be due to any one or a combination of the following; if more than the required dose of insulin or oral drug is taken; if a meal is skipped, is inadequate or is unduly delayed after insulin injection or oral antidiabetic drugs and; unusual heavy physical exertion, after taking insulin.

In early diabetes with partial decompensation there is islet inertia and insulin is not released till blood glucose level reaches 200 mg/dL. Blood sugar then falls rapidly due to sudden release of insulin, leading to hypoglycaemia (reactive hypoglycaemia). Rapid gastric emptying in post-gastrectomy patients with brisk absorption of glucose results in excessive insulin release, leading to rapid fall of glucose concentration and hypoglycaemia symptoms.

When the liver function is severely impaired, hypoglycaemia occurs because glycogen stores in liver are poor and perhaps insulin destroying complex (insulinase) is deficient in hepatic disease. Recurrent hypoglycaemia can occur in patient with deteriorating renal function. Accumulation of serum insulin leads to fasting hypoglycaemia, (**Table 2**), diabetic type of glucose tolerance test due to inability of the liver to store glucose as glycogen, and poor glucose response to administration of glucagon or epinephrine. Alcohol induces slowing of the Krebs cycle with impairment of gluconeogenesis, giving rise to reduced glucose output and hypoglycaemia. There is no rise of serum insulin during fed state hypoglycaemia (**Table 3**).

Table 2: Causes of Fasting Hypoglycaemia

Underproduction	Overutilisation
Hormone deficiencies	Hyperinsulinism
Hypopituitarism	Insulinoma
Adrenal insufficiency	Exogenous insulin overdose
Catecholamine deficiency	Sulphonylurea overdose
Glucagon deficiency	Insulin autoimmunity
Enzyme defects	Inappropriate insulin level
Glucose-6-phosphatase	Extrapancreatic tumours
Liver phosphorylases	Carnitine deficiency
Pyruvate carboxylase	Cachexia with fat depletion, e.g. advanced cancer
Substrate deficiency	
Ketotic hypoglycaemia of infancy	
Severe malnutrition, muscle wasting (?)	
Late pregnancy	
Acquired liver disease	
Hepatic congestion	
Cirrhosis	
Severe hepatitis	
Drugs	
Alcohol	
Propranolol	
Salicylates	

Table 3: Fed State (Reactive) Hypoglycaemia

Underproduction	Overutilisation
Early (alimentary) within 2 to 3 hours after meals	Late (occult) diabetic 3 to 5 hours after meals
Alimentary hyperinsulinism	Delayed insulin release due to β-cell dysfunction
Post-gastrectomy (dumping syndrome)	Counter-regulatory deficiency of growth hormone, glucagon, cortisone, epinephrine
Hereditary fructose intolerance	
Galactosaemia	
Leucine sensitivity	

Non-specific reactive functional hypoglycaemia is the most frequent cause of hypoglycaemia in the normal population and is associated with anxiety. These patients tolerate physical exercise and prolonged fasting very well. In early diabetes, hypoglycaemia is seen to occur 3 to 5 hours after a carbohydrate-rich meal. Specially in patients with a strong

family history of diabetes. Fasting blood sugar is normal or elevated and prolonged fast is well tolerated. In reactive hypoglycaemia due to leucine sensitivity which releases insulin from the β-cells, hypoglycaemic convulsions occur after an injection of leucine in infants and small children. There is a fall in blood glucose within 20 minutes and marked rise of serum insulin levels. It is a self-limiting disease occurring in infants up to 5 months of age and is rarely seen in adults.

Pseudohypoglycaemia

Pseudohypoglycaemia occurs in certain chronic leukaemias when the leucocyte counts are markedly elevated. This artefactual hypoglycaemia reflects utilisation of glucose by leucocytes after the blood sample has been drawn. Such a hypoglycaemic condition, therefore, is not associated with symptoms. Other artefactual hypoglycaemias may be seen with improper sample collection or storage, errors in analytic methodology.

CLINICAL FEATURES

The signs and symptoms of hypoglycaemia can be divided into those due to autonomic hyperactivity and those resulting from neuroglycopaenia, as shown in **Table 4**. The manifestations are varied and will depend mainly on the rate of fall of blood glucose level and the ability of the patient's endocrine system to counteract. For example, a patient on insulin may complain of few symptoms despite very low glucose levels whereas a patient with Sheehan's syndrome may feel very uncomfortable even with moderately low blood glucose level.

Table 4: Signs and Symptoms of Hypoglycaemia

Autonomic Hyperactivity	Neuroglycopaenia
Adrenergic	Headache
Palpitation	Fatigue
Sweating	Mental dullness
Anxiety	Dizziness
Tremors	Blurring/clouding of vision
Parasympathetic	Confusion
Hyperactivity	Amnesia
Nausea	Seizure
Hunger	Unconsciousness

Patient may present with weakness, palpitation, nervousness, sweating and mental confusion, progressing to unconsciousness. History of insulin being administered or history of having consumed oral hypoglycaemic may be available. Short acting insulin may produce hypoglycaemia up to 4 to 6 hours after injection whereas intermediate acting insulin may produce hypoglycaemia in the evening or at midnight. It is rare to find prolonged hypoglycaemia with short-acting oral drugs like tolbutamide and glipizide whereas prolonged hypoglycaemia leading to coma is more commonly encountered in elderly diabetics who are on chlorpropamide or glibenclamide. Whipple's triad consisting of symptoms of hypoglycaemia, low blood glucose values during this period and immediate relief of symptoms and signs after ingestion of glucose is characteristic of β-cell tumours. Occasionally the tumour is associated with severe diarrhoea, muscle wasting or carcinoid syndrome. These patients get tired easily and do not tolerate prolonged exercise. It may also present as a part of multiple adenomatosis or neurofibromatosis. Even gastrin producing Zollinger-Ellison syndrome may be associated. After a severe bout of alcohol, hypoglycaemia can occur especially if the patient takes very little food. Hypoglycaemia is intermittent and cannot be reproduced by fasting. Patients who have undergone gastrectomy complain of nausea, abdominal discomfort, diarrhoea, sweating, palpitation and giddiness (dumping syndrome).

After ingestion of sugar or a fruit, severe vomiting and hypoglycaemia occur in hereditary fructose intolerance. Liver enlargement, jaundice, cirrhosis, albuminuria, aminoaciduria, and mental retardation due to chronic hypoglycaemia have been observed in children. Older children show strong dislike for sugar and fruits.

INVESTIGATIONS

Diagnosis of post-prandial hypoglycaemia, the only unequivocal diagnostic test is the demonstration of low plasma glucose concentration (less than 50 mg/100 mL) during spontaneously developed symptoms. A 5-hour oral glucose tolerance examination showing a plasma glucose value of 50 mg/mL or less is suggestive.

Diagnosis of β-cell adenomas (insulinoma) is based on serum insulin level of 20 µg/mL or more in the presence of blood glucose values below 40 mg/mL. Elevated circulating proinsulin level, differentiates between insulinoma and factitious hyperinsulinism. The ratio of insulin to glucose and absence of suppression of C-peptides during hypoglycaemia induced by 0.1 unit of insulin per kg body weight per hour are diagnostic. A normal person would suppress the peptide level to 50% or more during hypoglycaemia. Glucose tolerance test is not helpful. CT scan may not pick-up the tumour and pancreatic arteriography may be required to locate the tumour preoperatively.

In normal persons, the insulin/glucose ratio is always less than 0.4. In insulinomas, the ratio is greater than 0.4 and often above 1.0. Multiple sampling is required because patients with insulinoma may secrete insulin episodically. In islet cell tumours, provocative tests with tolbutamide, glycogen or leucine may be of help but the overlap between normal and insulinoma patients is so great as to render the tests of little value.

In factitious hypoglycaemia, the triad of low blood sugar, high immunoreactive insulin and low C-peptide level are pathognomonic of exogenous insulin administration. When sulphonylureas are suspected as being responsible, a chemical test of the plasma to detect the drugs may be required.

DIFFERENTIAL DIAGNOSIS

Hypoglycaemia may be misdiagnosed as hyperglycaemia and if not treated promptly may lead to death. Chronic hypoglycaemia may lead to loss of memory, clouding of vision, blunted mental activity, confusion, abnormal behaviour, convulsions and coma.

Hypoglycaemia should be differentiated mainly from hyperglycaemia especially when a patient is in coma. **Table 5** shows differential diagnostic features of hyperglycaemia and hypoglycaemia. Hypoglycaemia may also present as transient ischaemic attacks, giddiness, mental confusion, convulsion or

Table 5: Differential Diagnosis of Hypoglycaemic and Hyperglycaemic Coma

Symptoms, Signs and Laboratory Findings	Hypoglycaemic Coma	Hyperglycaemic Coma
Physical findings		
Pulse rate	Increased	Increased
Pulse volume	Full	Weak
Temperature	May be decreased	May be decreased
Respiration	Shallow or normal	Rapid and deep (air hunger)
Blood pressure	Normal, may be increased	Decreased
Skin	Clammy, sweating	Dry
Tongue	Moist	Dry
Tissue turgor	Normal	Reduced
Eyeball tension	Normal	Reduced
Breath	No acetone	Acetone may be present
Reflexes	Brisk reflexes	Diminished reflexes
Laboratory tests		
Urine glucose	Negative to positive depending on time of last voiding	Positive
Plasma glucose	Negative* to positive**	Positive** >200 mg/dL
Plasma acetone	Negative	Usually present
Plasma bicarbonate	Normal	Low <20 mg/L
Plasma CO_2	Normal	Diminished***
Blood pH	Normal	<7.35

** In case of diabetic ketoacidosis with very severe complicating lactic acidosis, urine and plasma acetone may be negative. Rarely, uraemic patients with diabetic ketoacidosis have positive plasma acetone but negative urine acetone.*
*** Sometimes urine is negative for sugar but positive for acetone in patients with hypoglycaemic coma. This is due to starvation ketosis.*
**** In patients with severe acute or chronic respiratory failure, plasma bicarbonate may be normal or increased despite concomitant presence of metabolic acidosis or diabetic ketoacidosis.*

coma and may be mistaken for a neurological illness. Although food, especially free carbohydrates, will relieve symptoms regardless of the cause, persons without a hypoglycaemic disorder may feel better after eating. A suspected patient has to undergo a 5-hour oral glucose tolerance test with plasma sampling every half hour and at the time the symptoms occur. A good history will clinch the diagnosis of iatrogenic hypoglycaemia.

COURSE AND PROGNOSIS

If detected early, hypoglycaemia is reversible and can be prevented. Surgical removal of β-cell tumour alleviates all symptoms. If hypoglycaemia occurs only at night and is not detected, it might lead to loss of memory and mental dullness.

SOMOGYI EFFECT

Insulin treated diabetic patients may show a rapid swing to hyperglycaemia after episodes of hypoglycaemia , the rebound hyperglycaemia or Somogyi effect is thought to be caused by actions of hormonal antagonists of insulin secreted in response to hypoglycaemia.

HYPOGLYCAEMIA UNAWARENESS

Some elderly long standing diabetics on sulphonylurea do not get adrenergic symptoms and present with severe neuroglycopaenic symptoms such as convulsions or coma during the hypoglycaemic episodes. About a decade back, when patients taking porcine insulin were shifted on human insulin in UK, some insulin-dependent diabetic patients also developed hypoglycaemia unawareness. It is characterised by low sympathetic response with insignificant increase in circulating epinephrine and glucagon. Since the hypoglycaemia-induced glucagon response is invariably reduced in patients with diabetes after 5 years, the main factor responsible for unawareness of hypoglycaemia is inadequate response of epinephrine. Autonomic neuropathy was initially thought to be the main factor responsible for inadequate counter-regulation. However, many with inadequate response have no evidence of autonomic neuropathy. It is postulated that the hypothalamus has a specialised area which detects hypoglycaemia and triggers autonomic response. Exposure of this area to hypoglycaemia would reset the trigger threshold at a lower level resulting in diminished counter-regulation.

TREATMENT

Hypoglycaemia associated with unconsciousness or stupor should be treated as an emergency. The treatment of choice is to give 25 to 50 mL of 50% glucose solution over a period of 2 to 3 minutes. One mg of glucagon injected IV is preferable in an emergency where peripheral veins are collapsed, the patient regaining consciousness within 15 min to permit ingestion of sugar. History of the precipitating cause of hypoglycaemia must be ascertained and the future course of action chalked out to prevent further episodes.

The treatment of reactive hypoglycaemia of fed state is alteration in dietary habits. Frequent small feeds are advised in non-specific reactive hypoglycaemia; the diet should contain some slowly absorbable carbohydrates and more protein. Anticholinergic drugs such as probanthine, 15 mg 3 times a day, may be useful in reducing rapid gastric emptying. Tolbutamide in small doses may be given twice daily before meals in patients with early diabetes. Reactive hypoglycaemia in leucine sensitivity can be treated by avoiding leucine containing protein

such as milk. Diazoxide has also been tried. Propranolol in small doses may be useful in both situations. Alcohol induced hypoglycaemia is prevented by reducing the intake of alcohol and increasing the ingestion of food. Hereditary fructose intolerance requires avoiding foods containing sugar or fructose. Other carbohydrates and milk can be taken without fear.

β-CELL TUMOURS

Surgical removal, chemotherapy and irradiation help in eradication of the tumour. If hypoglycaemia occurs it is treated symptomatically, e.g. carbohydrate feeding every 2 to 3 hours is usually effective in preventing hypoglycaemia. Glucagon should be available for emergency use. Diazoxide 300 to 600 mg daily orally has been useful along with a thiazide diuretic. Octreotide, somatostatin analogues have been used in metastatic tumours.

NON-β-CELL TUMOUR HYPOGLYCAEMIA

Mesenchymal tumours—45% to 64% of reported cases of non-β-cell tumour cause hypoglycaemia. Histological types – fibrosarcoma, lymphosarcoma, liposarcoma, rhabdom-yosarcoma, haemangiopericytomas, leiomyosarcoma, mesotheliomas. In both sexes; 5th to 7th decade; 1/3 in chest, 2/3 in abdomen; large and easily detectable, hepatomas, large adrenal tumours and carcinoma lung. These large tumours metabolise large amount of glucose. They may secrete insulin like material.

NEONATAL HYPOGLYCAEMIA

Hypoglycaemia in the immediate postpartum period needs recognition, as this phenomenon is transient. Associated with hypoglycaemia there are other parameters like hypocalcaemia, hyperbilirubinaemia, polycythaemia and hyperviscosity, respiratory distress syndrome and necrotising enterocolitis which must be recognised and treated. Every newborn of diabetic mothers must be given a 5% glucose infusion for the first six hours and subsequently blood glucose monitored to prevent fatal hypoglycaemia and hypoglycaemic convulsions.

AUTOIMMUNE HYPOGLYCAEMIA

This may be associated with insulin antibodies or insulin receptor antibodies. The age of onset varies from a few days to the elderly. Hypoglycaemia occurs at any time and is often limited. Insulin receptor antibodies are observed in diabetic patients with type B insulin resistance associated with acanthosis nigricans. Most of these patients have pre-existing insulin resistant diabetes and evidence of autoimmune disease before the development of hypoglycaemia.

Hypoglycaemia risk factor reduction. It is, of course, preferable to prevent rather than treat iatrogenic hypoglycaemia. The prevention of hypoglycaemia requires the practice of hypoglycaemia risk factor reduction (**Table 6**).

Table 6: Risk Factors for Hypoglycaemia in Diabetes

Absolute or relative therapeutic insulin excess

1. Insulin or insulin secretagogue doses are excessive, ill-timed, or of the wrong type
2. Exogenous glucose delivery is decreased (e.g. following missed meals and during the overnight fast)
3. Glucose utilisation is increased (e.g. during and shortly after exercise)
4. Endogenous glucose production is decreased (e.g. following alcohol ingestion)
5. Sensitivity to insulin is decreased (e.g. in the middle of the night and following weight loss, improved fitness or improved glycaemic control)
6. Insulin clearance is decreased (e.g. with renal failure)

PROPHYLACTIC MEASURES

Minimising the risk of hypoglycaemia while maintaining meaningful glycaemic control is a challenge for people with diabetes and their caregivers, adequate education of diabetic patients and their relatives is necessary so that hypoglycaemia can be avoided or treated effectively at an early stage. Patients should carry a card stating that they have diabetes and are treated with insulin or oral hypoglycaemic agents. Relatives, friends or colleagues at work or at school should be familiar with the signs of hypoglycaemia and its emergency treatment. The importance of regular meals and snacks must be emphasised, and treatment should be adjusted appropriately for sporting activities or for special situations such as fasting before radiological procedures or minor surgery. If Beta-blocking drugs are needed, cardioselective agents should be used. The widespread use of highly purified human insulins should reduce the problem of hypoglycaemia associated with high titres of insulin antibodies. The therapeutic goal has to be modified in diabetic patients with autonomic neuropathy, hypoglycaemia unawareness of severe diabetic complications. Very strict glycaemic control should be avoided where the risks of hypoglycaemia outweighs any potential benefit, such as in long-standing, type 1 patients who have impaired glucose counter-regulation, or in elderly or mentally subnormal patients. Intensive insulin therapy may also be impractical in treating infants or very young children. Moderate hyperglycaemia may have to be accepted in these individuals to avoid the greater risks of low blood glucose concentrations. Although there is no evidence in humans that hypoglycaemia causes foetal damage in early pregnancy, very tight glycaemic control reduces the ability to perceive hypoglycaemic symptoms and increases the risk of coma and convulsions, which are clearly undesirable for foetal development. Rapid tightening of glycaemic control is now considered to have an initial potentially adverse effect on established microangiopathy and also increase vulnerability to hypoglycaemia. Because of the potential risk of hypoglycaemia, type 1 individuals are usually advised not to participate in high-risk sporting activities such as hand-gliding, parachute jumping or scuba-diving. They may also be excluded from certain types of employment. They are usually debarred from driving public-service vehicles, fly aeroplanes and may not be permitted to operate some forms of machinery.

9.11 Diabetic Ketoacidosis, Hyperosmolar Hyperglycaemic State and Lactic Acidosis

Rajesh Rajput

INTRODUCTION

Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are potentially life-threatening complications in patients with diabetes mellitus representing two extremes in the spectrum of uncontrolled diabetic state. DKA happens predominantly in those with type 1 diabetes, while HHS is seen in patients with type 2 diabetes under certain circumstances. HHS differs from DKA in the magnitude of dehydration, ketosis, and acidosis. In as many as one-third of cases, the clinical features of HHS and DKA overlap and are observed simultaneously (overlap cases).

PATHOPHYSIOLOGY

In both DKA and HHS, the underlying metabolic abnormality results from combination of absolute or relative insulin deficiency and increased amount of counter-regulatory hormones (**Figure 1**). In DKA, the lack of insulin and corresponding excess of glucagon promotes gluconeogenesis, glycogenolysis, and ketone body formation in the liver. The combination of insulin deficiency and hyperglycaemia reduces hepatic levels of fructose 2,6-biphosphate, which alters the activity of phosphofructokinase and fructose 1,6-bisphosphate. Glucagon excess decreases the activity of pyruvate kinase, whereas insulin deficiency increases the activity of phosphoenolpyruvate carboxykinase and, thus, promoting gluconeogenesis. Ketosis results from marked increase in free fatty acid release from adipocytes secondary to insulin deficiency and increases ketone body (acetoacetate and β-hydroxybutyrate) formation in the liver through activation of carnitine palmitoyl-transferase I secondary to hyper-glucagonaemia. This enzyme is crucial for regulating fatty acid transport into the mitochondria, where β-oxidation and conversion to ketone body occurs. The ketone bodies, however, have a low pH and cause metabolic acidosis. The absence of ketosis in HHS is not completely understood. Contributing factors include availability of insulin in amounts sufficient to inhibit ketogenesis but not sufficient to prevent hyperglycaemia. Additionally, hyperosmolarity itself may decrease lipolysis, limiting the amount of free fatty acids available for ketogenesis. Also, lower levels of counter-regulatory hormones have been found in patients with HHS compared with those with DKA.

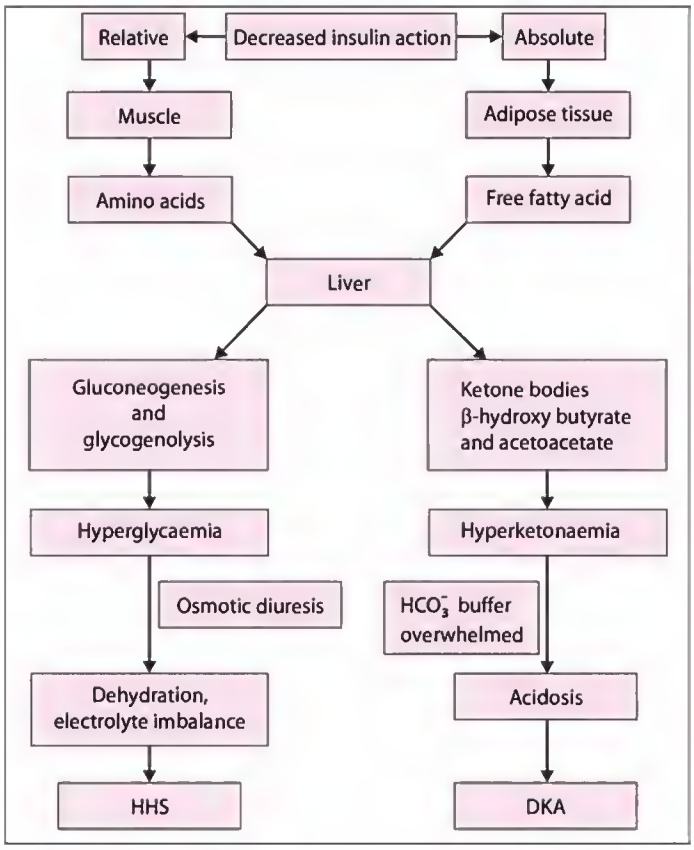

Figure 1: Pathophysiology of DKA and HHS.

CAUSES

Infections, especially pneumonia and urinary tract infection, remain the most common precipitating factor in the development of DKA and HHS. DKA may also be the first presentation in patients with type 1 diabetes. Young patients with recurrent episodes of DKA may have an underlying eating disorder, or may be using insufficient insulin for fear that it will cause weight gain. In around 5% of cases, no cause for the DKA is found. Any illness that predisposes to dehydration may lead to HHS. Various other precipitating factors for HHS are silent myocardial infarction, cerebrovascular accident, mesenteric ischaemia, acute pancreatitis and use of various medications, such as steroids, thiazides, diuretics, calcium channel blockers, propranolol, and phenytoin.

CLINICAL FEATURES

DKA usually develops in younger, lean type 1 diabetes patients and develops within a day or so while HHS is usually occurs in older and obese type 2 diabetic patient and develop over days or weeks and is often preceded by illness, e.g. vomiting or chronic co-morbidity, e.g. dementia, immobility that results in several days of increasing dehydration. Predominant symptoms in DKA are nausea and vomiting, pronounced thirst, excessive urine production, and abdominal pain that may be severe. In severe DKA, breathing becomes laboured and of a deep, gasping character known as 'Kussmaul respiration'. The abdomen may be tender to the point that an acute abdomen may be suspected, such as acute pancreatitis, appendicitis or gastrointestinal perforation.

On physical examination there is usually clinical evidence of dehydration, such as a dry mouth and decreased skin turgor. If the dehydration is profound enough to cause a decrease in the circulating blood volume, tachycardia and low blood pressure may be observed. In DKA a 'ketotic' odour is present, which is

often described as 'fruity'. If Kussmaul respiration is present, this is reflected in an increased respiratory rate. The patient of HHS may present with focal or global neurologic changes like drowsiness, lethargy, delirium, coma, focal or generalised seizures, hemiparesis, and sensory deficits.

DIAGNOSIS AND LABORATORY INVESTIGATIONS

Laboratory features differentiating between DKA and HHS are summarised in **Table 1**. DKA is characterised by hyperglycaemia, ketosis and increased anion gap metabolic acidosis. American Diabetes Association categorises DKA into one of the three stages of severity:

Mild: Blood pH mildly decreased to between 7.25 and 7.30 (normal 7.35 to 7.45); serum bicarbonate decreased to 15 to 18 mmol/L (normal above 20); the patient is alert

Moderate: pH 7.00 to 7.25, bicarbonate 10 to 15, mild drowsiness may be present

Severe: pH below 7.00, bicarbonate below 10, stupor or coma may occur.

Table 1: Differences Between DKA and HHS

	DKA	HHS
Plasma glucose (mg/dL)	>250	>600
Arterial pH	<7.3	>7.3
Sodium bicarbonate (mEq/L)	<15	>15
Serum and/or urinary ketones	Positive (>1:2 dilution)	Negative
Effective serum osmolality (mOsm/kg)*	Variable	>320
Anion gap**	>12	<12
Mental status	Variable (depends on severity)	Usually stupor or coma
Total water deficit (mL/kg)	100	100 to 200
Sodium (mEq/kg)	7 to 10	5 to 13
Chloride (mEq/kg)	3 to 5	5 to 15
Potassium (mEq/kg)	3 to 5	4 to 6

**Total and effective serum osmolality:*
Total serum osmolality (mOsm/kg): 2[measured serum sodium (mEq/L) + glucose (mg/dL)/18] + BUN (mg/dL)/2.8] (normal 290 ± 5)
Effective serum osmolality (mOsm/kg): 2[measured serum sodium (mEq/L) + glucose (mg/dL)/18] (normal 285 ± 5)
*** Anion gap: Na^+-Cl^- + HCO_3^- (normal 12 ± 2)*

While diagnostic features of HHS include plasma glucose level of 600 mg/dL or greater, total serum osmolality of 330 mOsm/kg or greater and absence of severe ketoacidosis. Since pH on a venous blood gas level is 0.03 lower than pH on an arterial blood gas (ABG) analysis, venous pH may be used for repeat pH measurements. Because this difference is relatively reliable and not of clinical significance, there is almost no reason to perform the more painful ABG. The Acetest and Ketostix products measure blood and urine acetone and acetoacetic acid. They do not measure the more common ketone body, β-hydroxybutyrate, so the patient may have paradoxical worsening of ketosis as the latter is converted into the former during the treatment. However, this should not be a matter of concern when patient is improving as suggested by change in pH and bicarbonate levels. Serum or capillary β-hydroxybutyrate can be used to follow response to treatment. Levels greater than 0.5 mmol/L are considered abnormal, and levels of 3 mmol/L correlate with the need for DKA treatment. Patients with DKA who are in a coma typically have effective osmolalities >320 mOsm/kg H_2O. If the osmolality is less than this in a patient who is comatose, search for another cause of obtundation such as cerebrovascular accident, head injury, hyponatremia, meningitis and or rhinocerebral mucormycosis. Hyperamylasemia may be seen, even in the absence of pancreatitis. BUN level is increased due to dehydration. Other relevant investigations include measurement of serum potassium, blood culture, urinalysis and urine culture, chest radiography and electrocardiography.

DIFFERENTIAL DIAGNOSIS

Ketoacidosis is not always the result of diabetes. It may also result from alcohol excess and from starvation; in both states the glucose level is normal or low. Metabolic acidosis may occur in diabetics for other reasons, such as chronic renal failure, shock due to any cause and poisoning with ethylene glycol or paraldehyde (**Tables 2 and 3**).

MANAGEMENT

Volume contraction is hallmark of DKA and HHS. It contributes to hyperglycaemia by decreasing renal clearance of glucose, causes insulin resistance by decreasing insulin delivery to the site of insulin-mediated glucose disposal and through stimulation of catecholamine and glucocorticoids. If severe enough to cause hypotension, it contributes to

Table 2: Differential Diagnosis of Acidosis and Coma

	Diabetic Ketoacidosis	Lactic Acidosis	Uraemic Acidosis	Alcoholic Ketosis	Starvation Ketosis	Methanol or Ethylene Glycol Toxicity	Rhabdomyolysis
Plasma glucose	↑	N	N	↓	N or ↓	N	N
Glucosuria	++	–	–	–	–	–	–
Plasma ketones	↑↑	N	N	↑	↑	N	N
pH	↓	↓	↓	N or ↓	N	↓↑	↑
Anion gap	↑	↑	↑	↑	↑	↑	↑
Osmolality	↑	N	↑	N	N	↑↑	N or ↑
Others		Serum lactate >5 mmol/L	↑ Urea and creatinine			Serum levels positive	Myoglobinuria Haemoglobinuria

acidosis through lactic acid production as well as decreased renal clearance of organic as well as inorganic acids. Therefore, fluid resuscitation is a critical part of treating DKA and HHS and it should be started even before insulin therapy. Intravenous solutions replace extravascular and intravascular fluids and electrolyte losses. They also dilute both the glucose levels and the levels of circulating counter-regulatory hormones.

Administer high volumes of isotonic saline (1 to 3 L) in 2 hours. Further isotonic saline should be administered at a rate appropriate to maintain adequate blood pressure and pulse, urinary output, and mental status. After initial stabilisation with isotonic saline, switch to half-normal saline at 200 to 500 mL per hour (half-normal saline matches losses due to osmotic diuresis).

Table 3: Clinical Pearls in Diagnosis and Management

Pseudohyponatraemia: Osmotic effect of hyperglycaemia moves intravascular water to the extravascular space and causes pseudohyponatraemia. Correct serum sodium by approximately 1.6 mEq/L for 100 mg/dL of glucose over 100 mg/dL.

Potassium: May be normal despite depletion of body stores due to metabolic acidosis.

Serum creatinine: May be falsely elevated due to elevated acetoacetate (ketone body).

Captopril (ACE-Inhibitor): May cause false positive reaction for ketone by nitroprusside test/ketostix.

Total leucocytes: Raised with DKA *per se* and does not suggest presence of infection until more than 15×10^9/L or marked left shift is present.

Body temperature cannot be used as a guide to the presence of infection: vasodilation causes warm feeling while core body temperature is reduced.

Hyperamylasaemia: Seen in DKA and is of salivary origin. Cannot be used as a marker for the diagnosis of pancreatitis.

Hypertriglycridaemia: Seen in DKA due to enhanced lipolysis and decreased uptake by liver. It can cause pseudohyponatraemia and when marked, precipitates pancreatitis.

Ketosis may worsen paradoxically with treatment due to conversion of β-hydroxybutyrate to acetoacetate.

Bicarbonate should be given only if pH is less than 6.9 or if pH is less than 7.1 along with hypotension or if hyperkalaemia is present.

Euglycaemic DKA: Plasma glucose may be normal in patient with decreased oral intake and in pregnancy.

Insulin is needed to help switch from a catabolic state to an anabolic state, with uptake of glucose in tissues and the reduction of gluconeogenesis as well as free fatty acid and ketone production. It should be started about an hour after intravenous fluid replacement. It is stared at a dose of 0.2 U/kg, intravenous, bolus followed by 0.1 U/kg per hour as continuous infusion. The rationale to give bolus dose is to saturate insulin receptors fully before beginning insulin infusion and to avoid lag time necessary to achieve steady-state insulin levels. There is no need to add albumin to prevent insulin absorption to the infusion set. However, intravenous tubing should be flushed with insulin infusate before use. In case glucose does not decrease by at least 10% or 50 mg/dL in an hour, insulin infusion rate should be doubled and a second bolus of insulin should be administered. When glucose levels have dropped to 250 mg/dL in DKA and 300 mg/dL in HHS, intravenous fluids should be switched to D5/1/2 NS to prevent hypoglycaemia, recognising that insulin is still needed to treat ketonaemia and rate of insulin infusion should be reduced to 1 to 2 U per hour. The glucose should be checked every 2 hours initially and at least every 4 hours subsequently until a stable insulin regimen is determined. After resolution of DKA (i.e. HCO_3^- >18, anion gap ≤12, and pH >7.3) or HHS (i.e. serum osmolality < 315 mOsm/kg and patient is alert) patient should be switched to subcutaneous insulin. In DKA insulin drip should be discontinued 30 minutes after giving subcutaneous insulin. In newly diagnosed diabetic patients, the initial dose of insulin should be 0.6 U/kg per day divided into a mixed regimen including both short- and long-acting insulin, until an optimal dose is established.

Potassium Replacement

Potassium replacement should be started with initial fluid replacement if potassium levels are normal or low. Add 20 to 40 mEq/L of potassium chloride (KCl) to each litre of fluid once K^+ is under 5.5 mEq/L. Potassium should ideally be given as two-thirds as KCl, one-third as potassium phosphate. If patient is oliguric do not administer potassium unless serum concentration is less than 4 mEq/L or there are ECG changes of hypokalaemia (U waves).

Bicarbonate typically is not replaced in DKA since acidosis will improve with the above treatments alone. Administration of bicarbonate has been correlated with cerebral oedema in children. Bicarbonate should be given only if pH is less than 6.9 or if pH is less than 7.1 along with hypotension or if hyperkalaemia is present. When indicated it should be given at the rate of 1 mEq/kg of bicarbonate as rapid infusion over 10 to 15 minutes with further therapy based on repeated ABG measurement done every 30 to 120 minutes. Additional potassium should be given with bicarbonate therapy as transient hypokalaemia is not uncommon during alkali administration.

Phosphate and magnesium replacements are not typically needed, since levels correct when the patient resumes eating.

COMPLICATIONS

Most patients with DKA recover when treated properly and majority of deaths result from late complications rather than from DKA itself (**Table 4**). Patients with HHS are predisposed to develop thromboembolic complications including cerebrovascular accident, myocardial infarction, mesenteric thrombosis, pulmonary embolism and disseminated intravascular coagulation. Various other complications seen in patients with HHS are cerebral oedema, adult respiratory distress syndrome and rhabdomyolysis.

PROGNOSIS

DKA accounts for 14% of all hospital admissions among diabetics and 16% of all diabetes-related fatalities. In children younger than 10 years, DKA causes 70% of diabetes-related fatalities. When managed appropriately the overall mortality is less than 5%. The overall mortality rate in HHS is between 10% and 20% and is dependent on co-existing conditions and complications.

Table 4: Complications in DKA

Complication	Clues	Treatment
Hypoglycaemia	Rebound ketosis, adrenergic or neurologic sign	Shift to DNS once plasma glucose falls to < 250 mg/dL and reduce insulin infusion to 2 to 3 U per hour
Hypokalaemia	Cardiac arrhythmia	Potassium replacement
Infection	Fever, WBC >15 × 10^9/L or marked left shift	Appropriate antibiotics
Myocardial infarction	Chest pain, new onset heart failure, hypotension despite adequate fluid therapy, ECG	Thrombolysis and other adjunctive measures
Cerebral oedema	Drowsiness, coma with or without neurological signs, especially if occurring after initial improvement	Intravenous mannitol 1 mg/kg, forced hyperventilation with aim to keep PCO_2 around 28 mm Hg
Acute gastric dilatation or erosive gastritis	Vomiting of blood or coffee ground material	Proton pump inhibitors
Mucormycosis	Facial pain, bloody nasal discharge, blackened nasal turbinates, blurred vision, proptosis	Intravenous amphotericin
Respiratory distress syndrome	Hypoxemia in the absence of pneumonia, chronic pulmonary disease or heart failure	Ventilatory support
Acute pulmonary oedema	Bilateral basal crepts with raised pulmonary capillary wedge pressure	Judicious fluid replacement, especially in those with co-morbidities such as renal failure or congestive heart failure. Diuretics, if needed
Vascular thrombosis	Stroke like picture or signs of ischaemia in non-nervous tissue	Anti-fibrinolytic and anti-coagulant therapy

PATIENT EDUCATION AND SICK DAY GUIDELINES

All patients with diabetes should be educated about the importance of monitoring plasma glucose levels during infection, trauma, and other periods of stress and not to stop insulin therapy in presence of any intercurrent illness (**Table 5**).

Table 5: Sick Day Guidelines

Never stop insulin and check for ketones
Measure plasma glucose four times a day
If RBG <200 mg/dL continue normal insulin
If RBG 200 to 250 mg/dL add extra 4 U with meals
If RBG >250 mg/dL add extra 6 U with meals, drink milk, fruit juice, plenty of fluids
If nausea, vomiting and RBG >250 mg/dL, consult your physician immediately

LACTIC ACIDOSIS

Definition and Epidemiology

Lactic acidosis is a condition of increased anion gap metabolic acidosis characterised by an excess of serum lactate due to lactate production that exceeds its systemic consumption. The normal blood lactate concentration in unstressed patients is 0.5 to 1 mmol/L. Patients with critical illness can be considered to have normal lactate concentrations of less than 2 mmol/L. Hyperlactataemia is defined as a mild-to-moderate persistent increase in blood lactate concentration (2 to 5 mmol/L) without metabolic acidosis, whereas lactic acidosis is characterised by persistently increased blood lactate levels, i.e. >5 mmol/L in association with metabolic acidosis. The overall incidence of lactic acidosis in critically-ill patients is unknown; however, increasing acid-base evaluations of critically-ill patients indicate that its presence is associated with increased morbidity and mortality.

Pathophysiology and Aetiology

Lactate is a product of anaerobic glycolysis and is generated from pyruvate with lactate dehydrogenase as a catalyst. Pyruvate is normally aerobically metabolised to CO_2 and H_2O in the mitochondrion in the process of gluconeogenesis. In the setting of decreased tissue oxygenation, lactic acid is produced as the anaerobic cycle is utilised for energy production. Lactate is cleared from blood, primarily by the liver (80% to 90%) and kidneys (10% to 20%). The lactate exits the cells and is transported to the liver where it is oxidised back to glucose. With a persistent oxygen debt and overwhelming of the body's buffering abilities (whether from chronic dysfunction or excessive production), lactic acidosis ensues. Lactic acidosis was described and classified into 2 types:

1. ***Type A lactic acidosis***

Occurs with decreased tissue ATP production due to poor tissue perfusion or oxygenation. It can further be sub-classified into two types:

(a) *Overproduction:* Circulatory, pulmonary, or haemoglobin transfer disorders are commonly responsible.

(b) *Underutilisation:* Liver disease, gluconeogenesis inhibition, thiamine deficiency, and uncoupled oxidative phosphorylation.

2. ***Type B lactic acidosis***

Occurs when evidence of poor tissue perfusion or oxygenation is absent. It is further divided into 3 subtypes based on underlying aetiology.

(a) *Type B1:* Seen in association with systemic disease, as such diabetes mellitus, bowel ischaemia, severe iron-deficiency anaemia, liver disease, alcoholic ketoacidosis, pancreatitis, malignancy (leukaemia, lymphoma, lung cancer), infection, renal failure, seizures, heat stroke, pheochromocytoma, thiamine deficiency, short gut syndrome, and other carbohydrate malabsorption syndromes.

(b) *Type B2:* Several classes of drugs and toxins are implicated including biguanides (phenformin, metformin), acetaminophen, alcohols, iron, isoniazid, nucleoside analogues (zidovudine, didanosine, lamivudine), β-adrenergic agents

(epinephrine, ritodrine, terbutaline), sodium nitroprusside, 5-flourouracil, sugars and sugar alcohols (fructose, sorbitol and xylitol), salicylates, sulphasalazine, strychnine and valproic acid.

(c) *Type B3:* Is due to inborn errors of metabolism. These include glucose-6-phosphatase deficiency (von Gierke disease), fructose-1,6-diphosphatase deficiency, pyruvate carboxylase deficiency, pyruvate dehydrogenase deficiency, oxidative phosphorylation deficiency, and methylmalonic aciduria.

Clinical Features

No single clinical feature itself is indicative of the presence of lactic acidosis, as symptoms are dependent on the underlying aetiology. Nevertheless, a careful history is vital to determine the underlying pathology. The onset of acidosis may be rapid (i.e. within minutes to hours) or progressive (i.e. over a period of several days). The physical examination also depends on the underlying cause of lactic acidosis. Signs of cardiovascular compromise frequently include cyanosis, cold extremities, tachycardia, hypotension, dry mucous membranes, dyspnoea, confusion, lethargy, stupor, or coma. Hyperventilation is common as a compensatory mechanism causing respiratory alkalosis.

Laboratory Work-Up

No significant differences in serum lactate levels are noted in arterial and venous blood samples. The concentration of serum lactate must be measured as quickly as possible (within 4 hours of collection) in a sample transported on ice. The normal serum lactate level is approximately 1 mmol/L with a range up to 2 mmol/L. Values above 5 mmol/L in the setting of acidaemia are indicative of lactic acidosis. Additional laboratory tests may be selected on the basis of the suspected underlying aetiology of lactic acidosis.

Treatment

Treatment of lactic acidosis requires identification of the primary illness and appropriately directed therapy. Restoration of tissue oxygen delivery, thereby causing cessation of acid production, remains the primary therapeutic focus. Early goal-directed therapy for sepsis is well described and is associated with improved outcomes. Appropriate measures include treatment of shock, restoration of circulating fluid volume, improved cardiac function, identification of sepsis source and appropriate therapy, and resection of any potential ischaemic regions. Vital signs and cardiac rhythms must be monitored closely because acidosis predisposes to arrhythmias including tachyarrhythmias and fibrillation. Specific medications for the treatment of lactic acidosis include sodium bicarbonate, tris-(hydroxymethyl) aminomethane, carbicarb, and dichloroacetate. Toxic aetiologies of lactic acidosis such as methanol, ethylene glycol, and cyanide poisoning are unique circumstances that require bicarbonate therapy to facilitate the detoxification processes.

Prognosis

The duration and degree of increased serum lactic acid appear to predict morbidity and mortality. Normalisation of serum lactate concentration (<2 mmol/L) within the first 24 hours is associated with 100% survival, 78% survival if normalisation occurred in 24 to 48 hours, and only 14% survival if after 48 hours. The lactate level should be used only as a single tool in combination with clinical findings and other measures of circulatory failure rather than as a decisive indicator of disease severity.

9.12 Infections in Diabetes Mellitus

Samar Banerjee

INTRODUCTION

Infection in diabetes mellitus (DM) is very common and important complication. DM predisposes to infection and infection in turn overwhelms the metabolic control. Effective control of each affects the control of the other condition. Diabetes is considered as a secondary immune deficiency disorder by World Health Organization (WHO).

Chronic hyperglycaemia impairs host defence. Some infections occur more in diabetics, whereas some other infections occurs both in diabetics and non-diabetics. The different types of immune alterations that occur in diabetes are described below.

IMMUNE ALTERATIONS IN DIABETES

1. Diminished chemotaxis, phagocytosis, and killing activity, of lymphocyte function (especially CD4 cells)
2. Lower levels of immunoglobulins and complement level (C4, C4A, C1q and C3)

Beyond these immune factors, local factors also predispose to infections as follows:

(a) Hyperglycaemia alters the endothelial function and increase the oxidative stress

(b) Angiopathy both micro and macro, produces anoxia and results in microbial proliferation, impairment of oxygen dependent polymorphonuclear function, and perfusion of antibiotics, etc.

(c) Sensory motor neuropathy produces pressure sores, ulcers, abnormal pressure points in the foot due to small joint arthropathy and small muscle myopathy of foot and microangiopathy predisposing to diabetic foot.

(d) Autonomic neuropathy is a predisposing cause of chronic urinary tract infection because of retention of urine in bladder. It also impairs the microvascular circulation. Microvascular impairment also leads to reduced renal blood flow and frequent renal infection and papillary necrosis is the consequence.

OTHER CONTRIBUTORY FACTORS

As part of disease management and the disease process, factors which make a diabetic more vulnerable to infection are as follows:

- Frequent hospitalisations
- Diabetic ketoacidosis
- Administrations of drug/fluid/blood intramuscularly or intravenously
- Inappropriate antibiotic usage
- Peripheral vascular diseases
- Neuropathy
- Gastroparesis, reflux and pulmonary aspiration
- Indwelling catheterisation
- Frequent minor/major surgery
- Chronic renal failure requiring dialysis and blood transfusion.

Infections commonly seen in diabetics are presented in **Table 1**. Out of all these chronic infections, which are most important are diabetic foot, cholecystitis, pyelonephritis, candidiasis, rhinocerebral mucormycosis, Hepatitis C and HIV, etc.

Table 1: Common Infections in Diabetes

Bacterial
Tuberculosis, bacterial pneumonia
Malignant otitis externa
Pyelonephritis
Necrotising fasciitis
Staphylococcal infections
Erythrasma
Perinephric abscess
Non-clostridial gas gangrene
Cholecystitis
Periodontal infection
Fungal
Candidiasis
Mucormycosis
Viral
Viral hepatitis, particularly C
HIV infections

HEPATITIS C AND DIABETES

Hepatitis C virus (HCV) infection and diabetes both are slowly and silently developing, diagnosed very late and often with complications at diagnosis. Patients with chronic HCV infection can lead to the development of type 2 diabetes. Allison *et al*, in 1994 reported in a study of 100 patients, with cirrhosis, 50% of cases related to hepatitis had diabetes whereas hepatitis C negative cirrhosis group had diabetes in 9% of cases. Similarly, higher incidence of HCV infection is noted amongst diabetics than non-diabetics.

Amarapurkar *et al*, in 2002, from India compared the aetiology of chronic liver diseases with and without DM, and found higher evidence of HCV than hepatitis B virus (HBV) in diabetics than non-diabetics.

DM may also be significantly associated with hepato-carcinogenesis in chronic HCV patients. Incidence of DM amongst HCV chronic infection are much higher than those with chronic HBV infection, alcoholic liver disease, and biliary cirrhosis. Older age, obesity, severe liver fibrosis and family history of DM are related to potential risk or developing DM in HCV infected patients. In patients with cirrhosis planned for hepatic transplantation, development of type 2 DM is 5 times higher than of HCV origin.

Though finger prick for blood sugar examination and insulin injection is a mode of transmission, different studies have ruled out the possibility.

Pathogenesis of Diabetes in HCV Infection

Multiple patho-mechanisms have been suggested but none is definitely confirmed. These are presented in **Table 2**. HCV infection is reported to induce insulin resistance due to liberation of different cytokines like TNFα, which inhibits tyrosine kinase phosphorylase pathway.

Table 2: Pathogenesis of Diabetes Mellitus in Hepatitis C Virus Infection

Hyperinsulinaemia, insulin resistance
Insulin deficiency or poor insulin secretion
Pancreatic infection by hepatitis C virus
Autoimmune β-cell damage
Non-alcoholic fatty liver disease
Increased iron stores

Effect of DM on HCV Positive Chronic Liver Disease

The three way interaction between the stages of chronic liver disease, diabetes and enzymatic cholestasis suggests that diabetes is a risk factor for the progression of viral liver disease at least in part by induction of cholestasis. High blood glucose in HCV infected persons leads to advanced and higher fibrosis.

DIABETES MELLITUS AND TUBERCULOSIS

Tuberculosis (TB) in diabetes is 2 to 5 times higher, diagnosed late, asymptomatic, and is usually due to reactivation of an old focus than fresh infection. In a large cohort of 8793 patients from India, Patel reported TB to be the most common associated illness (5.9%) with DM in India. Swai *et al*, in a prospective 7-year follow-up of 1250 diabetes patients, found that 5.4% cases developed pulmonary TB and 0.2% spinal TB. In 25.7% cases, TB was detected before DM, in 45.7% after DM and in 20.6% simultaneously. Though chances of TB are higher in diabetics, infection rate by *Mycobacterium tuberculosis* and tuberculin sensitivity are not higher compared to non-diabetics. Higher sputum positivity, more incidences of lung involvement particularly cavitations than other lung changes are noted. Though lower lobe involvement was claimed to be more in diabetes in earlier reports, recent observations are in consensus that distribution of lung affection are same as in non-diabetics (involving upper zone predominantly). Anorexia, weakness, sweating, and weight loss are common both to TB and DM. So appearance of any one illness over the other is detected very late.

Additional causes of increased susceptibility to TB in diabetes are: (a) thickened alveolar epithelium and pulmonary basal lamina leading to reduction of lung diffusion capacity, lung capacity and elastic recoil; and (b) reduced bronchial reactivity and dilation due to diabetic autonomic neuropathy.

Bacteriological conversion, relapse rate are same with diabetics and non-diabetics. But relapse in diabetes are mostly with resistant strain and with poor prognosis.

Probable causes of higher prevalence of DM in TB are shown in **Table 3**. Diabetic state usually improves with anti-TB drugs. But rifampicin can produce alimentary glycosuria and early phase hyperglycaemia.

Table 3: Various Causes of Higher Prevalence of Diabetes Mellitus (DM) and Tuberculosis (TB)

Reciprocal worsening by one of the other
Malnutrition and low body mass index
Pancreatic tuberculosis in rare cases
Stress induced DM due to TB
Pituitary and adrenocortical hyper-reactivity
Vitamin D deficiency

DM does not alter the symptomatology, drug response, resistance or localisation of the lung lesion. But in persons above 40 years and in females genders, lower lung field involvement is significantly high. Smear positive cases and radiologically reticulo-nodular appearance were less in TB with DM than opacity, cavitation, and pleural involvement. Cavitary lesions were higher in type 1 DM than type 2 DM.

Cavitary lesions though maintain high bacterial population, less smear positivity are noted in diabetes because this may be related to muscle weakness due to uncontrolled glycaemia and less effective expectoration. Higher frequency of lower lobe disease in elderly may be due to immunological alteration or higher frequency of primary TB, increased alveolar oxygen pressure in lower lobes.

Management strategy in TB and DM requires some special attention.

1. Requirement of high calorie and high protein diet (2,000-2,400 cal per day)
2. Problems with anti-tuberculosis drugs in DM
   (a) Rifampicin
   Accentuates destruction of sulphonylurea by drug interaction through P450 cytochrome oxidase enzyme
   Augments intestinal glucose absorption
   (b) Isoniazid
   Antagonises sulphonylurea action
   Rarely causes pancreatitis
   (c) Biguanides
   Loss of appetite and weight
   Malabsorption of glucose

Choice of anti-diabetic agents: sulphonylurea and biguanides have its real problems in TB. Moreover to combat higher calorie intake and rare cases of pancreatic TB, pancreatic stimulant oral hypoglycaemic should be avoided. Insulin is the only mode of treatment for lowering any degree of blood sugar within minimum time as few days of hyperglycaemia may affect the anti-TB drug response. Insulin also helps in inflammatory response and healing process.

Peculiarities of TB in DM

In DM, TB has got the following characteristics:

1. Relative paucity of physical signs and diagnosis made at far advanced stage.
2. Extensive caseation of lung tissue and cavitary lesions (bilateral or unilateral) are more in number.
3. Little pleural involvement.
4. Greater tendency of haemoptysis.

5. Less chance of extra-pulmonary involvement and endobronchial TB.
6. More cases of sputum positive disease

The intensity of TB depends upon the duration of DM in uncontrolled stage and if controlled judiciously, response of TB is same as in non-diabetic groups.

Preventive management

1. Persons who were Monteaux test negative and have recent conversion to tuberculin test should have isoniazid prophylaxis, if they are in close contact with an infective person.
2. All diabetics at the initial diagnosis and every year must have a chest radiograph done.
3. All diabetics with abnormal weight loss, unexplained cough or sudden increase of insulin requirement should have sputum examination and chest radiograph.

PERIODONTAL DISEASE AND DIABETES MELLITUS

Periodontitis or infection of the anchoring tissues surrounding the teeth due to anaerobic Gram-negative organisms has been claimed as sixth complication of DM. Poorly controlled diabetics are likely to develop this chronic infection as periodontal disease (PD) and in turn, this has the potential to alter blood sugar control also.

It has been postulated that sub-gingival bacterial content are higher in DM, leading to more severe disease. This is equally for type 1 and type 2 diseases but is dependent upon glycaemic control. Severe degree PD is also considered to be associated with higher risk of diabetic complications like proteinuria, stroke, angina, myocardial infarction, and heart failure than in diabetic patients with mild PD.

Treatment of PD shows significant reduction of HbA_1c. Finally these can be accepted that, periodontopathic bacteria increase cytokine release, which may amplify advance glycation end products (AGE) mediated cytokine response and *vice versa*. Thus, PD either precipitates or aggravates the diabetic process and its complications, and PD and DM enjoy a two-way relation. Proper dental health is another avenue to diabetes control.

HIV INFECTION AND DIABETES

The prevalence of frank DM in people with HIV is low with study reports from 0.5% to 15%. But IGT is much higher as estimated to be 15% to 25%. Some degree of insulin resistance is also noted up to 50% cases on protease inhibitor therapy. Co-infection with HCV is found in 40% cases of HIV positive persons and is more likely to develop DM or insulin resistance. If HCV infection occurs in HIV positive cases, the risk of developing hyperglycaemia becomes five times. Elevated levels of ALT liver enzyme is an indicator for liver inflammations and predicts insulin resistance in HIV cases with lipodystrophy in the presence or absence of hepatitis B and C. HIV-related hyperglycaemia, whether will have the negative health sequences like complications of DM are not yet settled but probably will have the same fate as in HIV negative cases with hyperglycaemia.

Common causes of insulin resistance in HIV infection are shown in **Table 4**.

Table 4: Common Causes of Insulin Resistance in HIV Infection

Protease inhibitor therapy
Lipodystrophy
Increased local or systemic inflammatory mediators
Hepatic lipid accumulation
Muscle lipid accumulation
Hepatitis C infection
Reduced systemic adiponectin, leptin and increased resistin
Low testosterone

Protease Inhibitor Therapy

Protease inhibitor therapy directly affects blood glucose metabolism than due to alteration of body fat gain or loss.

Among the protease inhibitors (PIs), indinavir is strongly related to glucose intolerance and insulin resistance has been detected within 2 to 8 weeks of treatment even in HIV-negative persons. Regarding other proteases inhibitor, atazanavir has lowest effect and amprenavir (after 48 weeks of therapy) and saquinavir have got moderate effect on insulin glucose axis.

Diagnosis and Monitoring of DM in HIV Positive Cases

International acquired immunodeficiency syndrome (AIDS) Society recommends (2002 guidelines) fasting blood glucose before HAART, 3 to 6 months after drugs and at least annually or protease inhibitor therapy. For person's high-risk for insulin resistance, OGTT may be performed. Substitution of protease inhibitor by other antiretroviral drugs if possible (e.g. nevirapine or efavirenz or abacavir) may be practiced.

Diabetic patients are at higher risk for acquiring HIV infection because of multiple needle pricks. Diabetics can also contract HIV from multiple surgical interventions or dialysis and blood transfusion when chronic renal failure develops.

Whether HIV infections alone like HCV infection can produce DM or IGT is not yet clear but it is proved beyond doubt that HAART regimen particularly indinavir is definitely correlated. The risk of acquiring DM in HIV positive cases are more with concomitant HCV infections, obesity, genetic background, etc. Screening for DM should be done with protease inhibitor therapy and more frequently in high-risk cases. Lifestyle modification is of choice, metformin or glitazones can be added subsequently.

RHINOCEREBRAL MUCORMYCOSIS

50% cases of these occurs in a diabetic person and is a life-threatening flare in a person chronically infected with the organism, *Rhizopus oryzae*. During diabetic ketoacidosis the inhibitory effect of serum passes away and the disease flares. But this inhibitory effect is restored after correcting acidosis. Early manifestations are facial, ocular or nasal pain with nasal stuffiness and discharge. Subsequent manifestations are proptosis, chemosis, necrotic black lesions on palate or nasal mucosa, fever, headache, ophthalmoplegia, and visual loss from cavernous sinus thrombosis. Haemiparesis may be seen due to thrombosis of carotid artery or jugular vein.

Diagnosis is confirmed by demonstration of non-septate, haphazardly branching hyphae from biopsy of necrotic tissue. Magnetic resonance imaging is essential to identify the extent of involvement. Surgical debridement of infected tissue,

drainage of the sinuses with amphotericin B injection is the treatment of choice.

CHOLECYSTITIS

Chronic cholecystitis with or without cholelithiasis is very common in diabetes, probably because of supersaturation of bile, chronic infection, impaired gall bladder motility, decreased cholecystokinin release and hepatic impairment. Emphysematous cholecystitis, an uncommon gas producing virulent infection is similar to acute cholecystitis, but more frequent in males, with higher mortality due to gangrene or perforation. 35% of cases occur in diabetes and 50% contain gallstone. Crepitus on abdominal palpation, demonstration of gas in radiograph or computed tomography (CT) helps in diagnosis. Prompt cholecystectomy with broad-spectrum antibiotics like ampicillin-sulbactam 3g intravenously every 6 hours are the choice of treatment. Autonomic nervous dysfunction, BMI, LDL cholesterol, and advancing eye have been shown to have adverse impact on function of gall bladder.

CHRONIC PYELONEPHRITIS AND CYSTITIS

Chronic urinary tract infection is 2 to 4 times common in diabetics, particularly in women and in the presence of autonomic neuropathy and retained bladder. Bilateral infection is also more frequently seen with diabetes. Acute manifestations as emphysematous pyelonephritis presenting with fever, loin pain, haematuria, pneumaturia, is a life-threatening situation and in 90% cases occurs in diabetes only. It is produced by gas forming organisms, *Escherichia coli* in 50% to 70% cases and is complicated by papillary necrosis in 21% of cases.

Failure of remission of fever with therapy for urinary tract infection after 3 to 4 days in diabetics, possibility of emphysematous pyelonephritis and perinephric abscess should be thought of. Abdominal CT is better than other radiological methods for the diagnosis. Vigorous hydration and intravenous antibiotics with percutaneous CT guided drainage or nephrectomy are the modalities of treatment. Chronic fungal urinary tract infection particularly due to candidiasis is also common in diabetes. It can involve both upper and lower urinary tracts. Affection localised to the bladder may be also due to colonisation than infection but pyuria supports the later. Indwelling catheter if any should be removed. Bladder irrigation with amphotericin B, single dose of amphotericin B or oral fluconazole for 4 days is the treatment of choice.

CHRONIC INFECTIONS IN DIABETIC FOOT

This is a frequent complication and most neglected issue by both the patient and the treating physician. This is discussed in a separate chapter (Chapter 19 of this section).

FUNGAL INFECTIONS IN DIABETES

These are very common but most neglected situation presenting as oropharyngeal candidiasis, candidial vulvovaginitis a common mode of presentation in type 2 DM, inter-triginous candidiasis leading to gangrene of foot and paronychia.

Prevention of infections in diabetes can be adopted as follows:

Maintenance of good hygiene
Standard immunisation
Frequent check-ups
Foot care
Antibiotics usage
Catheterisation, IV lines with proper care

CONCLUSIONS

DM produces immune alterations of both cellular and humoral immunity and often complicated by acute or chronic infections. Common infections in DM are TB, pyelonephritis, *Staphylococcal* infections, cholecystitis, candidiasis, viral hepatitis, etc. Hepatitis C may be an aetiological agent for DM. TB in DM is 2 to 5 times higher. Chances of recurrence with multidrug resistant bacteria are common. More cavitary lesions, less sputum positivity and with relative paucity of symptoms and signs are the features. Treatment for DM should be done with insulin. Periodontitis is a complication of DM and DM may worsen from periodontitis also. Proper dental care should be a part of diabetic control. Protease inhibitor therapy in HIV infection can lead to development of insulin resistance. But whether HIV produces β-cell damage is not known. HIV and DM may be complicated by HCV infections. Rhinocerebral mucormycosis, cholecystitis, chronic urinary tract infection, and candidiasis are other common chronic infections in DM.

9.13 Macrovascular Complications of Diabetes

Murlidhar S Rao

Diabetes mellitus (DM) directly and indirectly affects on human vascular tree and these constitute major source of morbidity and mortality in both type 1 and type 2 diabetes. Generally, injurious effects of hyperglycaemia are divided into: (a) macrovascular complications, viz. coronary artery disease (CAD), peripheral artery disease (PAD), and cerebrovascular stroke; and (b) microvascular complications, viz. diabetic nephropathy, neuropathy, and retinopathy.

MACROVASCULAR DISEASE IN DIABETES

Unlike the microvascular disease which gets clicked with the onset of diabetes, the macrovascular disease antedates the development of diabetes by several years. Around 75% to 80% of all diabetic patients will die, many prematurely of cardiovascular (macrovascular) disease (CVD), particularly coronary heart disease (CHD). Diabetic foot problems (gangrene, large non-healing infected ulcers) are the commonest cause of non-traumatic lower limb amputation. In one Indian study done at Chennai, the prevalence of CHD was 21.4% among diabetic patients, 14.9% among IGT subjects and 11% among non-diabetic patients. The prevalence of PAD in the same population was 6.3%. There is a close relationship existing between pre-diabetes, diabetes and macrovascular (cardiovascular) disease throughout life; and the substantial body of evidence supports the concept that increased risk of morbidity and mortality due to CVD is associated with abnormalities in glucose metabolism across the entire continuum of glucose tolerance ranging from normal to clinical diabetes.

Aetiopathogenesis

The central mechanism in macrovascular disease is the process of atherosclerosis which leads to narrowing of the arteries throughout the body. Atherosclerosis is a progressive disease of the arterial wall involving the components of inflammation, vascular lipid deposition and remodelling, fibrosis, and thrombosis. Diabetes is a major independent risk factor for CHD resulting from accelerated atherosclerosis of the coronary arteries occurring at a much earlier age and advancing more rapidly to clinical cardiovascular events in persons with diabetes than in those without it. This was shown in the very early studies like 'Framingham study' and more recent studies have shown that the risk of myocardial infarction (MI) in people with diabetes is equivalent to the risk in non-diabetic patients with a history of previous MI. American Diabetes Association (ADA) and American Heart Association (AHA) have declared that diabetes is a coronary artery disease equivalent rather than a risk factor. Multivariate analyses of a number of large prospective studies with a follow-up of 12 to 20 years have shown that diabetes is associated with 2- to 5-fold increase in CHD and premature cardiovascular-related deaths in both type 1 and type 2 diabetes.

Atherosclerosis in diabetes is typically more diffuse, heterogeneous and extensive, occurring earlier and faster and more often associated with high-risk, unstable and vulnerable plaque with a large lipid core covered by thin fibrous cap which can easily rupture and result in acute coronary syndrome and death than in those without the diabetes. Diabetes, therefore, has definite accelerating impact on the pathogenesis of atherosclerosis which, in fact, is not qualitatively different from that occurring in non-diabetic individuals.

EFFECTS OF DIABETES ON PATHOGENESIS OF ATHEROSCLEROSIS

1. Endothelial Dysfunction

Endothelium which is the innermost layer of the blood vessels and in fact the largest organ of the body is the initial and common target of all cardiovascular risk factors. The functional impairment of the vascular endothelium in response to injury occurs long before the development of visible atherosclerosis. The endothelial cell behaves as a receptor-effective structure which senses different physical or chemical stimuli that occur inside the vessel and, therefore, modifies the vessel shape or releases the necessary products to counteract the effect of the stimulus and maintain homeostasis. The endothelium is capable of producing a large variety of different molecules including the vasodilators (nitric oxide [NO] and prostacyclin) and vasoconstrictors (endothelin-1 and angiotensin II) and nicely balancing their effects. When this delicate balance is lost, the conditions are given for the endothelium to be invaded by lipids and leucocytes (monocytes and T-lymphocytes). The inflammatory response is incited and fatty streaks appear – the first step in the formation of the atheromatous plaque which may later rupture and set the conditions for thrombogenesis and vascular occlusion. Therefore, endothelial dysfunction which is universal in diabetes is the starter in the process of atherosclerosis and many other factors are the chasers. As a result of this, vascular NO synthesis and stability are reduced and there is an impairment of endothelium-dependent NO-mediated vasodilatation in diabetes. In the presence of endothelial dysfunction the powerful vasoconstrictors like endothelin-I and angiotensin-II replace the vasodilators, NO and prostacyclin.

2. Oxidative Stress

Oxidative products are produced as a consequence of normal aerobic metabolism. These molecules are highly reactive with other biological molecules and are referred to as reactive oxygen species (ROS). Under normal physiological conditions, ROS production is balanced by an efficient system of antioxidants, molecules that are capable of neutralising them and, thereby, preventing oxidant damage. In pathological states, ROS may be present in relative excess. This shift of balance in favour of oxidation termed 'oxidative stress' may have detrimental effects on

cellular and tissue function and the cardiovascular risk factors generate oxidative stress.

Both type 1 and type 2 diabetic patients are under enhanced oxidative stress. Hyperglycaemia causes non-enzymatic glycosylation of proteins and phospholipids, thus increasing the intracellular oxidative stress. Therefore, advanced glycosylation end products (AGEs) formed later in this process are stable and virtually irreversible and generate ROS with consequent increased vessel oxidative damage and atherogenesis.

3. **Activation**

Activation of polyol pathway and diacylglycerol (DAG), protein kinase C (PKC) cascade are the other consequences of persistent hyperglycaemia (uncontrolled diabetes). Excess of intracellular glucose is metabolised by sorbitol pathway; and there is also rise in DAG, PKC levels intracellularly consequent to persistent hyperglycaemia. This occurs in many tissues including heart, aorta, glomeruli and retina.

4. **Other Factors**

There are many cardiovascular risk factors in diabetes and insulin resistance (IR). These are metabolic and lipid-related factors, coagulation and inflammatory factors and vascular-related factors (**Table 1**). Some of them are primarily related to diabetes while others may be found in diabetic as well as non-diabetic individuals.

Type 2 diabetes and IR typically occur in the setting of metabolic syndrome which also includes visceral (abdominal) obesity, hypertension, dyslipidaemia, and increased coagulability all of which lead to atherosclerosis (**Figure 1**). Even in this setting of multiple risk factors, type 2 diabetes acts as an independent risk factor for the development of ischaemic heart disease (IHD), stroke, and death. Among people with type 2 diabetes women may be at a higher risk for CHD than men. The prevalence of microvascular disease in itself is also a predictor of CHD.

Diabetes is a strong independent predictor of risk for stroke and cerebrovascular disease. Patients with type 2 diabetes have a much higher risk of stroke nearing 150% to 400%. Stroke-related dementia, cognitive disturbances, recurrence as well as stroke-related mortality are elevated in patients with diabetes. The impressive correlation between CAD and alteration in glucose metabolism has raised the hypothesis that atherosclerosis and diabetes may share common antecedents. Large vessel atherosclerosis can precede the development of diabetes suggesting that rather than atherosclerosis being a complication of diabetes both conditions may share common genetic and environmental antecedents, a 'common soil'.

Important steps in the initiation and growth of atherosclerotic plaque are:

1. Endothelial dysfunction and injury
2. Sub-endothelial monocyte/macrophage accumulation
3. Lipoprotein infiltration
4. Smooth muscle cell proliferation
5. Influence of T lymphocytes and other inflammatory cells and protein lipid accumulation in foam cells finally leading to plaque formation and adhesion thrombosis.

Table 1: Cardiovascular Risk Factors Associated with Diabetes and IR

Metabolic Factors
- Hyperglycaemia
- Insulin resistance
- Visceral obesity
- Hyperinsulinaemia
- Hypertriglycerdaemia
- Reduced HDL cholesterol
- Small dense LDL
- Hyperhomocysteinaemia
- Increased lipoprotein (a)
- Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH)

Coagulation and Inflammatory Factors
- Increased PAI-1 (plasminogen activator inhibitor-1)
- Increased platelet activation
- Increased fibrinogen
- Increased adhesion molecules (VCAM1 and ICAM1)
- Increased tissue factor and factor 7
- Decreased NO bioavailability
- Increased C-reactive protein
- Infections: Cytomegalovirus, *Chlamydia pneumoniae*, *Helicobacter pylori*, *Bacteroides gingivalis*

Vascular-Related Factors
- Hypertension
- Impaired endothelium-dependent vasorelaxation
- Chronic smoking
- Microalbuminuria
- Increased arterial calcification
- Decreased arterial compliance

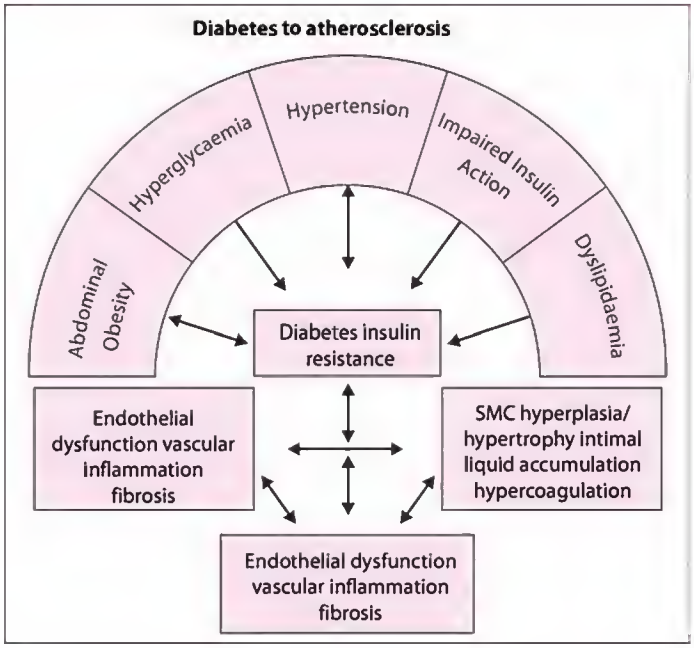

Figure 1: Diabetes to atherosclerosis

SMC = Smooth muscle cell

CLINICAL MANIFESTATIONS OF MACROVASCULAR DISEASE

Cardiovascular Disease

Cardiovascular syndromes in patients with diabetes present in similar ways to those in non-diabetic population, although many patients are younger, outcomes are worse, and ischaemic

events are more likely to be 'painless' (or rather silent) due to associated cardiac autonomic neuropathy. A cluster of cardiovascular risk factors clinically relevant are associated with diabetes, pre-diabetes, and IR and have to be looked into while evaluating the diabetic patients. These are:

1. Abdominal obesity with increased waist circumference (> 90 cm in men and >80 cm in women) *acanthosis nigricans*, 'hump'-like fatty bulge nape of the neck
2. Hypertension (>140/90 mmHg)
3. Dyslipidaemia
   - Increased triglycerides
   - Decreased HDL cholesterol
   - Small dense atherogenic LDL particles
   - Post-prandial lipaemia
4. Microalbuminuria
5. Increased levels of PAI-1 activity and fibrinogen

The clinical syndromes of myocardial ischaemia due to occlusive CAD are:

1. Angina

Angina may be relatively painless and can present atypically in long-standing type 2 diabetic patients, particularly the older ones with autonomic (sensory) neuropathy. Diabetic patients are more likely to remain asymptomatic while showing the ECG changes during exercise testing or ambulatory (Holter) ECG monitoring. Such diabetic patients of angina show reversible ischaemia on myocardial isotope perfusion scanning in the absence of obvious angina. Silent myocardial ischaemia carries a more ominous prognosis in diabetic patients than in the non-diabetic people.

2. Acute coronary syndromes

Unstable angina, non-ST elevation MI, and ST elevation MI represent a major cause of death in the diabetic population. These may also be painless or present with other symptoms like acute dyspnoea (left ventricular failure, LVF), a variety of cardiac arrhythmias often lethal, cardiogenic shock, or sudden death. Malaise, nausea and vomiting, profuse sweating or collapse are the accompanying features. Because of loss of normal circadian pattern of autonomic cardiovascular regulation, most acute ischaemic events occur during the evening and at night among diabetic patients. Diabetic patients who suffer an MI have a higher mortality than non-diabetic patients both in acute phase and on long-term follow-up. Infarct expansion or/and extension and recurrence of infarction, acute LVF, and congestive heart failure (CHF) all occur more commonly in the diabetic population than the non-diabetic population.

Serial determinations of CK-MB and quantitative estimation of troponins are more useful in assessing the infarct size and recurrence. All modes of echocardiography (2-D, Doppler and myocardial contrast echo) are extremely useful in assessing the LV size and function, myocardial viability, presence of any thrombus in the LV or its walls and other mechanical complications like mitral regurgitation, ventricular septal rupture or ventricular aneurysm. A major cause of adverse outcomes is the five-fold higher frequency of cardiac failure.

3. Heart failure

Heart failure (HF) is 2 to 5 times more common in diabetic population than in non-diabetic population. HF can occur even in the absence of obvious CAD. Aetiology of HF in diabetes is complex; factors include the systolic and diastolic performance of the LV affected by diabetic cardiomyopathy (diabetic heart muscle disease), the superimposed deleterious consequences of hypertension and further loss of functioning myocardium following acute coronary artery occlusion. The contractility of the non-infarcted myocardium in diabetes is much reduced which adds further to HF.

4. Cardiac dysrhythmias

They are related to ischaemia, left ventricular hypertrophy or CAN and frequently occur in diabetic subjects following MI and may result in sudden death. Decreased heart rate variability and subtle changes in CV reflexes due to CAN in the diabetic patients result in lethal cardiac dysrhythmias.

5. Diagnosis of ischaemic heart disease

ECG, stress testing either treadmill (TMT) or pharmacologic (Dobutamine), ambulatory ECG (Holter) monitoring, echocardiography and ultimately coronary angiography should be done at appropriate times in the diabetic patients with IHD with or without symptoms. Coronary revascularisation can be very beneficial in the diabetic patients with CAD.

Cerebrovascular Disease

Transient ischaemic attack and stroke are more frequent among diabetic patients, than in the non-diabetic patients particularly those who had acute coronary ischaemic event earlier. Lacunar infarcts, large infarcts and multi-infarct disease occur more often among the diabetic population than in the non-diabetic population. Haemorrhagic strokes occur less commonly. The prognosis of stroke is also worse in the diabetic patients. Hypertension often coexists and worsens the situation. Coma, convulsions and dense hemiplegias are often present. Carotid artery Doppler and B-Mode ultrasound imaging to measure the carotid intima-media thickness (IMT, abnormal if more than 1.1 mm) is an extremely simple and yet accurate indication of the diffuse atherosclerosis occurring in coronary and other arteries. The obstructive athero-plaques may be found in the carotid arteries by ultrasound and colour Doppler. CT or MRI brain and MR angiography of the brain are extremely useful in diagnosis as well as in prognosticating the stroke. Stroke-related dementia and recurrence of stroke are more frequent in diabetic patients. Cerebrovascular mortality rate is higher in both type 1 and type 2 diabetic patients.

Peripheral Arterial Disease

PAD is 2 to 3 times more frequent in diabetic males and 5 to 6 times more common in diabetic females. Diabetes is the commonest cause of non-traumatic limb amputation. Smoking, hypertension and dyslipidaemia and associated peripheral neuropathy contribute to the increased prevalence of PAD in diabetic patients. Clinical presentation of ischaemic limb disease extends over a wide spectrum of intermittent claudication, critical limb ischaemia, and gangrene resulting from total peripheral artery occlusion. Limb pain either at rest or on walking is suggestive of occlusive PAD. Acute limb ischaemia

characterised by pain, paraesthesia, pallor, pulselessness and perishingly cold limb may also occasionally occur. Chronic lower limb ischaemia involving popliteal and tibial arteries results from atherosclerosis in the diabetic individuals. The combination of ischaemic PAD, peripheral neuropathy, injury and infection results in diabetic foot disease.

MANAGEMENT OF CARDIOVASCULAR DISEASE IN DIABETES

The principles of management are the same as in normal population and are dealt with in detail in respective chapters. The difference is that diabetic patients require high degree of suspicion and aggressive treatment plan because of their poor prognosis as compared to non-diabetic patients.

HEART FAILURE AND DIABETIC CARDIOMYOPATHY

Please see chapter on Heart Failure and Cardiomyopathy in Cardiology Section 12, Chapter 10.

MANAGEMENT OF CEREBROVASCULAR DISEASE AND PERIPHERAL ARTERIAL DISEASE IN DIABETES

This is broadly similar for diabetic and non-diabetic patients although additional impact of neuropathy and microvascular disease presents special problems in treating ischaemia in the diabetic leg and foot. The outcomes tend to be worse and mortality rates higher. Cilostazol 100 to 200 mg/day and anti-platelet drugs along with exercise programme are useful in improving limb ischaemia. Percutaneous transluminal angioplasty with stenting is performed for claudication. The role of bypass grafts for longer arterial occlusions remains poorly defined. Acute limb ischaemia should be treated with thrombolysis.

9.14 Microvascular Diseases—Pathogenesis of Chronic Complications

Suman Kirti

INTRODUCTION

Chronic microvascular complications of diabetes mellitus are retinopathy, sensory motor, and autonomic neuropathy and nephropathy. Three-fourth of diabetics develops retinopathy after more than 15 years of diabetes, half of the diabetics have neuropathy, and one-third have nephropathy in large population studies in the US. The prevalence rates of retinopathy and overt nephropathy are reportedly lower while that of microalbuminuria is comparable with that reported in other ethnic groups in a study from South India. Risk factors for overt nephropathy in this study were poor glycaemic control, long duration of diabetes and systolic blood pressure, while for microalbuminuria smoking, and diastolic blood pressure were additional risk factors.

Risk of chronic complications in type-1 and type-2 diabetes result from chronic hyperglycaemia. Large randomised clinical trials of individuals with type-1 or type-2 diabetes have conclusively demonstrated that a reduction in chronic hyperglycaemia prevents or delays retinopathy, neuropathy, and nephropathy. Other incompletely defined factors may moderate development of complications. For example, despite longstanding diabetes, some individuals never develop nephropathy or retinopathy though they may have similar glycaemic control to patients with microvascular complications suggesting genetic susceptibility for developing particular complications.

MECHANISM

Though hyperglycaemia is an important factor, the mechanism of such diverse cellular and organ dysfunction is unknown. Four prominent theories have been proposed.

AGEs Theory

Increased intra-cellular glucose causes nonenzymatic glycosylation of intra- and extra-cellular proteins by interaction of glucose with amino acid groups on proteins, resulting in formation of advanced glycosylation end products (AGEs). Early non-enzymatic glycation products are reversible. As hyperglycaemia continues, intermediate poorly reversible products are formed and later irreversible AGEs are formed. Serum levels of AGEs correlates with the level of glycaemia and these products accumulate as glomerular filtration rate declines. AGEs have been shown to crosslink proteins (e.g. collagen, extracellular matrix protein), accelerate atherosclerosis, promote glomerular dysfunction, reduce nitric oxide (NO) synthesis, induce endothelial dysfunction, and alter extra-cellular matrix composition and structure. AGEs bind to specific receptors in endothelial cells, macrophages, and cultured mesangial cells. Interaction of AGEs with the receptors in mesangial cells leads to increased transforming growth factor-β (TGF-β) expression and extra-cellular matrix synthesis. Aminoguanidine, a compound that inhibits AGEs, was useful in experimental studies but resulted in occurrence of ANCA positive vasculitis and is not approved for clinical use.

Sorbitol Pathway (Polyol Pathway)

Intra-cellular glucose is pre-dominantly metabolised by phosphorylation and subsequent glycolysis, but when increased some glucose is converted to sorbitol by the enzyme aldose reductase. Increased sorbitol concentration alters redox potential, increases cellular osmolality, generates reactive oxygen species and increases AGEs formation, and likely leads to other types of cellular dysfunction. Cataract formation and neuropathy and retinopathy to some extent have been linked to this pathway. However, testing this theory in humans, using aldose reductase inhibitors, has not demonstrated significant benefit on clinical endpoints of retinopathy or nephropathy, and marginal benefits in neuropathy. Newer aldose reductase inhibitors like fidarestat are undergoing clinical trials; epelrestat has been approved for use.

Protein Kinase C Pathway

Hyperglycaemia increases formation of diacylglycerol, leading to activation of protein kinase C (PKC). PKC is a family of serine-threonine kinases that alter the transcription of genes for fibronectin, type IV collagen, contractile proteins and extracellular matrix protein in endothelial cells and neurons. Thereby PKCs regulates diverse vascular functions like contractility, blood flow, cellular proliferation, and vascular permeability. PKC mediates TGF-β1, angiotensin-II and vascular endothelial growth factor (VEGF) and modulates mitogen activated protein kinase (MAPK), which mediates sclerosis. Inhibitors of PKC-b like ruboxistaurin mesylate that reduce the direct cellular actions of AGEs, VEGF, Endothelin-1, reduce oxidised lipids and oxidant production, are being studied in clinical trials in diabetes mellitus (DM) for retinopathy and neuropathy.

Hexosamine Pathway

Hyperglycaemia increases flux through the hexosamine pathway, which generates fructose-6-phosphate, a substrate for O-linked glycosylation and proteoglycan production. Hexosamine pathway may alter function by glycosylation of proteins, such as endothelial nitric oxide synthase, or by changes in gene expression of transforming growth factor β (TGF-β) or plasminogen activator inhibitor-1 (PAI-1).

Growth Factors

Growth factors appear to play an important role in DM related complications and their production is increased by most of these proposed pathways. VEGF-A is increased locally in diabetic proliferative retinopathy and decreases after laser photocoagulation. Inhibition of angiotensin-II also reduces VEGF, which could explain one of the beneficial effects of angiotensin-II receptor blockers on microangiopathic diseases. Monoclonal antibodies to VEGF like ranibizumab in experimental studies have

shown improvement in proliferative diabetic retinopathy. TGF-β is increased in diabetic nephropathy and stimulates basement membrane production of collagen and fibronectin by mesangial cells. Other growth factors, such as platelet derived growth factor, epidermal growth factor, insulin like growth factor, growth hormone, basic fibroblast growth factor, connective tissue growth factor and even insulin, have been suggested to play a role in DM related complications. Figure 1 shows the pathways and their interaction in the pathogenesis of microvascular disease.

Angiotensin-II

The renin-angiotensin system (RAS) in the kidney is abnormally activated in diabetes. Angiotensin-II directly binds to receptors in renal cells and induces matrix deposition in mesangial and tubular cells through TGF-β1. Angiotensin-II stimulates VEGF production in mesangial cells and impairs glomerular structure and function. Similar effects are observed in the retina.

Glycaemic Control and Complications

The diabetes control and complications trial (DCCT) provided definitive proof that reduction in chronic hyperglycaemia can prevent many early complications of type 1 DM. This large multicentre clinical trial randomised 1,400 type 1 diabetics to either intensive or conventional diabetes management and prospectively evaluated the development of retinopathy, nephropathy, and neuropathy. The intensive group achieved a substantially lower HbA1c (7.3%) than the conventionally managed group (9.1%).

DCCT showed that improvement of glycaemic control reduced non-proliferative and proliferative retinopathy by 47%, microalbuminuria by 39%, and clinical nephropathy by 54% and neuropathy by 60%. Improved glycaemic control also slowed the progression of early diabetic complications. A non-significant trend in reduction of macrovascular events was observed during the trial (most individuals were young, with a low risk of cardiovascular disease). Results of DCCT predicted that type-1 diabetics with intensive management gain 7.7 additional years of vision, 5.8 additional years free from ESRD and 5.6 additional years free from lower limb amputations. If all the complications were combined, intensively managed group would experience 15.3 more years of life without significant

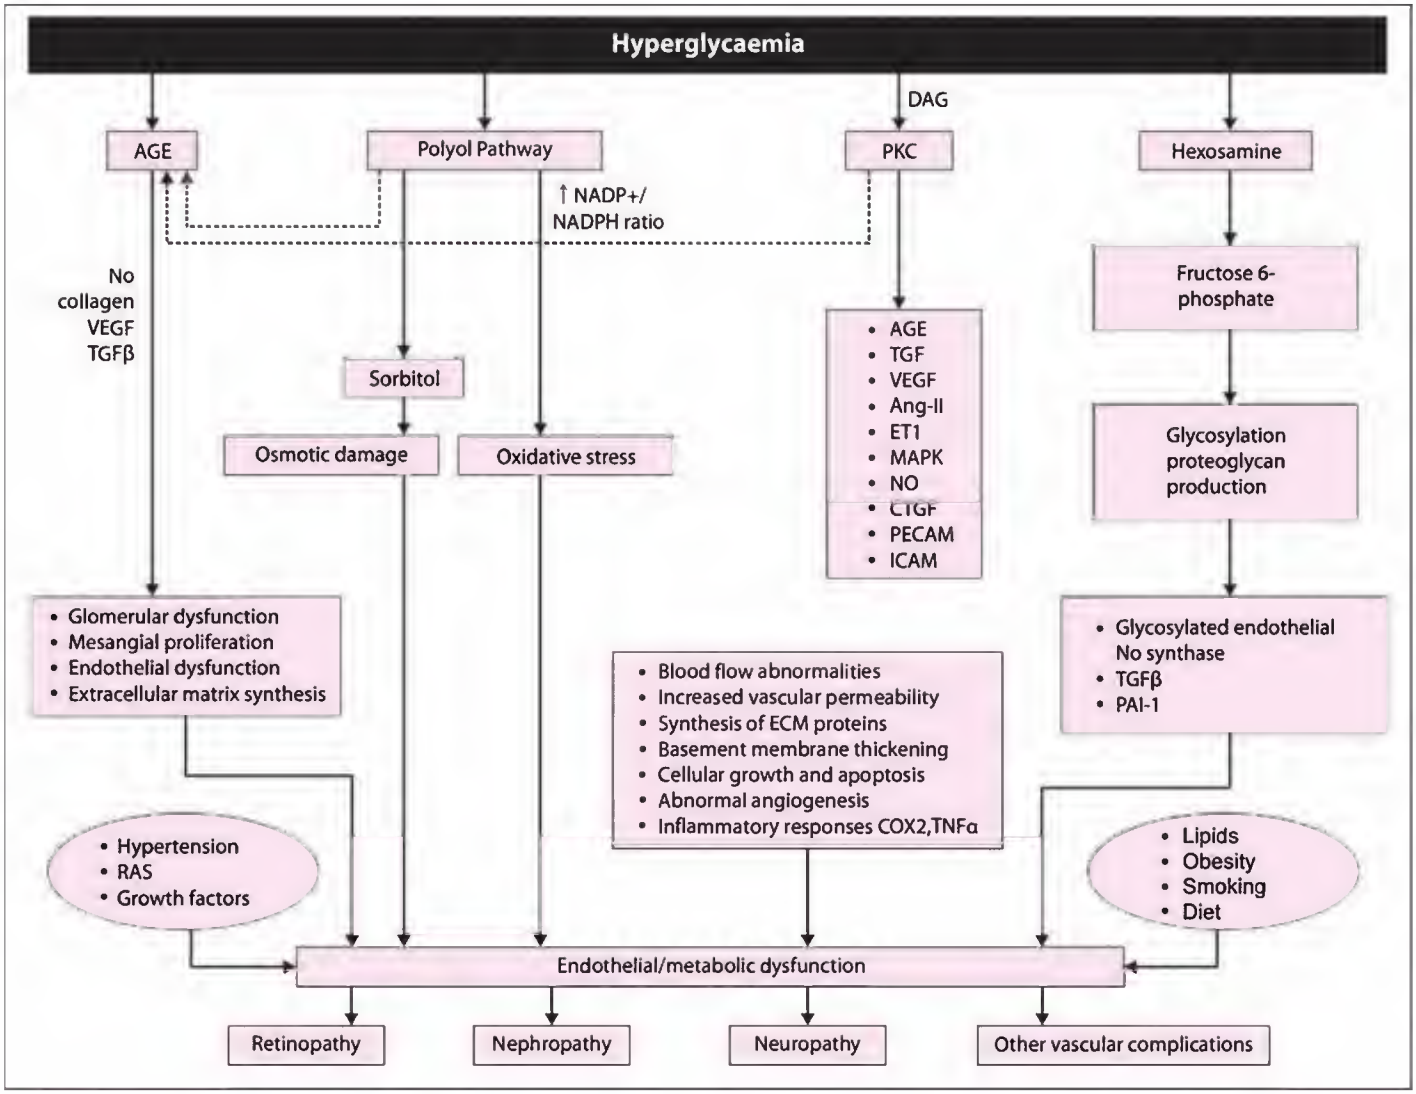

Figure 1: Pathways leading to microvascular diseases in diabetes mellitus.

AGE = Advanced glycation end products; PKC = Protein kinase C; NO = Nitric oxide; DAG = Diacylglycerol; TGF = Transforming growth factor; VEGF = Vascular endothelial derived growth factor, Ang-II-Angiotensin-II, ET1, endothelin1; MAPK = Mitogen activated protein kinase; CTGF = Connective tissue growth factor; PECAM = Platelet/endothelial cell adhesion molecules; ICAM = Inter-cellular cell adhesion molecules; PAI-1 = Plasminogen activator inhibitor; COX = Cycloxygenase; TNF = Tumour necrosis factor; RAS = Renin-angiotensin system; NADPH = Nicotinamide adenine dinucleotide phosphate

microvascular or neurological complications of diabetes as compared to diabetics receiving standard therapy. This translates into an additional 5.1 years of life expectancy for the intensively treated diabetic. Intensive control for a mean of 6.5 years resulted in 42% to 57% reduction in cardiovascular events (nonfatal myocardial infarction, stroke or death from cardiovascular event) when followed-up for a mean of 17 years even though their subsequent control was same as the conventionally treated group. Thus, the benefit of improved glycaemic control during the DCCT persisted even after the study concluded and the glycaemic control worsened. There is a benefit of improved glycaemia over an entire range of HbA1c values. The goal of therapy is to achieve HbA1c levels as close to normal as possible without excessive risk of hypoglycaemia.

The United Kingdom Prospective Diabetes Study (UKPDS) studied the course of more than 5,000 newly diagnosed type-2 diabetics randomised to: intensive management using various combinations of insulin, a sulphonylurea or metformin or; conventional therapy using dietary modification and pharmacotherapy with goal of symptom prevention. Individuals were also randomly assigned to different antihypertensive regimens. Intensively managed group achieved an HbA1c of 7.0% compared to HbA1c of 7.9% in the standard treatment group. UKPDS demonstrated that each percent point reduction in HbA1c was associated with 35% reduction in microvascular complications. As in the DCCT, there is a continuous relationship between glycaemic control and development of complications. Improved glycaemic control was associated with improvement in lipoprotein risk profiles such as reduced triglycerides and increased HDL, though conclusive evidence of any change in cardiovascular risk was not seen. An important finding of the UKPDS was that strict blood pressure control significantly reduced both microvascular and macrovascular complications, and the beneficial effects of blood pressure control were greater than those of glycaemic control. Lowering the blood pressure to moderate goals (144/82 mm Hg) reduced the risk of death, stroke, microvascular endpoints, retinopathy, and heart failure (risk reduction between 32% and 56%). Deterioration in maculopathy and visual acuity was also reduced. Post-trial follow-up of 10 years of these patients showed that the beneficial effect of BP control during the trial did not persist as did the glycaemic control effects and the outcomes depended on the subsequent control of blood pressure.

Action to control cardiovascular risk in diabetes eye subgroup (ACCORD-Eye) trial on 4065 type 2 diabetics from 77 centres over US and Canada also showed 40% reduction in retinopathy with intensive glycaemic control, and lipid control especially with fenofibrate within a short period of 4 years.

The Action in Diabetes and Vascular Disease

Preterax and diamicron modified release-controlled evaluation (ADVANCE) randomised-controlled trial at 215 centres in 20 countries in Asia, Australia, Europe, and US involving 11140 type 2 diabetics, studied over 5 years showed 21% reduction in development of new or worsening nephropathy and reduction in new onset microalbuminuria with intensive glycaemic control (HbA1c 6.5%) versus standard glycaemic control (HbA1c 7.3%). These two large trials also confirm the importance of glycaemic control in prevention of microvascular disease.

Other Risk Factors

Hypertension is a major determinant of microangiopathy and macroangiopathy in diabetes. It causes endothelial dysfunction, impaired NO availability, renal vasoconstriction and decreased glomerular filtration, impaired tubuloglomerular feedback, decreased medullary flow and impaired pressure natriuresis, and progressive proteinuria. Intraglomerular pressure rise and stretch set off series of matrix changes. Strict blood pressure lowering with ACE-inhibitors (ACE-I) or angiotensin receptor blockers (ARBs) that reduce intraglomerular pressure and block the RAS, along with glycaemic control has been shown to reduce nephropathy. Large trials like microalbuminuria, cardiovascular and renal outcomes-heart outcomes prevention evaluation (MICRO-HOPE), showed that adding ramipril, an ACE-I, slowed the progress and reduced the occurrence of nephropathy in diabetics by 24%. ARBs are more effective blockers of the RAS and also target the angiotensin-II, VEGF and endothelial dysfunction, as well as acting favourably through the peroxisome proliferator-activated receptor (PPAR) in case of newer ARBs.

Dyslipidaemia has been implicated in increase in urinary albumin excretion in diabetics and causes endothelial damage by oxidative stress. Treatment of dyslipidemia with fenofibrate [fenofibrate intervention in event lowering in diabetes (FIELD)] and atorvastatin [collaborative atorvastatin diabetes study (CARDS)] in large multicentric trials has shown improvement in retinopathy and maculopathy. Fibrates acting through PPAR suppress endothelial proliferation and inhibit VEGF production.

Obesity contributes to microangiopathy by multiple factors including mediators, directly secreted by adipocytes, such as non-esterified fatty acids (NEFAs), tumour necrosis factor-α (TNF-α), leptin and adiponectin, which modulate microvascular changes, endothelial function, NO production and inflammation. Smoking aggravates microangiopathy by inducing endothelial damage, oxidative stress, and vasoconstriction. Diets containing excess of saturated and trans fats result in oxidative stress. Definitive benefit is demonstrated in clinical studies by targeting hyperglycaemia, hypertension, obesity, smoking, dyslipidemia and modifying diet and lifestyle in microangiopathic disease.

9.15 Diabetes and Kidney Disease

Jamal Ahmad

DEFINITION AND EPIDEMIOLOGY

Diabetic kidney disease (DKD) is characterised by excessive urinary albumin excretion (UAE) followed by loss of kidney function. Proteinuria is a hallmark of diabetic kidney disease (DKD). DKD has been classically defined by the presence of proteinuria ≥0.5 gm/24 hours or persistent albuminuria (≥ 300 mg/24 hours or ≥200 µg/min) if one of the following additional criteria are fulfilled: presence of diabetic retinopathy and the absence of clinical or laboratory evidence of the other kidney and renal tract disease. Persistent albuminuria in the range of 30 to 299 mg/24 hours (microalbuminuria) has been shown to be the earliest stage of diabetic nephropathy (DN) in type 1 diabetes and marker for development of nephropathy as well as cardio vascular disease (CVD) risk in type 2 diabetes.

STAGES OF DIABETIC NEPHROPATHY

According to UAE values, DKD has been didactically categorised into stages. The cut-off values used to characterise these stages are described in **Table 1**. Recent studies suggest that only 30 to 45% of microalbuminuria patients will progress to proteinuria over 10 years of follow-up and some might regress to normoalbuminuria.

Table 1: Diabetic Nephropathy Stages Based on Urinary Albumin Excretion

Stages	Urine with Marked Time (µg/min)*	24 hours Urine (mg/24 h)*	Random Urine Sample	
			Albumin Concentr-ation (mg/Lit)**	Albumin Concentr-ation Ratio (mg/g)*
Normoalbuminuria	<20	<30	<17	<30
Microalbuminuria	20 to 199	30 to 299	17 to 173	30 to 299
Macroalbuminuria	≥200	≥300	≥174	≥300

** Values according to the American Diabetic Association.*

*** Gross et al, Diabetes Care 2005.*

AETIOPATHOGENESIS

The important mechanism of proteinuria cited for excessive protein excretion in general are increased filtration, inadequate tubular absorption, overflow, and increased glomerular filtration, inadequate tubular absorption, and increased tubular secretion with the dominant mechanism being glomerular. Angiotensin exerts complex haemodynamic and non-haemodynamic actions that includes induction of systemic vasoconstriction, increased glomerular arteriolar resistance, glomerular capillary pressure and glomerular capillary permeability, reduction in the filtration surface area, stimulation of extracellular matrix proteins, and stimulation of renal proliferation and fibrogenic chemokinase.

SCREENING AND DIAGNOSIS

Screenings for microalbuminuria (MA) can be performed by measurement of the albumin-to-creatinine ratio in a random spot collection (preferred method), as 24 hours or timed collections are more burdensome and add little to prediction or accuracy. Because of variability in UAE , two of the three specimens collected within a 3 to 6 months period should be abnormal. Exercise within 24 hours, infection, fever, congestive heart failure (CHF), marked hyperglycaemia, and marked hypertension may elevate UAE over baseline values. Serum creatinine should be measured at least annually in all adults with diabetes, regardless of the degree of UAE. Estimated GFR (eGFR) is commonly co-reported by laboratories or can be estimated using formulae such as the modifications of diet in renal disease (MDRD) study equation. Based on GFR the chronic kidney disease may be graded into five grades (**Table 2**). These have prognostic importance. DM screening must be performed at diagnosis in patients with T2DM and fifth year onwards in T1DM patients.

Table 2: Chronic Kidney Disease Stages

Stages	Description	GFR (mL/min/1.73 m²)
1	Renal damage with GFR* normal increased	≥90
2	Renal damage with GFR* slightly decreased	60 to 89
3	GFR moderately decreased	30 to 59
4	GFR severely decreased	15 to 29
5	End-stage chronic renal failure	<15 or dialysis

** Renal damage is defined by abnormalities in urine and below tests, imaging exams or in pathology, GFR= glomerular filtration rate.*

MANAGEMENT OF DIABETIC KIDNEY DISEASE

The best treatment for DKD is multiple risk factor interventional approach. The goal to be pursued is retarding the development or progression of DKD and to decrease cardiovascular risk and mortality.

Hyperglycaemia

Hyperglycaemia is a significant risk factor for the development of microalbuminuria; both in type 1 and in type 2 DM. A reduction of 1% in haemoglobin A1c is associated with a 37% decrease in microvascular endpoints.

Clinical trials have demonstrated that intensive treatment of hyperglycaemia is associated with a decreased risk for the development of DKD in type 1 and type 2 diabetic patients. In the Intensive Blood Glucose Control and Vascular Outcomes in patients with type 2 Diabetes (ADVANCE) trial, the group in the intensive arm for an average of 5 years showed a small reduction in the number of cases with new onset microalbuminuria compared to the standard therapy group.

Arterial Hypertension

Arterial hypertension is a main risk factor for the development of DKD and probably the best known relevant factor related to its progression. Analysis of UK prospective diabetes study (UKPDS)

showed that every 10 mm Hg reduction in systolic BP is associated with a 13% reduction in the risk of microvascular complications, with the smallest risk among those patients with systolic BP <120 mm Hg. In order to reach the BP goal of 130/80 mm Hg diabetic patients in general or 125/75 mm Hg in patients with proteinuria >1.0 g/24 hours, three to four antihypertensive agents are usually necessary. Due to the known renoprotective effect of ACE-inhibitors and ARB, these agents should be used initially along with a diuretic.

Renin-Angiotensin System Blockade

Angiotensin-converting enzyme (ACE) inhibitors could be used in normotensive subjects to prevent or postpone the development of microalbuminuria. The aim of ACE inhibitors and ARBs use is not only to diminish the risk for the development of microalbuminuria and macro-albuminuria but also to decrease the occurrence of cardiovascular events.

An acute increase in serum creatinine up to 30% to 35% that stabilises within 2 months is expected. Increase in serum creatinine above these values should raise the possibility of renal artery stenosis. Acute hyperkalaemia (>5.5 mEq/L) is an indication to stop these medications. Therefore, albuminuria, serum creatinine and potassium should be checked monthly in the first 2 to 3 months after starting treatment with ACE inhibitors or ARB.

Dual RAS blockade has been suggested to have an additive effect on renoprotection. A recent large trial (ONTARGET) in diabetic and non-diabetic subjects showed that the association of the two classes of drugs had a major effect on decreasing proteinuria but not on GFR decline or mortality. More recently, the dual blockage of the renin-angiotensin-aldosterone system with Aliskiren, a direct renin inhibitor, and losartan at maximal recommended dose (100 mg daily) showed a greater reduction in proteinuria (20%) compared to Losartan and placebo.

Dietary Intervention

There are several modalities for a dietary intervention in DKD, whether changing protein content or through the manipulation of lipid content. In patients with type 1 DM, in different stages of renal disease, protein restriction in the diet has shown to reduce the decline of renal function and albuminuria.

Dyslipidaemia

The desired target of low density lipoprotein (LDL) is <100 mg/dL for patients with DM in general, and <70 mg/dL when cardiovascular disease is present. No data based on a large clinical trial is available showing that the treatment of dyslipidaemia is able to prevent the development or progression of DKD. In the Heart Protection Study (HPS), simvastatin, 40 mg, reduced vascular event rates and GFR decline in patients with DM by 25%, independent of baseline cholesterol levels. Collaborative atorvastatin diabetes study (CARDS) showed a modest beneficial effect of atorvastatin on eGFR, particularly in those with albuminuria.

Renal Replacement Therapy

Diabetic patients with advance renal disease may require renal replacement therapy to restore their body homeostasis and reduce symptoms of renal failure. Renal replacement can be provided by continuous ambulatory peritoneal dialysis (CAPD, or haemodialysis). In some patients, where a kidney is available, renal transplant may be considered. The indications and contraindications are the same as for any other patient requiring RRT. It is advisable to start therapy early rather than delaying it for terminal stages. These modalities are discussed in details in section 19, chapter 11 and 12.

9.16 Diabetic Retinopathy

Amod Gupta, Reema Bansal

DEFINITION AND EPIDEMIOLOGY

Diabetic retinopathy (DR) is a retinal microvasculopathy resulting from prolonged hyperglycaemia. The prevalence of DR increases with the duration of diabetes and nearly all with type 1 and 60% with type 2 diabetes mellitus (DM) may develop some retinopathy after 20 years. The major risk factors for the onset and progression of DR are duration of diabetes, degree of glycaemic control, hypertension, and hyperlipidaemia.

Prevalence rate of DR in the Indian subcontinent is reported from 12% to 37% in type 2 DM.

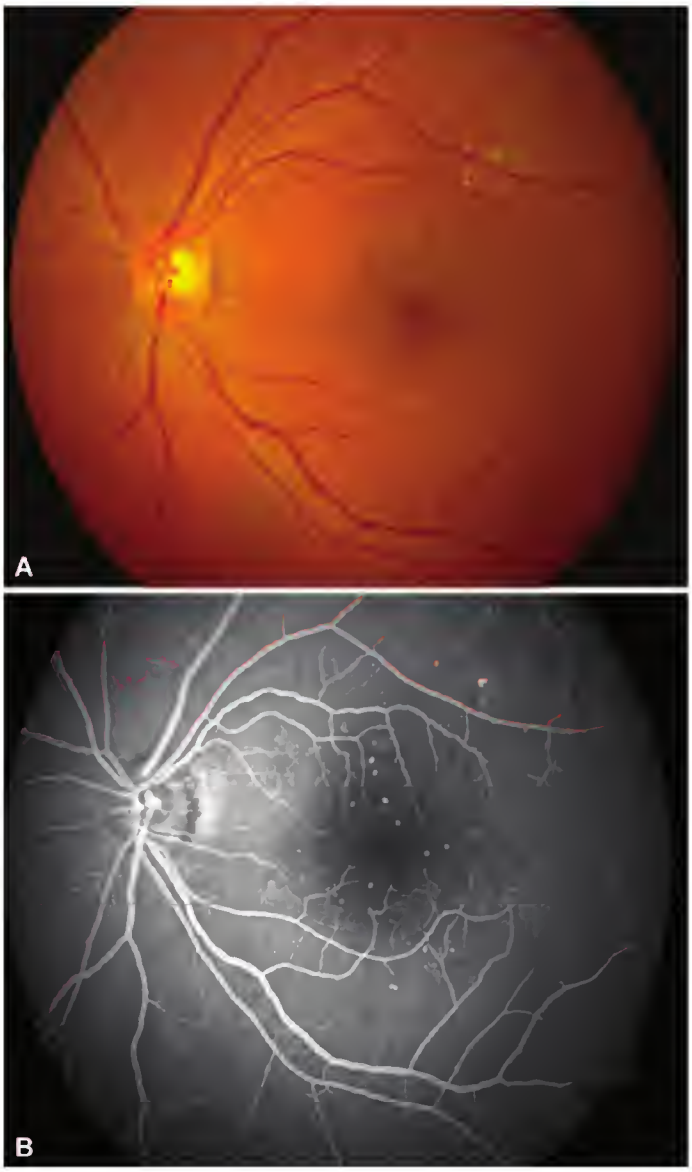
AETIOPATHOGENESIS

Diabetic retinopathy (DR) starts from hyperglycaemia-induced vascular injury. The earliest histological lesion is loss of pericytes and thickening of the basement membrane of the retinal capillaries. These changes result from various biochemical, haemodynamic and endocrine factors, and eventually lead to closure/incompetence of the capillaries.

SPECTRUM OF DIABETIC RETINOPATHY

Non-Proliferative Diabetic Retinopathy

Mild



Microaneurysms are out pouching of the retinal capillary walls and are the first clinically detectable lesions on ophthalmoscopy. The microaneurysms tend to cluster around small areas of capillary non-perfusion (**Figure 1**). Hard exudates, located in the outer plexiform layer of the retina, are extracellular accumulation of lipids derived from leakage of serum from microaneurysms. These are small white or yellowish white deposits with sharp margins and glistening appearance (**Figure 2**). Dot and blot-retinal haemorrhages are also seen.

Moderate

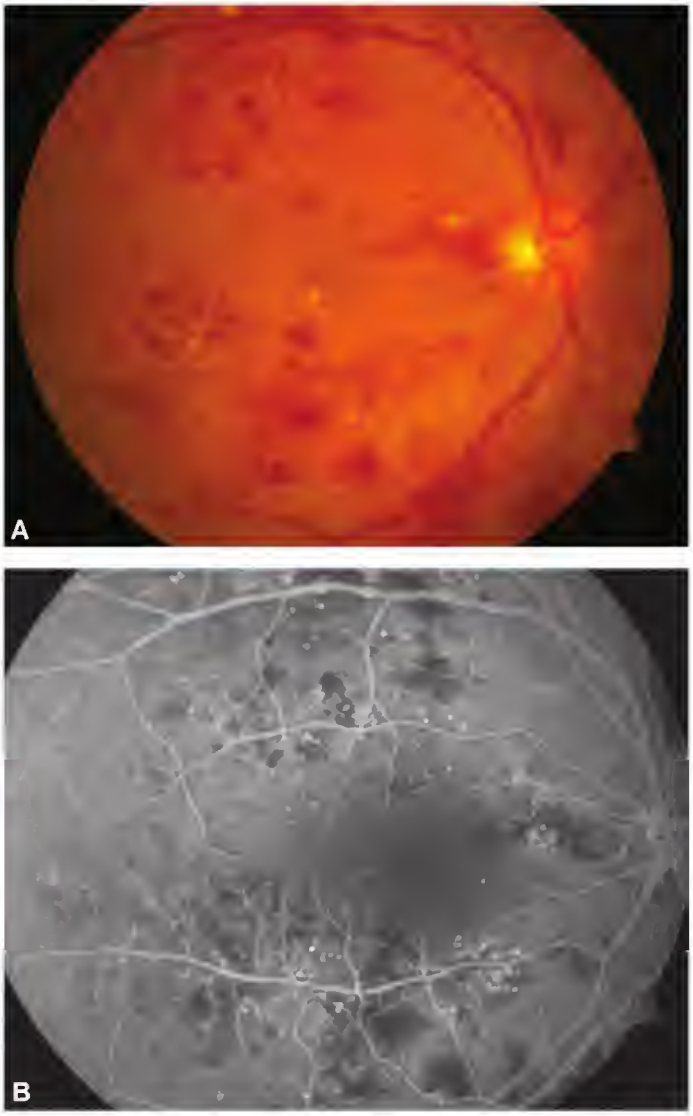
Soft exudates or cotton wool spots reflect an increasing sign of ischaemia secondary to pre-capillary arteriolar occlusion. In the area of retinal ischaemia the axoplasmic flow is impaired resulting in accumulation of the axonal intracellular fluid or organelles which is clinically seen as swelling of the retinal nerve fiber layer or cotton wool spots (**Figure 3**).

Severe

Venous beading and loops, intra-retinal microvascular abnormalities (IRMA), and widespread areas of capillary non-perfusion develop as parts of the retina are deprived of blood and nourishment. Venous loops are hairpin or semi-circular deviations of the vein from its normal course. The IRMAs are narrow, tortuous, intra-retinal vascular segment representing either dilated retinal capillaries and/or intra-retinal new vessels (**Figure 4**). These may represent intra-retinal neovascularisation. These serve as warning signs of future proliferative DR (PDR).

Figures 1A and B: Fundus photograph of (A) the left eye with non-proliferative diabetic retinopathy showing dot and blot haemorrhages with hard exudates, and (B) leaking microaneurysms on fundus fluorescein angiography.

Proliferative Diabetic Retinopathy



It is defined as the presence of newly formed blood vessels and/or fibrous tissue arising from the retina or optic disc, extending along the posterior hyaloid surface. Ischaemia of the inner retinal layers stimulates the production of angiogenic factors, namely vascular endothelial growth factor (VEGF) which act locally, diffuse through the vitreous to other areas of the retina, to the optic disc and also into the anterior chamber. The new vessels may be found on the optic disc (neovascularisation on the disc or NVD) or elsewhere (neovascularisation elsewhere or NVE) on the retina (**Figures 5 and 6**).

Figure 2: Fundus photograph of the left eye showing hard exudates.

Figure 3: Fundus photograph of the left eye showing soft exudates as cotton wool spots.

Figures 4A and B: Fundus photograph of the right eye with severe non-proliferative diabetic retinopathy showing superficial haemorrhages in all quadrants of retina (A) with venous beading and intra-retinal microvascular abnormalities on fundus fluorescein angiography (B).

Advanced Disease

Complications of PDR include vitreous haemorrhage (**Figure 7**) or subhyaloid haemorrhage (**Figure 8**), tractional/combined retinal detachment (**Figure 9**), and neovascular glaucoma that lead to severe visual loss and blindness if left untreated.

Role of Statins

In case of high basal serum cholesterol levels, it has been established that statins enhance the efficacy of macular gril in exudative maclupathy but definitive evidence is lacking that statins benefit patient's exudative maculopathy.

CLINICAL COURSE OF DIABETIC RETINOPATHY

In the initial stages, DR is asymptomatic, and hence, it is recommended that patients with type 1 DM undergo annual dilated fundus examination till they develop signs of retinopathy. Since in patients with type 2 DM, the onset and duration of the disease is unknown, they should undergo fundus examination at the time of diagnosis of DM. Frequency of the fundus examination thereafter will depend on the severity of the DR.

Diabetic macular oedema (DME) develops insidiously and is the most common cause of moderate visual loss in patients with DR. It is caused primarily by a breakdown of the inner blood retinal barrier resulting in leakage of fluid and plasma constituents from abnormally permeable microaneurysms, IRMAs and dilated retinal capillaries. It may be focal or diffuse.

The early treatment of diabetic retinopathy study **Table 1** (ETDRS) defined clinically significant macular oedema (CSME) as follows (**Figure 10**):

1. Retinal thickening at or within 500 µm of the centre of the macula, and/or
2. Hard exudates at or within 500 µm of the centre of the macula, if associated with thickening of the adjacent retina, and/or
3. Zone(s) of retinal thickening at least one disc area in size part of which is within one disc diameter of the centre.

Patients may present with acute onset cobwebs/floaters or complete obscuration of vision caused by vitreous

Figure 5: Fundus photograph of the right eye showing neovascularisation on the optic disc.

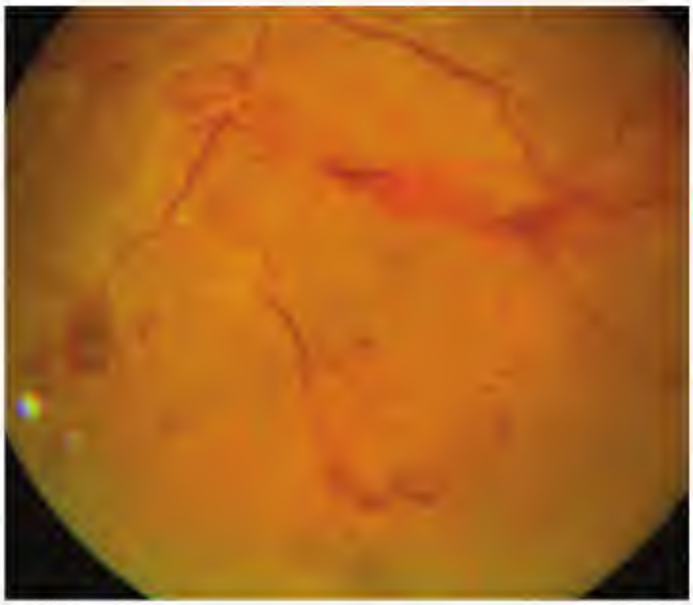


Figure 6: Fundus photograph of the left eye showing neovascularisation elsewhere on the retina.

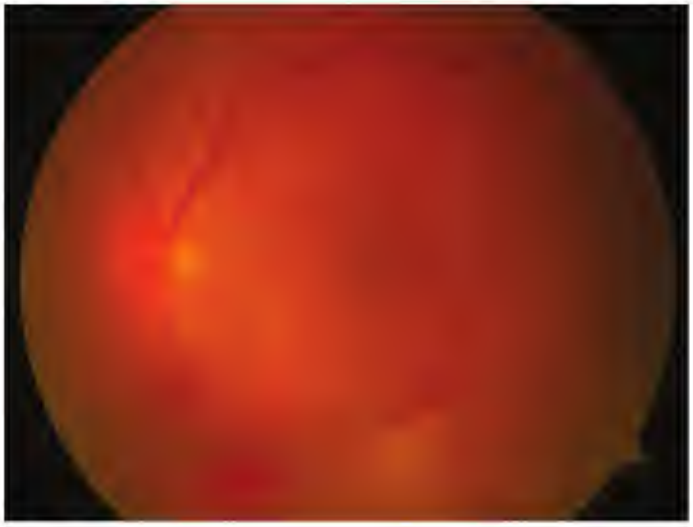

Figure 7: Fundus photograph of the left eye showing vitreous haemorrhage.

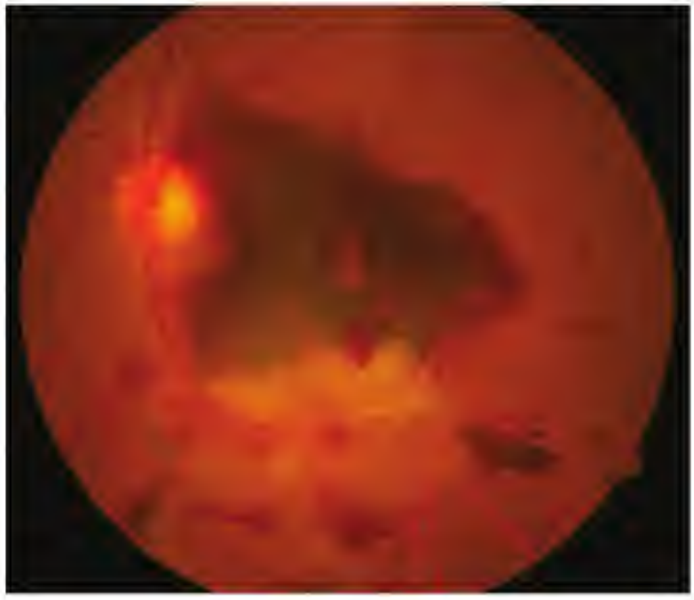

Figure 8: Fundus photograph of the left eye showing extensive subhyaloid haemorrhage over the macula.

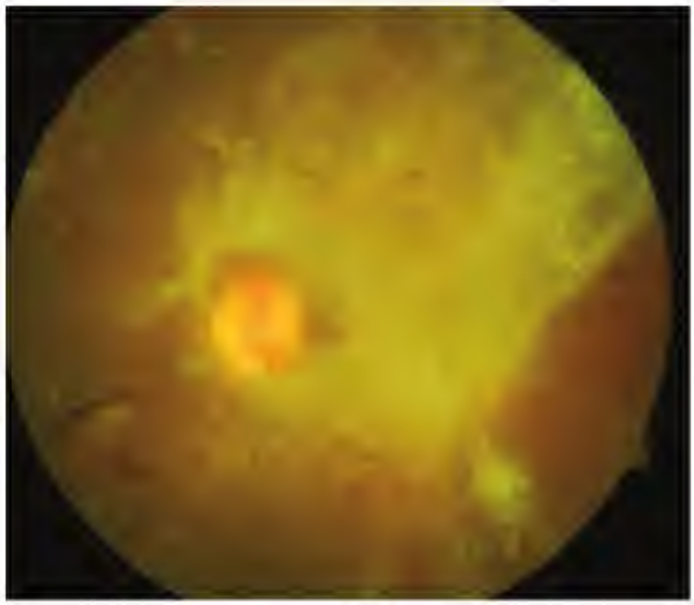

Figure 9: Fundus photograph of the left eye showing extensive fibrovascular proliferation around the optic disc causing tractional retinal detachment.

Figure 10: Fundus photograph of the right eye showing clinically significant macular oedema.

haemorrhage from new vessels growing on the retina or optic disc. The vitreous haemorrhage may absorb spontaneously over the next few days/weeks but is often complicated by recurrent attacks of fresh haemorrhage. The accompanying scar tissue may contract leading to tractional retinal detachment. In severe cases constant traction on retina may lead to retinal tearing resulting in combined rhegmatogenous retinal detachment. Patients with extensive retinal ischaemia tend to develop neovascularisation of the iris and angle of the anterior chamber leading to intractable neovascular glaucoma.

Correlation Between Pathogenesis of Retinopathy and HbA1c

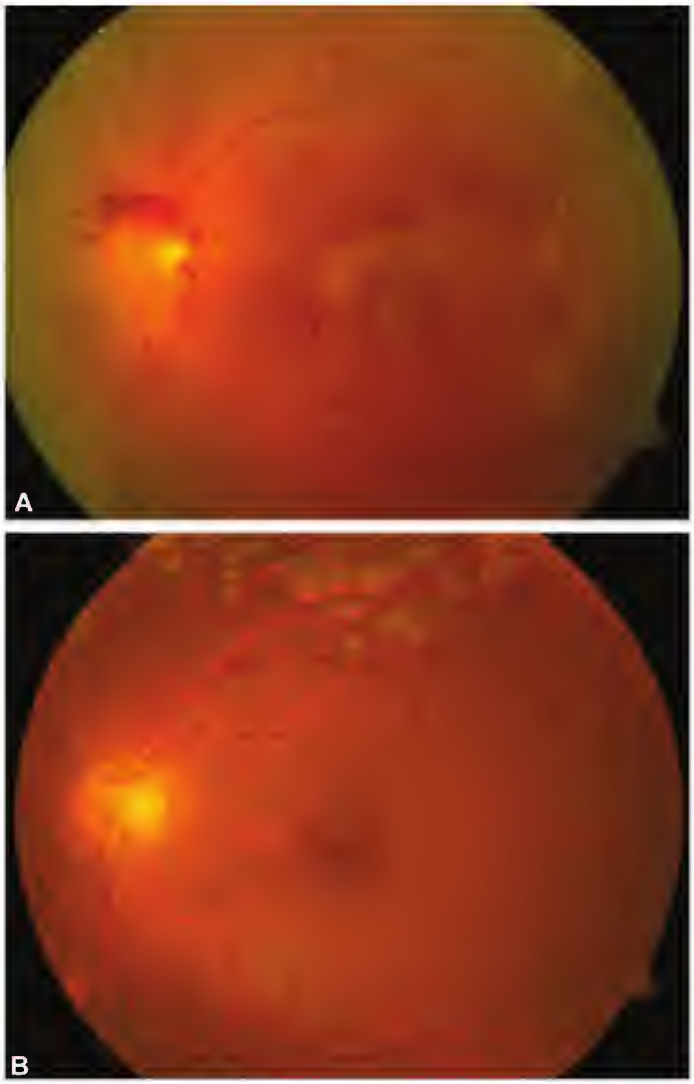
It is well established that good control of diabetes leads to reduction in the microvascular complications including DR by as much as 37% by 1% reduction in HbA1c (UKPDS) other studies also prove this point.

DIAGNOSIS AND MANAGEMENT (TABLE 1)

The diagnosis of DR is essentially clinical by using a direct ophthalmoscope. The ophthalmologists may, however, use stereoscopic biomicroscopic fundus examination besides several ancillary investigations such as fundus fluorescein angiography, and optical coherence tomography to plan treatment and monitor the response to treatment. In patients with obscure media, ultrasonography is helpful in surgical planning.

Table 1: Early Treatment Diabetic Retinopathy Study (ETDRS) Levels of Diabetic Retinopathy, Non-Proliferative Diabetic Retinopathy (NPDR)

Non-Proliferative Diabetic Retinopathy (NDPR)
Mild NPDR
At least one microaneurysm
Moderate NPDR
Haemorrhages or microaneurysms (H/Ma)
Soft exudates, venous beading (VB), and intraretinal microvascular abnormalities (IRMAs) definitely present
Severe NPDR
H/Ma in all 4 quadrants
VB in 2 or more quardrants
Intra-retinal microvascular abnormalities (IRMA) in at least 1 quadrant
Very Severe NPDR
Any two or more of severe NPDR levels
Proliferative Diabetic Retinopathy (PDR)
Early PDR
New vessels on the retina
Definition not met for high-risk PDR
High-Risk PDR
New vessels on the disc of 1/4 to 1/3 or more of the disc area or
Any new vessel and vitreous or preretinal or vitreous haemorrhage
Clinically Significant Macular Oedema (any one of the following):
Thickening of the retina located 500 µm or less from the centre of the macula
Hard exudates at 500 µm or less from the centre of the macula with thickening of the adjacent retina
A zone of retinal thickening, one disc area or larger in size, any portion of which is one disc diameter or less from the centre of the macula



TREATMENT

Since DM has multifactorial origin, an optimal metabolic control of hyperglycaemia, HbA1c levels, hypertension, dyslipidaemia, anaemia and nephropathy should be an important treatment goal. Medical management of diabetic macular oedema (DME) includes systemic control of risk factors combined with local treatment that includes laser photocoagulation.

Laser Photocoagulation

Laser photocoagulation for CSME is currently the standard of care. The goal of macular laser photocoagulation for diabetic macular oedema is to limit vascular leakage through focal laser burns of leaking microaneurysms or grid laser burns in areas of diffuse breakdown of the blood-retinal barrier. The green wavelength (Argon green, Frequency doubled Nd:YAG) is better absorbed by the haemoglobin and hence ideal for laser photocoagulation.

In recalcitrant cases pharmacological agents including intravitreal corticosteroids and anti-VEGF agents are being

Figures 11A and B: Fundus photograph of the left eye showing (A) vitreous haemorrhage with fibrovascular proliferation, and (B) same eye following pars plana vitreous surgery.

increasingly used as adjuvant to the standard laser photocoagulation therapy.

Pan retinal photocoagulation (also called scatter laser photocoagulation) is indicated in patients with severe NPDR and PDR. This involves applying 1,500 to 2,000 spots of 500 μ size laser burns of moderate intensity to ablate the peripheral ischaemic retina. This leads to significant reduction in the release of VEGF from the hypoxic retinal tissues. Full scatter treatment for PDR results in partial or complete regression of retinal and optic disc neovascularisation.

Pars Plana Vitreous Surgery

The major indications are non-clearing vitreous haemorrhage, macula-threatening traction retinal detachment and combined traction-rhegmatogenous detachment. The surgical objective includes clearing the media, relieving all anterior-posterior and tangential traction using delamination, segmentation or en-bloc techniques and performing adequate platelet-rich plasma (PRP) to prevent development of subsequent immune reconstitution inflamm-atory syndrome (IRIS) neovascularisation (**Figures 11 A and B**).

PROGNOSIS AND PREVENTION

All people with DM (type 1 as well as type 2) are at risk. The longer a person has diabetes, the higher the risk of developing DR. Early detection, education, and research are the key to prevent visual impairment/blindness from DR. Ophthalmoscopy is the most commonly used technique to screen for DR. It is critical to identify patients who are in immediate need of treatment with laser photocoagulation.

9.17 Diabetic Neuropathy

Manish Modi

DEFINITION AND EPIDEMIOLOGY

Diabetic neuropathy (DN) is defined as the presence of symptoms and/or signs of peripheral nerve dysfunction in people with diabetes after the exclusion of other causes. The importance of excluding nondiabetic causes was emphasised in the Rochester diabetic neuropathy study, in which up to 10% of peripheral neuropathy in diabetic patients was deemed to be of nondiabetic causes.

There is a higher prevalence of DM in India (4.3%) compared with the West (1% to 2%). Probably Asian Indians are more prone for insulin resistance and cardiovascular mortality. The prevalence of neuropathy increases with the duration of diabetes mellitus. The incidence of DN in India is not well known but in a study from South India 19.1% type 2 diabetic patients had peripheral neuropathy. According to an estimate, two-thirds of the diabetic patients have clinical or subclinical neuropathy.

AETIOPATHOGENESIS

The most important aetiological factors that have been associated with DN are poor glycaemic control, diabetes duration, visceral obesity and height, with possible roles for hypertension, age, smoking, alcohol consumption, hypoinsulinaemia, and dyslipidaemia. The pathogenesis of diabetic neuropathy involves an interaction between metabolic and microvascular injury to nerve.

1. Vascular Injury

Endoneural ischaemia occurs by several mechanisms. Vasodilatory signalling pathways including prostacyclins are inhibited and there is occlusion of vessels due to thickening of endothelial basal lamina and fibrin and platelet deposition.

2. Direct Metabolic Injury

Increased polyol production by overexpression of aldose reductase induces neuropathy in animal models. Advanced glycation endproducts (AGEs) are directly neurotoxic by promoting inappropriate crosslinks among proteins, which is further accelerated in response to hyperglycaemia and greater polyol pathway flux.

Reactive oxygen species (ROS) are induced by AGEs, hyperglycaemia and ischaemia. Reactive oxygen species damage proteins, and inhibit mitochondrial electron transport. Mitochondrial dysfunction may serve as a final common pathway for neuronal damage mediated by polyol, AGEs, and ROS. Mitochondrial dysfunction might account for persistent injury that occurs during periods of relative normoglycaemia and contributes to genetic differences in susceptibility to hyperglycaemic complications.

CLINICAL FEATURES

Table 1 gives the classification of DN which are discussed in the following paragraphs.

Table 1: Classification of Diabetic Neuropathies

Symmetrical Polyneuropathies
Distal sensory or sensorimotor polyneuropathy
Large-fibre neuropathy
Small-fibre neuropathy
Autonomic neuropathy
Asymmetrical Neuropathies
Cranial neuropathy (single or multiple)
Truncal neuropathy (thoracic radiculopathy)
Lumbosacral radiculopathy (asymmetrical proximal motor neuropathy)
Limb mononeuropathy (single or multiple)
Entrapment neuropathy
Combinations
Polyradiculoneuropathy
Diabetic neuropathic cachexia
Symmetrical polyneuropathies

Distal Symmetrical Polyneuropathy

Distal symmetrical polyneuropathy DSPN is the commonest type of DN and probably accounts for 75% of the DNs. It may be sensory and/or motor and may involve small or large fibres, or both. Sensory impairment occurs in glove and stocking distribution and motor signs are not prominent. Large fibre involvement causes painless paraesthesias with impairment of vibration, joint position, touch and pressure sensations, and loss of ankle reflex. In advanced stage, sensory ataxia may occur. Small fibre neuropathy on the other hand is associated with pain, burning, and paraesthesias.

Diabetic Autonomic Neuropathy

Diabetic autonomic neuropathy affects various organs of the body resulting in cardiovascular, gastrointestinal, urinary, sweating, pupils, and metabolic disturbances. It ranges from subclinical functional impairment of cardiovascular reflexes and sudomotor functions to severe cardiovascular, gastrointestinal, or genitourinary dysfunction. Orthostatic hypotension, resting tachycardia, and heart rate unresponsiveness to respiration are a hallmark of diabetic autonomic neuropathy.

Asymmetric Neuropathies

Cranial neuropathy

Cranial neuropathy in diabetic patients most commonly involves the oculomotor nerve, followed by trochlear and facial nerve in order of frequency. Third nerve palsy with pupillary sparing is the hallmark of diabetic oculomotor palsy and is attributed to nerve infarction. The pupillary fibres are peripherally located and, therefore, escape in diabetic oculomotor palsy.

Truncal neuropathy

Diabetic truncal neuropathy is associated with pain and paraesthesias in T4-T12 distribution in chest or abdominal

distribution. Bulging of abdominal wall may occur because of muscle weakness. It usually occurs in older patients with NIDDM. The onset may be abrupt or gradual and the patient may be confused with an intra-abdominal/thoracic disease, or herpes zoster.

Asymmetrical Proximal Diabetic Neuropathy

It is also referred to as diabetic amyotrophy. The patients complain of pain in the lower back, hip, anterior thigh, typically unilateral but may be bilateral. Within days or weeks, the weakness and wasting of thigh and leg muscles follows. Knee reflex is reduced or absent. Numbness or paraesthesias are a minor phenomena. Nerve biopsy shows multifocal nerve fibre loss suggesting ischaemic injury, and perivascular infiltrates suggesting an immune mechanism. This has prompted intravenous immunoglobulins (IVIg) and cyclophosphamide therapy, which have resulted in rapid recovery.

Limb Neuropathies

There are two major mechanisms of limb neuropathies in diabetics, viz. nerve infarction and entrapment. *Nerve infarctions* are associated with abrupt onset pain followed by variable weakness and atrophy. The recovery is slow over a period of months, as the primary pathology is axonal degeneration. Median, ulnar, and peroneal nerves are most commonly affected. In diabetic patients, *nerve entrapment* is commoner than nerve infarction. The entrapment neuropathies have insidious onset, have characteristic electrodiagnostic features such as conduction block or segmental nerve conduction slowing in the entrapped segment of the nerve. Carpal tunnel syndrome is three times more common in diabetic patients than the normal population. The other entrapment neuropathies in diabetic patients are ulnar, radial, lateral femoral cutaneous nerve of thigh, peroneal, and medial and lateral planter nerves.

DIAGNOSIS

The American Academy of Neurology recommends that DN is diagnosed in the presence of somatic or autonomic neuropathy when other causes of neuropathy have been excluded. At least two of the five criteria are needed: Symptoms, signs, electrodiagnostic test, quantitative sensory and autonomic testing.

For diagnosis of DN, bedside examination should include assessment of muscle pain; sensation of pin prick, joint position, touch, vibration and temperature in the hands and feet; and tendon reflexes. Electrodiagnostic tests like nerve conduction studies typically show low amplitude sensory response with prolonged distal latency. Compound muscle action potential (CMAP) amplitudes are initially normal, but decline with disease progression.

Nerve biopsy is useful only in situations, when other causes of neuropathy need to be ruled out. Skin biopsy has been used in diagnosis of small fibre neuropathy. Recently, confocal corneal microscopy in the assessment of diabetic polyneuropathy has been reported. In confocal microscopy, the cornea is scanned and images of Bowman's layer, which contains a rich nerve plexus, are examined for nerve fibre density, length and branch density, which is significantly reduced in DN and correlates with the severity of neuropathy.

TREATMENT

Currently, no medication has been shown to reverse neuropathy. The treatment is aimed at preventing the progression of neuropathy and providing symptomatic relief. Aggressive control of blood glucose is central to the treatment of diabetes and remains the only treatment shown to delay the onset and slow progression of neuropathy.

Agents that have been shown to slow and reverse nerve injury in animal models include aldose reductase inhibitors (ARIs) that reduce shunting of glucose into polyol pathway; drugs that decrease ROS (alpha lipoic acid, glutathione, dimethylthiourea and vitamin E), lipid lowering agents, and transition metal chelators (desferrioxamine and α lipoic acid). Although ARI have been shown to improve nerve conduction velocity and the density of small fibres on sural nerve biopsy and α lipoic acid showed improvement in pain following intravenous therapy, no agent has resulted in clinically meaningful improvement in human trials.

Immunosuppressing therapies have been used in diabetic lumbosacral radiculoneuropathy, based on the evidence that it may have an autoimmune basis. Therapies tried include corticosteroids, immunoglobulins and plasma exchange.

Symptomatic Treatment

Neuropathic pain relief is one of the most challenging issues in DN. The mainstays of therapy are anticonvulsant agents, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs) and opiates (**Table 2**). Each of these classes of medication has

Table 2: Therapeutic Agents for Neuropathic Pain

Class of Drugs	Compounds	Mechanism of Action	Dose Per Day	Adverse Effects
Tricyclic Antidepressants	Amitriptyline	Na-channel inhibition, 5-HT/noradrenaline inhibition	10 to 150 mg	Sedation, dry mouth, blurred vision, weight gain, urinary retention, cardiac effects
	Imipramine		25 to 150 mg	
	Nortriptyline		25 to 150 mg	
Serotonin/ reuptake inhibitor	Venlafaxine	5-HT/Noradrenaline reuptake inhibition	75 to 225 mg	Nausea, sedation, hypertension
	Duloxetine		20 to 120 mg	
Anticonvulsants	Carbamazepine	Sodium channel blocking	200 to 800 mg	Hyponatraemia, ataxia, hepatic dysfunction
	Oxcarbamazepine	Sodium channel blocking	600 to 2400 mg	Hyponatraemia, sedation
	Gabapentin	Calcium channel agonist	900 to 3600 mg	Sedation, dizziness
	Pregabalin	Calcium channel agonist	150 to 600 mg	Sedation, peripheral oedema
Ion channel blockers	Mexiletine	Sodium channel blocking	300 to 750 mg	Arrhythmia
Opioids	Tramadol	Opioid receptor agonist	50 to 400 mg	Nausea, vomiting, constipation, orthostatic hypotension, dizziness somnolence
	Oxycodone		Add on	

drug interaction and side-effects that may be more profound in the elderly. Transcutaneous nerve stimulation (TNS), magnetic field therapy, infrared high therapy and spinal cord stimulation has also been tried in a small number of patients with painful DN.

COMPLICATIONS

Foot Ulcers

The late sequelae of diabetic neuropathy are recognised to be foot ulceration, which may occasionally result in amputation and Charcot (neuropathic) arthropathy. Foot ulcers occur in 15% of the diabetic patients and are responsible for 20% of the hospitalisation among diabetic patients. Peripheral neuropathy causes loss of protective sensation. The intrinsic foot weakness and atrophy associated with moderate and advanced neuropathy alter the anatomy of the foot and potentiate friction injury. Autonomic neuropathy reduces foot sweating and increases foot oedema. On top of this, small and large vessel stenosis and loss of vasodilatory regulation result in distal limb ischaemia promoting tissue fragility and impaired wound healing.

PROGNOSIS

There is accumulating evidence suggesting that not only surrogate markers of microangiopathy such as albuminuria, but also those used for polyneuropathy, such as nerve conduction velocity and vibration perception threshold, may predict mortality in diabetic patients. Autonomic neuropathy may be associated with early mortality from cardiac involvement.

9.18 Sexual Dysfunction in Diabetes

Shashank R Joshi

BACKGROUND AND INTRODUCTION

Sexual and urologic complications of diabetes frequently occur in diabetes but are often under reported. Men may have difficulty with erections or ejaculation. Women may have problems with sexual response and vaginal lubrication. Urinary tract infections and bladder problems occur more often in people with diabetes. Diabetes mellitus (DM) may lead to abnormalities of normal sexual function in both men and women via diabetic induced vascular and neuropathic damage. Also, poorly-controlled diabetes may increase the morbidity associated with the treatment of erectile dysfunction (ED) in men. Erectile dysfunction is a common clinical problem and it seriously hampers quality of life for men and their spouse. It is well known that the incidence of ED increases with age and usually is often associated with co-morbid conditions like smoking, cardio vascular disease, hypertension, dyslipidemia and diabetes. The incidence of ED in men with diabetes is approximately 3 to 7 folds higher than in the general population. ED may also be the presenting symptom for DM and can predict both vascular or neurologic sequelae, which may occur later. Often ED is a marker of endothelial dysfunction. Fifty per cent of the Indian diabetic men in their lifetime will have the risk of developing ED if glycaemic control is not well controlled. As 50% of the diabetic men suffer from erectile dysfunction, the onset of ED in diabetics is associated with increasing age, duration of the diabetes, development of microangiopathy, neuropathy, alcohol intake and anti-hypertensive medication.

MECHANISMS OF ERECTILE DYSFUNCTION IN DIABETES

The pathophysiology of ED in diabetes is multifactorial with endothelial, vascular, autonomic, endocrine and neurologic factors either in isolation or in harmony. The neurogenic factors involve loss of unmyelinated C fibres in the early stage and large myelinated fibres in the late stage. The vascular factors implicated are atherosclerosis and microangiopathy, stenosis of internal pudendal artery, small penile vessels show changes like endothelial proliferation, subintimal fibrosis, endarteritis obliterans. Diabetes mellitus associated with hypercholesterolaemia and hypercoagulability which also additionally impair vascular function. There is impaired relaxation of the corpus cavernosal smooth muscle in diabetics in response to neuronal- and endothelial-derived nitric oxide, which may be due to the advanced glycosylation and its end products. It is now well known that adult male hypogonadism is seen with at least 10% of men who have ED with diabetes. Usually, the hypogonadism is central, viz. hypothal-amopituitary in origin. It is well known that the low levels of testosterone, lead to a decline in sexual desire as well as erectile dysfunction. Psychogenic factors are supplementary to the organic component and contribute to 30% of the ED in diabetes.

MANAGEMENT

Investigations

The patients with ED are often evaluated with the erectile function (EF) domain of the 15 item international index of erectile function (IIEF), two diary questions regarding the patient's ability to penetrate (SEP2) and have successful intercourse (SEP3), and a global assessment question (GAQ). The work-up includes fasting and prandial glucose, HbA1c, lipids profile, kidney function and prostate specific antigen (PSA). It also includes sometimes gonadal evaluation of testosterone, follicle-stimulating hormone (FSH), luteinising hormone (LH), prolactin and thyroid-stimulating hormone (TSH). It is useful to do an ultrasound of abdomen and pelvis for gonadal as well as bladder function/residual urine estimation. In few cases, semen and scrotal sonography and Doppler may also be done.

TREATMENT

Role of Phosphodiesterase Type-5 (PDE5) Inhibitors

The treatment of ED, in general, was revolutionised by the availability of sildenafil, followed by tadalafil and vardenafil. All the three medications work by inhibiting the enzyme PDE5 in the penile tissue. Sexual stimulation provokes the release of nitric oxide (NO), leading to increased cellular concentrations of cyclic guanosine monophosphate (cGMP) and subsequent penile smooth muscle relaxation. This process is reversed by the conversion of cGMP to guanosine monophosphate, which is mediated by phosphodiesterase type-5 (PDE5), the predominant functional PDE type found in the penis. Phosphodiesterase type-5 inhibitors (PDE5i) act at this step to maintain elevated levels of cGMP and continued smooth muscle relaxation. Since the release of NO is a neurologically-mediated event, neuropathy (as may occur with diabetes) may blunt the efficacy of PDE5i. This is indeed borne out clinically, as diabetics have a poorer response overall to PDE5i than men with ED of other causes. Therefore, diabetics need a higher dose as well as have a non-responder group.

Other Therapy Options

The other therapy options are intracavernosal alprostadil injection, vacuum erection devices (VED) penile prosthesis. Intracavernosal injections and penile prosthesis are useful in diabetics while VED are not very useful in diabetics.

Unlike the other modalities, prosthesis surgery is irreversible. In that the corporal tissue is permanently altered such that physiologic erections are no longer possible. If the prosthesis has to be removed, there will be complete erectile failure.

Treatment of Hypogonadism

There are now few studies of sexual function in hypogonadal, diabetic men treated with testosterone. It is now well known that testosterone improves sexual function (particularly sexual desire

and response to PDE5i in cases of initial failure to respond) in some selected patients. Additional testosterone replacement therapy also has beneficial effects on lean body mass and insulin sensitivity in diabetic men with hypogonadism. A number of different testosterone formulations are available which are discussed elsewhere (see Section 10 Chapter 11 Disorders of Gonads).

EJACULATORY DYSFUNCTION

Most men with diabetes may have sexual disorders other than erectile dysfunction like diminished sexual desire, lack of ejaculation with sexual climax (an ejaculation or retrograde ejaculation) and premature ejaculation. Successful antegrade ejaculation depends on the co-ordination of three neurologic events: seminal emission, bladder neck closure and contraction of the muscles of the pelvic floor (e.g. bulbocavernosus, ischiocavernous, etc.). In diabetes, neuropathy disrupts the ischiocavernosus nerve signals which control the closure of the connection between the bladder and urethra which, in turn, causes abnormal ejaculation. In this situation ejaculate is deposited in the innermost portion of the urethra but the connection between the bladder and urethra does not close. Since the bladder neck is open, some or all of the ejaculate may leak backwards into the bladder during the muscle contractions that normally expel the semen from the penis. In the most severe cases there may be total lack of seminal emission. Either of these conditions will impact fertility. It may also be a source of psychological disturbance to the man; indeed, some men report that they are not able to fully enjoy orgasm in the absence of ejaculation. From a fertility standpoint, sperm may be retrieved from post-ejaculate urine and then used for artificial insemination. Alternative strategies to overcome retrograde ejaculation generally focus on attempts to help the bladder neck close. A variety of pharmacologic agents have also been used including anticholinergics, antihistamines and alpha-adrenergics.

FEMALE SEXUAL DYSFUNCTION IN DIABETICS

This is a poorly understood and studied subject in diabetics. The best studied class of female sexual dysfunctions is arousal disorder; physiologically, this is accompanied by vasodilatation and engorgement of the female external genitalia. Given that the processes involved in female genital engorgement are governed by many of the same molecular processes that occur during male genital engorgement. Caruso *et al*, undertook a randomised controlled double-blinded (RCDB) trial of 100 mg sildenafil in type 1 diabetic women with sexual dysfunction. Of the 28 women, who have completed the trial, significant improvement was seen in both subjective and objective parameters. Subjectively, arousal, orgasm and dyspareunia were all improved in those taking sildenafil in comparison to baseline and those taking placebo. Colour Doppler ultrasonography was performed on the clitoral arteries, revealing an increase in blood flow in these women. However, it should be noted that the use of ultrasonography in the evaluation of women with sexual dysfunction is not routine and these results should be interpreted with caution. Usually, a gynaecological and urological test should be done.

THE IMPORTANCE OF MANAGING LIFESTYLE FACTORS IN TREATING SEXUAL PROBLEMS IN DIABETES

As with most aspects of diabetes care, routine exercise, careful monitoring of glucose levels and usage of appropriate therapies to prevent hyperglycaemia are the keys to prevent progression of diabetes-induced sexual problems. Weight management and dietary prudence are also critical in the management of diabetes. There is an evidence to suggest the weight loss may reverse erectile dysfunction in some men. In a study of 65 obese men with ED and the metabolic syndrome (MetS, obesity with associated abnormalities of blood pressure, abnormal glucose level/diabetes and abnormal cholesterol levels), eating a 'Mediterranean diet' (emphasising fresh fruit and vegetables) for 2 years led to normalisation of erectile function (as determined by an International Index of erectile function score greater than 22) in men as compared to men in the group that did not have dietary manipulation. A similar study in women with sexual dysfunction and metabolic syndrome showed a significant improvement in mean sexual function (mean increase on the female sexual function index from 19.7 to 26.1 in the treatment group versus no change from baseline in the control group). Also noted in both these studies were was improvements in serum insulin and glucose level in men and women who ate the Mediterranean diet. So, lifestyle plays a key role in sexual health in both sexes in a diabetic.

CONCLUSION

Sexual dysfunctions are common in people with diabetes but neglected and may arise from a variety of vascular, neurologic and hormonal causes. While PDE5i do not work as well in diabetics as in other populations, they still represent a good first-line treatment. If their use is unsatisfactory, intracorporal injections and implantable prosthesis are excellent alternatives. Vacuum devices represent another viable alternative, although satisfaction is generally not as high. Beyond erectile difficulties, men may complain of ejaculatory symptoms which arise from neuropathy of sympathetic nerves. Female sexual dysfunctions is mostly under reported in diabetics but further clinical advances may lead to increased hope and more efficacious treatments for these disorders.

9.19 The Diabetic Foot

Pendsey Sharad Purushottam

INTRODUCTION

Diabetic foot is one of the commonest chronic complications of diabetes. It is the leading indication for hospital admissions and prolonged stay.

A classical triad of neuropathy, ischaemia and infection characterises the diabetic foot.

The presence of infection rapidly worsens the clinical picture often requiring limb amputation. Diabetic foot ulcers are common and estimated to affect 15% of all diabetics. In India, it is estimated that approximately 40,000 legs are being amputated every year, of which 75% are neuropathic feet which are potentially preventable.

CLASSIFICATION

Diabetic foot is mainly classified into two types: neuropathic foot, in which neuropathy dominates; and neuroischaemic foot, in which occlusive vascular disease dominates although neuropathy is present. Neuropathy leads to fissures, dry skin, deformities, callus formation at plantar pressure points and plantar ulcerations (**Figure 1**), bullae and neuropathic (Charcot) joint. Ischaemia leads to pain at rest, ulceration on foot margins (**Figure 2**), digital necrosis and gangrene. Differentiating between these entities is essential because their complications are different and require different therapeutic strategies.

Wagner's (**Table 1**) and University of Texas wound classification (**Table 2**) are the most acceptable classifications. Wagner classification accounts only for wound depth and does not consider presence of ischaemia or infection. In Texas system, one needs to mention both the grade and the stage of the wound.

Figure 1: Neuropathic plantar ulcer.

Figure 2: Neuroischaemic foot.

Table 1: Wagner's Classification

Grade 0	No ulceration in a high-risk foot
Grade 1	Superficial ulceration
Grade 2	Deep ulceration that penetrates up to tendon, bone or joint
Grade 3	Osteomyelitis or deep abscess
Grade 4	Localised gangrene
Grade 5	Extensive gangrene requiring amputation

Table 2: The University of Texas Wound Classification System

Stages	**Description**
Stage A	No infection or ischaemia
Stage B	Infection present
Stage C	Ischaemia present
Stage D	Infection and ischaemia present
Grading	**Description**
Grade 0	Epithelialised wound
Grade 1	Superficial wound
Grade 2	Wound penetrates to tendon or capsule
Grade 3	Wound penetrates to bone or joint

AETIOPATHOGENESIS

Neuropathic Foot

Chronic symmetrical progressive sensorimotor neuropathy leads to loss of protective sensation. The majority of foot ulcers are a consequence of mechanical trauma unnoticed by the patient. Commonest sites of ulcerations are in the forefoot. Ulcers occur at sites of high pressure on either plantar or dorsal surfaces and are caused by bony prominences, ill-fitting footwear and toe deformities. Chronic hyperglycaemia leads non-enzymatic glycosylation of proteins causing limited joint mobility. Foot deformities occur as a result of atrophy of intrinsic muscles of the foot which alter the architecture of the foot. The combination

of these risk factors increase the plantar pressures significantly in the forefoot and the risk of foot ulceration (**Table 3**).

Table 3: Factors Contributing to Foot Ulceration

Extrinsic Factors	Intrinsic Factors
Inappropriate footwear	Bony prominences
Walking barefoot	Limited joint mobility
Falls and accidents	Joint deformity
Objects inside shoes	Callus
Sharp injuries	Fissures
Thermal trauma	Previous foot surgery
Activity level	Neuro-osteoarthropathic joint

Charcot Foot

A Charcot joint or neuroarthropathy is defined as a relatively painless progressive arthropathy of single or multiple joints. The most frequent location of the neuropathic joint is the tarsal-metatarsal region, followed by the metatarsophalangeal joints, and then the ankle and subtalar joints. The initial presentation is often a hot swollen foot (acute stage), the precipitating event usually being a minor trauma.

The process of destruction takes place over a few months (chronic stage, **Figure 3**) and leads to classic rocker bottom deformity. Multiple factors appear to contribute to the development of the Charcot foot. A peripheral neuropathy with loss of protective sensations, an autonomic neuropathy with increased blood flow to the bone, and mechanical trauma, have emerged as the most important determinants. Diagnosis is usually made on clinical grounds and typical radiological features such as fragmentation of bones, fractures, subluxation and dislocation of the joints. Osteolysis of bones leads to 'sucked candy' appearance of metatarsals or 'pencil-like' appearance of phalanges.

Figure 3: Radiograph showing Charcot Foot destruction of tarsal bones.

Goal of management is to convert destructive stage into phase of stabilisation. Strict rest, off loading by total contact cast and, finally, rehabilitation by using custom-made indepth shoes. Those with extensive destruction of ankle joint, may require surgical fixation.

Foot Infection

Infection in diabetic foot is a limb threatening condition because the consequences of deep infection in a diabetic foot are more disastrous than elsewhere mainly because of certain anatomical peculiarities. Foot has several compartments which are inter-communicating and the infection can spread from one into another, lack of pain allows the patient to continue ambulation further facilitating the spread. The foot also has soft tissues, which cannot resist infection, like plantar aponeurosis, tendons, muscle sheaths and fascia.

Osteomyelitis generally results from contiguous spread of deep soft tissue infection through the cortex to the bone marrow. Majority of the deep longstanding foot infections are associated with osteomyelitis (**Figure 4**).

Figure 4: Radiograph showing osteomyelitis of great toe phalanges.

The diagnosis of osteomyelitis can be made by plain radiography which usually shows focal osteopaenia, cortical erosions or periosteal reaction in early stage and sequestration in the late stage. A simple clinical test is probing to bone. A sterile metal probe is inserted into the ulcer, if it penetrates to the bone it almost confirms the diagnosis of osteomyelitis. Chronic discharging sinus and sausage-like appearance of the toe are the clinical markers of osteomyelitis. Definitive diagnosis requires obtaining bone biopsy for histopathology.

Newer imaging techniques are like nuclear bone scan, computerised tomography scan (CT), positron emission tomography (PET), magnetic resonance imaging (MRI). Of these, MRI is more sensitive and specific.

EXAMINATION AND DIAGNOSIS

Examination of feet is an integral part of physical examination of every patient, more so a diabetic patient. Look for changes like dry skin, fissures, interdigital mycoses, deformities, callus, abnormal shape of foot, ulceration, prominent veins and nail lesions.

Feel peripheral pulsations. Chronic sensorimotor neuropathy can be assessed by detecting sensation to pinprick and cotton wool and vibration using 128 Hz tuning fork. Hand-held biothesiometer can assess vibration perception threshold. 10 gm monofilament can detect the loss of protective pain sensation. The filament is applied perpendicular to the foot over metatarsal heads till it buckles. Buckling of the filament occurs at 10 g equivalent of linear pressure. Measuring ankle/brachial pressure index (ABI) using hand-held Doppler helps in assessment of vascular supply. Normal ABI is >0.9, in ischaemia it is <0.9.

MANAGEMENT

Diabetic foot should be managed using a multidisciplinary team approach. Off-loading and debridement are considered vital to the healing process for diabetic foot wounds. The goal of off-loading is to redistribute force from ulcers sites and pressure points at risk to a wider area of contact. There are multiple methods of pressure relief, including total contact casting, half shoes, removable cast walkers, wheelchairs and crutches. The open diabetic foot ulcer may require debridement if necrotic or unhealthy tissue is present. The debridement of the wound will include the removal of surrounding callus and aid in decreasing pressure points at callused sites on the foot. Additionally, the removal of unhealthy tissue can aid in removing colonising bacteria in the wound. It will also facilitate the collection of appropriate specimens for culture and permit examination for the involvement of deep tissues.

Infection in a diabetic foot is limb-threatening and at times life-threatening and must be treated aggressively. Superficial infections should be treated with debridement, oral antibiotics. All patients with deep infections should be hospitalised and started on broad-spectrum antibiotics. The choice of antibiotics initially should be empirical but once the culture reports are known, it should be specific. Surgical debridement should be carried out which should include all the devitalised tissues, sloughed tendons and infected bones.

Dressing Material

The selection of wound dressings is also an important component of diabetic wound care management. Saline-soaked gauze dressings are inexpensive, variety of new dressing materials have been developed, such as film and foam dressings, hydrogels, hydrocolloids and alginates.

Vaccum assisted closure (VAC), sterile maggots therapy have been shown to promote wound healing in diabetic ulcers. A recombinant platelet-derived growth factor (PDGF) is also currently in use and has been shown to stimulate wound healing in non-infected neuropathic ulcers.

Empiric Antibiotic Management of Patients

Antibiotic therapy is necessary for all infected wounds; all Grade 2 and Grade 3 ulcers; superficial ischaemic ulcers that are deteriorating, as ischaemia can mask signs of infection.

- Antibiotic therapy is insufficient without appropriate wound care. Proper wound cleansing, debridement of any callus and necrotic tissue and, especially, off-loading of pressure has to be done completely and early.
- Take into consideration any recent antibiotic therapy and, if concerns about resistant organisms exist (e.g. MRSA), treatment has to be modified accordingly.
- Treatment can be modified based on the clinical response, as determined by the diabetes specialist, podiatrist's clinical assessment. Microbiology results (cultures and sensitivities) can then be used to modify antibiotic usage, depending on clinical response.
- Continue antibiotic therapy until there is an evidence that the infection has resolved, but not necessarily until a wound has healed.

PREVENTION

Early detection and surveillance of potential risk factors for ulceration can decrease the frequency of wound development (**Table 4**). Patients should be educated regarding the importance of maintaining good glycaemic control, wearing appropriate footwear, avoiding trauma and performing frequent self-examinations.

Table 4: Risk Categorisation System

Category	Risk Profile	Check-up Frequency
0	No sensory neuropathy	Once a year
1	Sensory neuropathy	Once every 6 months
2	Sensory neuropathy with signs of peripheral vascular disease	Once every 3 months
3	Previous ulcer/amputation	Once every 1 to 3 months

Prevention of Diabetic Foot Includes

- Primary prevention: screening of high-risk feet and proper advice on preventive footwear.
- Secondary prevention: management of trivial foot lesions such as callus removal, treatment of nail pathologies, and deroofing blisters, etc.
- Tertiary prevention: prompt referral to specialist for advanced foot lesions.

Majority of patients with neuropathic feet require preventive footwear such as sandals or shoes. They should be strictly instructed to avoid slippers and 'chappals'. Therapeutic footwear are required for minority of patients who have partial foot amputation, Charcot foot, or grossly deformed feet.

Understanding the diabetic foot, proper examination of feet, investigations to classify the foot ulcers and proper management techniques using team approach along with preventive steps, would go a long way in limb salvage and prevention of limb amputation in people with diabetes.

9.20 Diabetes and Pregnancy

V Seshiah

INTRODUCTION

A new structure develops *de novo* during pregnancy and matures till it is expelled at the completion of the gestational period. The metabolic adaptations that occur during pregnancy are to accommodate a rapidly growing tissue transplant, the conceptus (placenta and foetus). For its own normal growth and development, the conceptus brings about alterations in maternal fuel metabolism and hormones. The placenta facilitates embryogenesis, growth, maturation and survival of the foetus. It has the capacity to synthesise steroid and peptide hormones and to modulate and transport maternal fuel to the foetus, 'an exquisite hormono-metabolic adaptation'.

CLASSIFICATION OF DIABETES IN PREGNANCY

Pregestational Diabetes

This term denotes pregnancy occurring in women who already have established type 1 or type 2 diabetes. They have to be followed-up taking into consideration the age of onset, duration of diabetes, mode of therapy and the existing complications.

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is defined as any degree of glucose intolerance with onset or first recognition during pregnancy. Abnormal glucose tolerance during pregnancy is not only associated with increasing pregnancy morbidity but also increases the likelihood of subsequent diabetes in the mother. Maternal hyperglycaemia has a direct effect on the development of foetal β-cell mass and is associated with increased susceptibility to the development of obesity and diabetes in the offspring (**Figure 1**). This effect on the offspring is independent of other genetic factors. As such GDM has implications beyond the index pregnancy, identifying two generations (mother and her offspring) at risk of future diabetes. The recognition of glucose intolerance during pregnancy is more relevant in the Indian context as Indian women have 11-fold increased risk of developing GDM compared to white women. It is important to detect these GDM cases because, if unrecognised, pregnancy may end in perinatal death and foetal wastage.

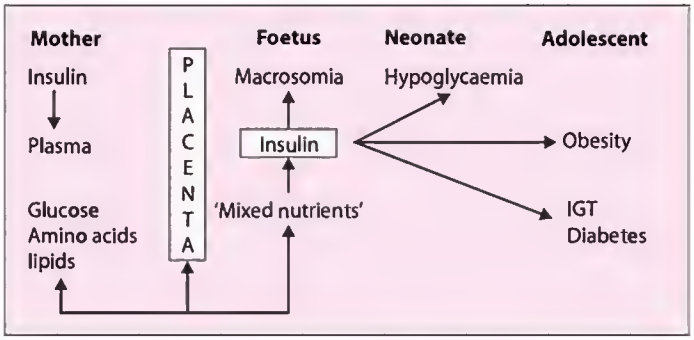

Figure 1: Pedersen/Freinkel hypothesis.

PATHOGENESIS OF GLUCOSE INTOLERANCE DEVELOPING DURING PREGNANCY

During pregnancy, there is an increased elaboration of placental chorionic somatomammotrophin (human placental lactogen or hPL), prolactin and cortisol. The surge of counter hormones results in the insulin resistance and stress the carbohydrate metabolism (diabetogenic stress). Normally a pregnant woman increases her endogenous insulin production by more than 30% from her non-pregnant insulin level. A pregnant woman, who is unable to secrete adequate insulin to compensate for the insulin resistance of pregnancy, develops gestational diabetes. Women with GDM are insulin resistant and have impaired β-cell function.

CONSEQUENCES OF THE CHANGES IN FUEL METABOLISM DURING PREGNANCY ON THE FOETAL DEVELOPMENT

Effect of Maternal Fuels on Foetal Development

The clinical hyperglycaemia-hyperinsulinism hypothesis of Pedersen (**Figure 1**) has been modified to include contributions of other maternal fuels besides glucose that are also responsive to maternal insulin. All of these can influence the growth of the foetus and the maturation of the foetal β-cell and increase in insulin secretion. Within this formulation, growth will be disparately greater in insulin-sensitive tissues (excessive abdominal fat deposition, organomegaly of liver, spleen and heart and accelerated skeletal maturation) than in insulin-insensitive tissues in the foetus.

Consequences of Maternal Hyperglycaemia on Foetus and Neonates

Prevention of foetal morbidity necessarily starts before conception, reflecting the importance of pre-pregnancy counselling in obtaining good glycaemic control and advising folic acid 400 µg per day to prevent neural defects. Consequences of maternal hyperglycaemia are described in **Table 1**.

Table 1: Consequences of Maternal Hyperglycaemia on Foetus and Neonates

First Trimester Foetal Problems	Second Trimester Foetal Problems	Third Trimester Foetal and Neonatal Problems
Malformations Growth retardation Foetal wastage	Hypertrophic Cardiomyopathy Polyhydramnios Erythraemia Placental insufficiency Pre-eclampsia Foetal loss Low IQ	Hypoglycaemia Hypocalcaemia Hyperbilirubinaemia Respiratory distress syndrome Macrosomia Hypomagnesaemia Intrauterine death

Consequences of Diabetes on the Pregnant Mother

Complications of diabetes in pregnancy occur almost exclusively in pre GDM.

- Hypoglycaemia
- Diabetic ketoacidosis
- Retinopathy
- Nephropathy
- Hypertension
- Diabetic gastropathy

DIAGNOSIS

World Health Organization Criteria

World Health Organization (WHO) recommends using a 2-hour 75 g oral glucose tolerance test (OGTT) with a threshold plasma glucose concentration of more than 7.8 mmol/L (140 mg/dL) at 2 hours similar to that of impaired glucose tolerance (IGT) outside pregnancy. This criterion is widely followed in much of the world including India; most suitable for universal screening in high-risk population for diabetes. It will be advantageous to estimate fasting plasma glucose also as this will help in planning treatment strategy.

National Institute for Health and Clinical Excellence (NICE) Guidelines

World Health Organization criteria of 2 hours plasma glucose >140 mg/dL with 75 gm oral glucose load for diagnosing GDM. Do not screen using fasting plasma glucose, random blood glucose or glucose challenge test.

International Association of Diabetes in Pregnancy Study Group

The International Association of Diabetes in Pregnancy Study group (IADPSG) suggest 75 gm glucose load for an OGTT in all clinical settings in or outside of pregnancy. The diagnosis of GDM is made if any one or two glucose value F >92 mg/dL/1 hour >180 mg/dL/2 hours >153 mg/dL, which is almost similar to the existing Carpenter and Couston criteria American diabetes association (ADA) criteria of FPG >95 mg/dL, 1 hour >180 mg/dL and 2 hours >155 mg/dL.

MANAGEMENT

The important predictor of foetal outcome either in pre-gestational or gestational diabetes is the glycaemic control attained immediately before and during pregnancy. The plasma glucose level of normal pregnant women is less than 90 mg/dL and 120 mg/dL, respectively during fasting and post-prandial states. Hence, the best foetal outcome can be expected by maintaining the mean plasma glucose level around 105 mg/dL in a pregnant diabetic woman.

Medical Nutrition Therapy

The expected weight gain during pregnancy is 300 to 400 gm per week and a total weight gain of 10 to 12 kg by term. Hence, the meal plan aims to maintain euglycaemia and to provide sufficient calories to sustain adequate nutrition for the mother and foetus and to avoid excess weight gain and post-prandial hyperglycaemia. Calorie requirement depends on age, activity, pre-pregnancy weight and stage of pregnancy. Approximately 30 to 40 kcal/kg ideal body weight, or an increment of 300 kcal/day above the basal requirement, is needed. Pregnancy is not the time for obesity correction but permitted weight gain is up to 9 kg. Underweight subjects are those not gaining weight as expected, particularly in the third trimester, require admission to ensure adequate nutrition to prevent low birth weight infants.

Insulin Therapy

Gestational diabetes mellitus

Fasting or postprandial plasma glucose exceeding 90 mg/dL or 120 mg/dL respectively after 2 weeks of medical nutrition therapy (MNT), on more than two occasions is an indication for insulin therapy. Human insulin is recommended. The patient may require a small dose of intermittent acting insulin about 4 to 6 units as initial dose given before breakfast. The dose has to be titrated on follow-up. A few of them may require combination of soluble and intermittent acting insulins. Usually, they may not require more than 20 units of insulin per day (the total dose is divided 2/3 in the morning and 1/3 in the evening). Recently short-acting analogues have been found to be safe and approved for use during pregnancy.

Pregestational type 1 diabetes mellitus: Maintenance of normoglycaemia before conception is essential to prevent foetopathy, since the organogenesis is completed by the sixth week after conception, at a time when most of the women are not even aware of their pregnancy. It has been proved in experimental animals and from observations in human pregnancies that glucose has to be normal before conception to avoid congenital malformation.

Two special diagnostic procedures in the first half of the pregnancy are relevant to detect any malformation in the foetus in a pregnant woman who attends the antenatal clinic after conception. Ultrasonography is performed to diagnose anomalies like anencephaly, cardiac and spinal abnormalities. Elevated serum alpha-foetoprotein at 14 to 16 weeks of gestation indicates neural tube defect.

In a pregestational type 1 diabetic woman, the requirement of insulin may fall during the early part of first trimester and increase as the pregnancy advances and plateaus during third trimester. They may require morning and evening 'split and mixed' dose of insulin, i.e. both short and intermittent acting insulins in the morning and evening. A few pregnant women may require less insulin in the last week of pregnancy attributed to foetal handling of maternal glucose. Sudden decrease in requirement of insulin in the third trimester of pregnancy indicates foetal jeopardy.

Type 2 diabetes mellitus in women: Pre-gestational type 2 diabetic women, desiring to become pregnant, should also undergo pre-pregnancy counselling. Pre-pregnancy control of diabetes with insulin is ideal. Sometimes a hitherto undiagnosed type 2 diabetic woman may progress through the early weeks of gestation at the risk of malformation in her offspring or a known type 2 diabetic woman who is already on oral hypoglycaemic agent (OHA) may present to antenatal clinic after conception and at times in second or third trimester of pregnancy. The best course at this juncture is to withdraw OHA and introduce insulin besides monitoring foetal well-being.

Insulin requirement

The insulin requirement varies from person to person, both in type 1 and type 2 diabetic pregnant women. The aim should

be to maintain plasma glucose at an acceptable level and not to unduly worry about the amount of insulin being administered. A few type 2 diabetic women may require very high dose of insulin, even more than 200 units/day compared with pregnant mothers with gestational diabetes. One should not be unduly concerned about the dose of insulin, as the aim during pregnancy is to have optimal glucose control for good foetal outcome.

Insulin Treatment During Delivery

The goal is to maintain the glucose level of 90 to 108 mg/dL to avoid the risk of neonatal hypoglycaemia. Insulin requirement declines after delivery to approximately 60% of the dose prior to pregnancy. Insulin dose has to be adjusted on follow-up.

Role of Oral Hypoglycaemic Agents

Normally, OHAs are not recommended during pregnancy. However, there are instances of women treated with OHAs completing their gestation successfully. A randomised unblended clinical trial compared the use of insulin and glibenclamide in women with GDM who were not able to meet glycaemic goals on meal plan. Treatment with either agent resulted in similar pregnancy outcomes. All these patients were beyond the first trimester of pregnancy at the initiation of therapy.

A randomised controlled study found that in women with GDM, metformin (alone or with supplemental insulin) was not associated with increased perinatal complications as compared with insulin. Metformin has been found to be useful in women with polycystic ovarian disease (PCOD) who failed to conceive. Continuing this drug after conception is still a controversy, but there are a few studies favouring continuation of metformin throughout pregnancy in these women. More studies are required before routinely recommending OHAs during pregnancy.

GESTATIONAL DIABETES MELLITUS LIKELY TO DEVELOP DIABETES

The future risk of developing diabetes for a gestational diabetic is 2-fold, if she becomes overweight, but maintaining the ideal body weight approximately halves the risk. The requirement of insulin in addition to diet to maintain euglycaemia during the index pregnancy is also predictive of future diabetes.

9.21 Prevention of Diabetes Mellitus

Yash Pal Munjal

INTRODUCTION

Diabetes mellitus has reached pandemic proportions. It is estimated that 285 million people corresponding to 6.4% of the adult population in the world were afflicted with diabetes in the year 2010. This figure is growing at a fast pace and it is expected to touch 438 million by the year 2030 and that will constitute 7.8% of the adult population globally. About 70% of this diabetic population will happen to be living in low and middle income group countries. In India it is estimated that there are 50.8 million patients of diabetes, followed by China which has 43.2 million. Most of these cases occur between the age group of 40 to 59 years which is a decade earlier than the western world. A large pool of diabetics remains undetected, ranging from 70% to 80% in different parts of the world. It is a matter of concern all over the world. Besides this there is a large population with impaired fasting glucose (IFG) and/or impaired glucose tolerance (IGT). The prevalence of this group in our country is around 14%. It is estimated that approximately 40% of the patients with IGT shall progress to diabetes in the next 5 years to 10 years. The cost of medicare for managing these patients will be quite staggering for the economy of any country, particularly the developing countries. The progression and onset of diabetes takes 10 years to 15 years, and therefore, provides a good opportunity for prevention of diabetes and thus prevent morbidity. Based on the demographic profile of this disease, prevention can be primary, secondary and tertiary as outlined in **Figure 1**. These preventive measures are based on the correction of the two major pathogenetic mechanisms, i.e. insulin resistance and insulin deficiency. The issue of lifestyle changes and pharmacological interventions are the hallmark in all stages of preventive strategy. In this chapter lifestyle measure and comparative value of pharmacological prevention are discussed in high-risk and IGT/diabetic patients.

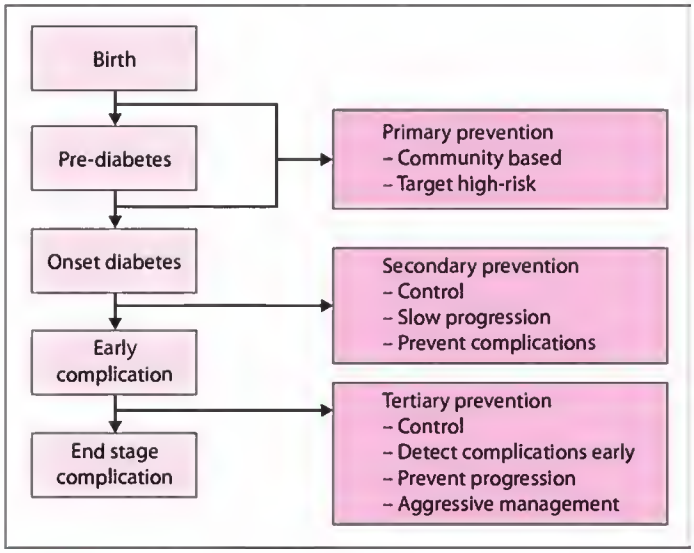

Figure 1: Stages of prevention of diabetes.

STRATEGIES FOR PREVENTION OF DIABETES

Two major strategies have been evaluated for reducing the incidence of type 2 diabetes, i.e. lifestyle interventions and drugs. Surgery (metabolic surgery) is emerging as the third arm of prevention. The first two steps aim at modifying the risk profile for diabetes. The risk factors of diabetes can be classified into modifiable risk factors and non-modifiable risk factors (**Table 1**). The modifiable risk factors are the subject matter of intervention.

Table 1: Risk Factors for Type 2 DM

Modifiable	Non-Modifiable
Overweight and obesity	Ethnicity
Sedentary lifestyle	Family history
Previously identified impaired glucose tolerance (IGT) and impaired fasting glucose (IFG)	Age
	Gender
	History of gestational diabetes mellitus
Metabolic syndrome	Polycystic ovarian disease
Elevated TG, reduced HDL	
Hypertension	
Dietary factors	
Intra-uterine environment	
Inflammation	
Use of drugs like corticosteroids, diuretics	

Lifestyle Interventions

Lifestyle interventions include medical nutrition therapy (MNT) and physical activity (PA). They serve to address the issue of overweight and obesity, improve insulin sensitivity and prevent the progression from IFG and/or IGT and to overt diabetes and control inflammation, an important aspect in prevention of micro- and macrovascular complications.

Obesity or overweight

The present epidemic of diabetes is very significantly fuelled by the growing problem of overweight and morbid obesity. Obesity is again a global problem increasing progressively. Excessive truncal adiposity is very well correlated with the risk for diabetes, hypertension and cardiovascular disease. The changing lifestyle, lack of physical activity and increasing stress are some of the important contributory factors. To sum up, the marked increase in the intake of energy dense food with very little or no physical activity and high level of stress contributes significantly to the progression of the epidemic. The question arises: how and at what level of natural history diabetes can be prevented especially by modifying lifestyle factors? To answer this, a prospective Nurses Health Study of 84,941 female nurses was conducted. They were followed for 16 years and a series of risk factors related to dietary behaviour, physical activity, weight and cigarette smoking were identified and targeted. This was associated with a remarkable 91% reduction in the risk of developing diabetes. Even with a family history of diabetes the risk reduction was 88%. In theory, therefore, diabetes can be

prevented, largely by lifestyle changes despite genetic background. In most of the trials reduction in weight predicts a decrease in incidence of diabetes. It is estimated that *each kilogram of weight loss is associated with approximately 16% reduction in the occurrence of overt diabetes*. Similar results were observed in the Finnish diabetes prevention programme (FDPP) in which weight loss averaging 3 to 4 kg over 4 years in overweight subjects with IGT led to a 58% decline in the occurrence of overt diabetes. A similar result was observed by the diabetes prevention programme (DPP) in the United States in which lifestyle interventions involving exercise and dietary changes in subjects with IGT reduced the occurrence of diabetes by 58%. The results of studies involving lifestyle modifications are shown in **Table 2**.

Table 2: Results of Lifestyle Modifications

Study	Duration (Years)	Relative Risk Reduction (%)
Malmo	6	63
Da Qing	6	42
Finnish DPP	3	58
DPP (USA)	3	58
DPP (Japan)	4	67
DPP (India)	3	28

The results of these lifestyle intervention programmes are quite impressive in the prevention of diabetes but practically lifestyle management is replete with problems. These interventions are labour intensive (one study needed 16 one to one sessions delivered by case managers to achieve target weight reduction and exercise levels). Although lifestyle interventions produced successful results, in research settings they are difficult to replicate even in well funded healthcare systems. After completion of DPP all the participants were offered an intensive lifestyle programme in a group sessions format. Those subjects who opted were enrolled in DPP outcome study (DPPOS). This study was conducted to evaluate whether the effects of diabetes prevention were sustained over a period of time. During the trial phase the training in group session format and follow-up was aggressive during the additional follow-up averaging over 6.8 years in DPPOS. Its results were published in the year 2009 thus giving a mean follow-up of approximately 10 years. In the intensive lifestyle modification (ILS) group, as compared to the other group, a 34% risk reduction was noted. The Japanese and Indian studies have shown similar results. (Though of shorter duration).

In case of over-weight individuals, reduction of weight by restricting calories and increasing exercise is of vital importance. However, it has been observed that it is not necessary to reduce the weight to the level of ideal body weight, but a reduction of about 5% to 10% in the body weight gives substantial reduction. In severely overweight subjects with IGT, gastric bypass surgery led to a weight loss of 22.5 kg (and 28 kg in the Swedish SOS Intervention Study), the incidence of diabetes reduced 30-fold compared with normal patients. Weight loss associated with improvement of gastrointestinal hormones is considered to, contribute in reducing the incidence of diabetes.

Nutrition

Diet: Recommendations for individuals should consider the following maintain calorific intake. The calories are to be distributed in various forms of food constituents.

Distribution of food/calories: This is dealt in Chapter 5 of this section.

Physical activity

Physical activity is an important element in the prevention and management of type 2 diabetes in all its stages. Large and well planned studies have established the importance of exercise. One has to do 30 to 45 minutes of aerobic exercise and resistance exercises for 6 days a week and preferably all the 7 days. The beneficial effects of physical activity are due to the mechanisms given in **Table 3**.

Table 3: Benefits of Physical Activity

Decreases insulin resistance/improve insulin sensitivity
Decreases overall adiposity
Reduces central adiposity
Improves blood glucose levels (glucose tolerance), lipid levels and blood pressure
Desirable changes in muscle mass

Though there are difficulties in implementing lifestyle measures, some of the tips that may help to achieve the goal are given in **Table 4**.

Pharmacotherapy for Prevention

Considerable emphasis has been focused on the prevention of diabetes with the drugs which are used for the treatment of diabetes as well. Table 5 gives the important drug trials and their results. The diabetes prevention programme research group study found a 31% reduction in the incidence of diabetes with metformin (at 2.8 years). Acarbose showed 25% risk reduction over 3 years in STOP NIDDM study. However, sustained effects with acarbose have not been studied. Troglitazone proved to be effective in controlling blood sugar levels but was removed from the market because of serious liver toxicity. In the DREAM

Table 4: Practical Tips for Nutrition and Physical Activity

Calculate Calorie Intake Based on Weight and Activity Profile
Fats – Restrict 20% to 25% of total calories
Increase fibre content (20 to 30 gm per day)
Small frequent meals
Encourage intake of whole grains, beans, fruits, vegetables and nuts
Emphasise on portion size/slow eating
Physical Activity
Set goal – 45 minutes exercise of moderate intensity aerobic and resistance exercise every day
Individual-based exercise programme is useful
May use small gadgets like pedometer
Start slowly and build up gradually
Others
Provide family help and support
Failures be circumvented
Close follow-up

trial rosiglitazone showed risk reduction of 60% over 3 years study period, but due to its cardiovascular side effects the drug has been withdrawn from the market. In case of obese people, orlistat has been shown to reduce the risk of diabetes by 37% as compared with placebo. Pravastatin when given to non-diabetics for cardiac or cholesterol lowering reasons reduced the number of new cases of diabetes. ACE-Inhibitors (ramipril, perindopril) and angiotensin receptor blockers (telmisartan and olmesartan) have shown improvement in glucose tolerance when given to non-diabetics. But these are not substantiated in subsequent well planned trials.

Table 5: Review of Drug Intervention Trials

Study	Drug	Study Duration (Years)	Relative Risk Reduction (%)
DPP	Metformin	3	31
India (IDPPI)	Metformin	3	26
TRI POd	Troglitazone	1	75
STOP NIDDM	Acarbose	3	25
XEN DOS	Orlistat	4	37
DREAM	Rosiglitazone	3	60

Lifestyle measures as compared with pharmacological intervention have shown better results and that is intensive lifestyle changes are two times better than pharmacotherapy.

In a cost benefit analysis discussed in American Diabetes Association Annual Scientific Sessions 2011 it was also demonstrated that though lifestyle measures are more effective in prevention of diabetes, the cost benefit ratio is better in patients being managed on metformin.

BARIATRIC SURGERY

The basic clinical outcome of bariatric surgery is to reduce weight and this in turn has proved to be useful in the prevention of diabetes. It is also postulated that there is a change in the intestinal hormones (incretins) which are known to control diabetes. In one of the prospective Studies of over 2000 patients who underwent various forms of bariatric surgery (the commonest being vertical banded gastroplasty) and compared with a standard-care group, it was demonstrated that the patients who underwent bariatric surgery, the risk of diabetes was reduced by 86% at 2 years and 75% at 10 years follow-up. It was also found out in the sub-group where there was 12% or more of weight loss from the baseline people did not develop diabetes at all.

Bariatric surgery is also reported to induce a remission in diabetic patients. Similarly another randomised control prospective trial of gastric banding versus conventional therapy there was remission in 73% as compared to 13% of control procedures. Gastric banding procedures improve glycaemic control in diabetic patients. The patient selection has to be careful and as compared to morbid obese patients bariatric surgery has to be considered in patients with a body mass index (BMI) of more than 35 kg/m^2 as compared to obese people with BMI of more than 40 kg/m^2. Large scale trials are underway to establish the long-term benefits of the various procedures for control and prevention of diabetes.

PREVENTION OF DIABETES IN THE INDIAN CONTEXT

The Indian Diabetes Prevention Programme 1 (IDPPI) was the first study to show that lifestyle modification was effective in preventing diabetes in native Asian Indians. IDPPI was a multicentre randomised, controlled and 3-year prospective study in subjects with IGT. The study groups were as follows:

Group 1: control group with no intervention (n = 133)

Group 2: subjects advised lifestyle modification (n = 120)

Group 3: subjects treated with 500 mg of metformin (n = 128)

Group 4: subjects treated with both lifestyle modification and metformin (n = 121)

The median follow-up period was 30 months and the 3 years decrease in cumulative incidence of DM was 55%, 39.3%, 40.5% and 39.5% in groups 1 to 4 respectively. The relative risk reduction in lifestyle modification (28.5%; P = 0.018), metformin (26.4; P = 0.029), lifestyle modification and metformin (28.2%; P = 0.022) compared with the control group was very similar. The study showed that progression from IGT to diabetes was high in Indians. Both lifestyle modification and metformin were equally effective and there was no added benefit in combining them.

The study thus showed that primary prevention of DM was possible in a comparatively lean but highly insulin resistant indian population by moderate changes in physical activity and diet. Family history of DM in first degree relatives of Indian diabetics was 45% to 54% compared to 38% in Europeans suggests a strong ethnic genetic susceptibility. Prevalence of overweight among Indian urban children (17.8% boys and 15.8% girls aged 14 to 19 years) with lack of physical activity and high carbohydrate, high fat and high calorie diet would be a forerunner of DM. Intrauterine malnutrition or overnutrition and poor control of gestational DM also increase the chance of future DM. Urbanisation and migration seem to increase the incidence of DM. Screening for glucose intolerance for preventive measures at an early age is a requisite in Indians as they develop hyperglycaemia at a younger age. It is ideal to achieve primary prevention of type 2 diabetes by non-pharmacological intervention in the relatively lean Asians as compared with western population.

Role of Vitamin D in Prevention

Recent studies (Women health study: nurses health study) have drawn attention to the role of vitamin D and calcium homeostasis in the metabolic syndrome. It was observed that low levels of vitamin D are contributory to insulin resistance, reduced calcium mediated insulin secretion and higher incidence of diabetes. Vitamin D along with calcium supplements has shown improvement in insulin resistance and insulin secretion. Asians have high prevalence of vitamin D deficiency and vitamin D with calcium supplements is likely to improve β-cell function.

POPULATION BASED-PREVENTION STRATEGIES

World health organisation and other member countries who are seized with the problem of chronic diseases especially diabetes have formulated a series of guidelines for implementation at the community level for the control and prevention of diabetes. international diabetes federation (IDF) has also given its guidelines. Based on the recommendations of WHO and IDF, the following strategies provide an insight in preventing DM at

community level. The approach with each country and sub-population will vary from place to place. However the basic plan of prevention will remain the same globally.

The prevention strategies can be grouped in three steps:

Identification of People at High-Risk

Large population based surveys for diabetes detection may be an expensive exercise and is not feasible. It is therefore, prudent to identify people at high-risk and screen them. This is more cost effective and beneficial exercise. The people at high-risk can be identified by so called opportunistic screening, by various questionnaire and diabetes risk tests which have been devised by several countries. These risk scores are based on the following:

- High BMI (cut-off values vary from continent to continent)
- IGT/IFG
- Gender
- Family history of diabetes
- Waist measurement
- Dyslipidaemia

India has also formulated its own diabetes risk score. These parameters contribute to one another but are not mutually exclusive. **Table 6** gives the details of the Indian population at risk.

Table 6: Measurement of Risk in Indian Population

Plasma glucose – fasting blood glucose followed by oral glucose tolerance test, if necessary
HbA1C > 6%
Waist circumference (85 cm for female and 90 cm for male)
Cardiovascular disease risk factors
Family history
Body mass index (BMI) more than 23 kg/m^2

Interventions

Based on these parameters the people at risk have been graded into high, medium and low-risk areas. According to the level of their risk grading the interventions can be planned based on their relative risk category. The interventions have to be aggressive especially in high and medium risk population. The possible role of various inventions medical nutrition therapy (MNT), physician assistant (PA), Bariatric Surgery) has been discussed above and need not be repeated. The interventions suggested by IDF and WHO provide the blue print but the exact programme has to be designed on geographical and ethnic basis in each country.

Prevention of Type 1 Diabetes

Type 1 diabetes is a T helper cell mediated autoimmune disease in a genetically susceptible individual. The susceptibility and protection loci are in the short arm of chromosome 6 in the major histocompatibilty complex. Environmental factors like infections including viruses especially coxsackie and rubella, ingestion of bovine milk proteins and nitrosourea compounds during childhood, malnutrition and infection during pregnancy have been attributed as environmental triggers. For an effective prevention strategy there is need for an efficient prediction strategy using genetic and immune markers (Islet cell antibodies, GAD antibodies). First phase insulin response in intravenous glucose tolerance test is also an early marker. Risk groups include first degree relatives of type 1 diabetics and offspring of auto-antibody positive, gestational diabetic parents, children born to older mothers especially in first born children of mothers over 40 years of age and high parental age. The groups more prone to develop type 1 diabetes have been tabulated in **Table 7**. In patients with new onset of diabetes, treatment with Anti CD3 monoclonal antibodies (teplizumab) have recently been shown to slow the decline in C-Peptide levels.

Table 7: Risk Factors in Various Groups

Group	Level of Risk
General population	0.7% to 1.5%
Offspring of diabetic parents (mother/father)	2% to 5%
Siblings	5% to 6%
Monozygotic twins	33% to 50%

From the Table above it is quite apparent that first degree relatives of diabetic patients, siblings and children born to older mothers have a higher propensity to develop diabetes.

Various studies to see the effect of interventional trials in type I diabetes like DPPTI (diabetic prevention trial of north America and European nicotinamide diabetes intervention trial (ENDIT) have been completed and have shown negative results.

Interventions in animal models have shown success in preventing or delaying type 1 DM. Interventions that target the immune system directly are immunosuppression, selective T cell subset deletion and induction of immunologic tolerance to islet proteins. Another approach is to prevent cell death by blocking cytotoxic cytokines or increasing islet cell resistance to the destructive process. However, these interventions have not been successful in preventing type 1 diabetes in humans. The diabetes prevention trial type 1 also concluded that insulin (IV and SC or PO) did not prevent type 1 DM. Therefore, the focus is shifting to develop a vaccine for prevention of type 1 diabetes, and this is being followed vigorously.

CONCLUSION

The evidence base for prevention of type 2 diabetes is quite robust. The cost involved and the benefits accruing may be considered acceptable at government and community level. Every doctor practicing curative medicine should also focus on the preventive aspects of DM. Relatives of patients with overt diabetes, children born to mothers with gestational DM, family history of DM in patients visiting for other ailments and over-weight individuals need to be screened and to be suggested lifestyle measures.

Exercise and nutrition counselling will go a long way in preventing diabetes. Provide healthy food alternatives and encourage physical activity. Use metformin and bariatric surgery wherever appropriate.

10.1 Basic Considerations of Endocrinology

Ashok Kumar Das

INTRODUCTION

The endocrine system consists of ductless glands which, by releasing chemical signals (hormones) in the blood stream, regulate function in distant organs. The endocrine system works closely with the nervous system to maintain homeostasis. The major endocrine glands are pituitary, hypothalamus, thyroid, parathyroid, islets of Langerhans (pancreas), adrenals and gonads (testes and ovaries).

Hormones act on multiple cell types by interacting with cell surface (protein hormones) or nuclear (steroid hormones) receptors. The effects of the hormones are both, short-term, due to enzymatic catalytic reactions within the cell and long- term, due to changes in the expression and upregulation of genes.

In addition to dedicated endocrine glands, there are endocrine cells within the organs whose primary function is not endocrine. These include cells within the heart that produce atrial natriuretic peptide (ANP), liver cells that produce insulin like growth factor type 1 (IGF-1), cells within the kidney that produce erythropoietin (EPO) and numerous cell types within the gastrointestinal tract that produce gastrointestinal hormones.

DEFINITION OF HORMONES

Hormones (endocrine signals) are chemical messengers that are secreted by ductless glands of the endocrine system and act on distant target organs via specific cell receptors resulting in the upregulation of specific second messengers which, in turn, brings about the changes in the cell structure/function.

Hormones secreted by various endocrine organs have been listed in **Table 1**.

CLASSIFICATION

Hormones can be classified based on the location of the target cell.

Autocrine Signals

These are chemical messengers secreted by cells into the extracellular fluid and affect the function of the same cell.

Paracrine Signals

These are chemical messengers secreted by cells which affect neighbouring cells of a different type. For example, glucagon produced by the alpha-cells of the Islets of Langerhans act on the adjacent insulin secreting beta cells.

Table 1: Hormones and Their Sites of Production

Gland	Hormone
Dedicated endocrine glands	
Hypothalamus	Anti-diuretic hormone (ADH), oxytocin, corticotrophin-releasing hormone (CRH), thyrotrophin-releasing hormone (TRH), gonadotrophin-releasing hormone (GnRH), growth hormone regulating hormone (GHRH), somatostatin, dopamine
Pituitary gland	Growth hormone (GH), adrenocorticotrophic hormone (ACTH), thyroid stimulating hormone (TSH), follicle stimulating hormone (FSH), luteinising hormone (LH), prolactin
Thyroid gland	T3, T4, calcitonin
Parathyroid gland	Parathyroid hormone (PTH)
Islets of Langerhans	Insulin, glucagon, somatostatin
Adrenal gland (cortex)	Cortisol, aldosterone, dehydroepiandrosterone (DHEA)
Adrenal gland (medulla)	Epinephrine, norepinephrine
Ovary	Oestradiol, progesterone, inhibin
Testis	Testosterone, inhibin, anti-müllerian hormone
Organs with primary function other than endocrine	
Brain (pineal gland)	Melatonin
Heart	Atrial natriuretic peptide (ANP)
Kidney	Erythropoietin
Adipose tissue	Leptin, adiponectin
Stomach	Gastrin, somatostatin, ghrelin
Intestines	Secretin, cholecystokinin, GLP-1, GLP-2, gastrin inhibitory peptide, motilin
Liver	Insulin-like growth factor (IGF)
Hormones produced to a significant degree by peripheral conversion	
Lungs	Angiotensin II
Kidney	1, 25$(OH)_2$ Vitamin D
Adipose, mammary glands	Oestradiol-17β
Liver	Testosterone
Genital skin, prostate	5-Dihydrotestosterone

Peptide hormone can remain bound on the membrane of one cell and interact with a receptor on juxtaposed cell. For example, sex steroids in the ovary, angiotensin II (AT II) in kidney and platelet derived growth factor (PDGF) in the vascular wall.

Intracrine

Hormones can act inside the cell without being released, e.g. insulin and somatostatin that can inhibit their own release from pancreatic β and δ cells, respectively.

Neurocrine

These are the hormones secreted by neural cells and they consist of neurotransmitters and neurotrophins. Neurotrophins foster the production of proteins associated with neuronal growth, differentiation and development. Neurotrophins include nerve growth factor, brain derived neurotrophic factor (BDNF), neurotrophin-3, neurotrophin 4/5.

Classification on the Basis of Chemical Structures

Hormones can also be classified based on their chemical structures and on their mechanisms of action. There are three general classes of hormones classified by chemical structure.

Steroid hormones

These hormones are derived from cholesterol and have the basic backbone of the cholesterol molecule, with variations in side chains providing functional specificity. The basic structure of steroid hormones is illustrated in **Figure 1**.

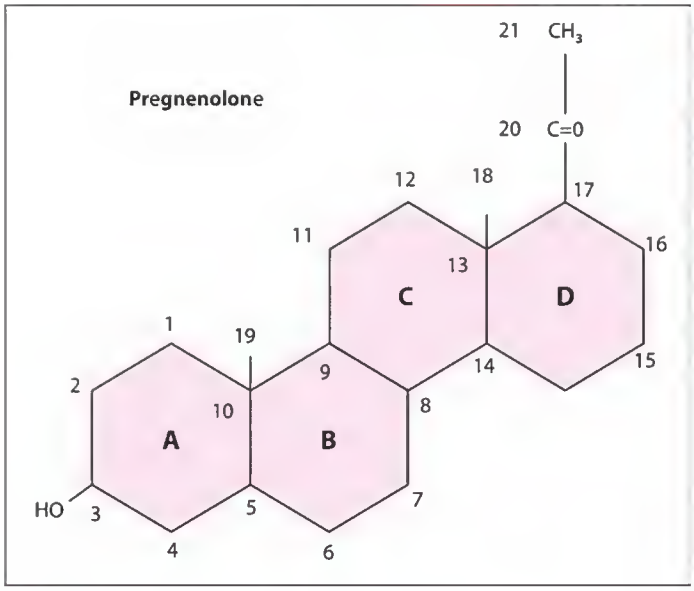

Figure 1: Chemical structure of steroid hormone.

The adrenal cortex and the gonads are the main sources of steroid hormones. The major steroid hormones are glucocorticoids (cortisol), mineralocorticoids (aldosterone), androgens (testosterone), oestrogens (including oestradiol and oestrone), progestogens (e.g. progesterone).

Amino acid derivatives

Amine-derived hormones are derivatives of the amino acids tyrosine and tryptophan. Examples are thyroxine, catecholamines such as dopamine, epinephrine and norepinephrine. The chemical structure of the amino acid derivatives is illustrated in **Figure 2**.

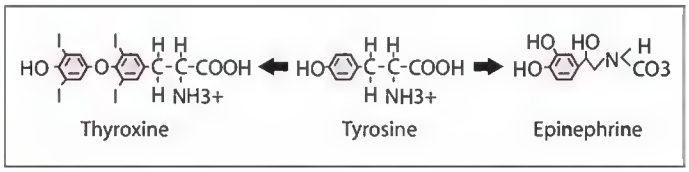

Figure 2: Chemical structure of thyroxine, tyrosine and epinephrine.

Peptide hormones

Peptide hormones are most prevalent and consist of chains of amino acids. Larger peptides are usually referred to as proteins, while complex protein hormones with carbohydrate side chains are called glycoprotein hormones. A summary of the classification based on the chemical structure is given in **Table 2**.

Peptide hormones can be classified into various families as listed in **Table 3**.

Table 2: Classification of Hormones Based on the Chemical Structure

Precursor	Type of compound	Examples
Protein	Protein	Growth hormone
	Peptide	ACTH
	Cleavage of peptide	Thyroxine → Triiodothyronine
	Cleavage of amino acid	Phenylalanine → Catecholamine
Cholesterol	Steroid	Cortisol
		$1,25(OH)_2D3$
Amino acid	Modified amino acid	Epinephrine
	Tripeptide	Thyrotropin-releasing hormone
Fatty acid	Retinoids	Retinoic acid
	Eicosanoids	Prostaglandin E

Table 3: Classification of Peptide Hormones

Growth hormone family	Growth hormone (GH) Prolactin (PRL) Human placental lactogen (hPL)
Glycoprotein hormone family	Gonadotrophins (LH, FSH, CG) Thyroid stimulating hormone (TSH)
Gastrointestinal hormones and peptides	Gastrin family: gastrin, cholecystokinin (CCK) Secretin family: glucagon, secretin, glicentin, vasoactive intestinal peptide (VIP), gastric inhibitory polypeptide
Proopiomelanocortin (a prohormone)	β Endorphins

MECHANISM OF ACTION OF HORMONES

Peptide Hormones

A peptide hormone binds to a cell-surface receptor, resulting in activation of an enzyme that catalyses the synthesis of cyclic AMP (cAMP) from ATP. Cyclic AMP then serves as a second messenger for perpetuation of hormone action. Other second messengers have been discovered.

Steroid Hormones

Steroid hormones enter the cell and bind to cytoplasmic receptors. The hormone-receptor complex enters the nucleus and activates specific genes, initiating transcription of the message followed by protein translation. Steroid hormones act more slowly than peptide hormones because of the time required to produce new proteins as opposed to activating proteins that are already present.

Hormone Receptors

As mentioned earlier, the two main sites of hormone receptors are: cell surface and nuclear.

Cell surface receptors

Cell surface receptors have ligand recognition domains that are exposed on the outer surface of the cell membrane. Cell surface receptors are of four types:

1. *G protein linked receptors (have seven transmembrane domains):* A common way to translate a signal to a biologic effect inside cells is by way of nucleotide regulatory proteins (G proteins). These are also called serpentine receptors, as the proteins span the cell membrane seven times. Hormones whose action is mediated by these receptors include catecholamines, prostaglandins, adrenocorticotropic hormone (ACTH), glucagon, parathyroid hormone (PTH), thyroid stimulating hormone (TSH) and luteinising hormone (LH).
2. *Receptors with intrinsic ligand regulated enzymatic activities:* These receptors have an intrinsic tyrosine kinase domain. When the ligand binds to the receptor, the tyrosine kinase domain undergoes autophosphorylation. This leads to production of transcription factors in the nucleus that alter gene expression. Hormones whose action is mediated by these receptors include growth factors, atrial natriuretic peptide (ANP), epidermal growth factor (EGF) and platelet-derived growth factor (PDGF).
3. *Cytokine and colony stimulating factor receptors:* These receptors contain a surface exposed amino terminal domain that binds the ligand (i.e. hormone), a single membrane spanning domain and a carboxy terminal effector domain. They initiate tyrosine kinase activity in the cytoplasm. In particular, they activate the so called Janus tyrosine kinases (JAKs) in the cytoplasm. These in turn phosphorylate signal transducer and activator of transcription (STAT) proteins. The phosphorylated STATs move to the nucleus where they act as transcription factors. Hormones whose action is mediated by these receptors include growth hormone (GH) and leptin.
4. *Receptors having serine-threonine kinase activity:* Their effects are mediated by SMADs, intracellular proteins which when phosphorylated move to the nucleus, bind to DNA and initiate transcription of various genes.

Nuclear receptors

These receptors mediate the actions of hormones such as steroid hormones and thyroid hormones. In particular, oestrogen and triiodothyronine (T3) receptors bind hormones in the nucleus. The T3 receptors also bind thyroxine (T4), but with lesser affinity. The glucocorticoid receptor is located mainly in the cytoplasm but migrates promptly to the nucleus as soon as it binds to its ligand. Nuclear receptors also include two families of retinoic acid receptors, RAR and RAX. These receptors have an extensive role to play in foetal development.

Second Messengers

Second messengers are intracellular molecules which link the hormone receptors with the effector pathways in the target cells. Examples of second messengers and the respective hormones have been listed in **Table 4**.

Table 4: Hormones Utilising Second Messengers

Second messenger	Examples of hormones which utilise this system
Cyclic AMP	TSH, FSH, LH, antidiuretic hormone, epinephrine, norepinephrine, glucagon, calcitonin, parathyroid hormone
Protein kinase activity	Insulin, growth hormone, prolactin, oxytocin, erythropoietin, several growth factors
Calcium and/or phosphoinositides	Angiotensin II, antidiuretic hormone, gonadotrophin- releasing hormone, thyrotrophin-releasing hormone
Cyclic GMP	Atrial natriuretic peptide, nitric oxide

Hormones secreted from various principal endocrine organs and their salient effects have been listed in **Tables 5 to 7**. Detailed description of each one of them is given in the respective chapters.

Table 5: Hormones Secreted by the Hypothalamus

	Effect on hormone secretion	Hormones affected
Thyrotrophin-releasing hormone (TRH)	Stimulates	TSH
	Stimulates	Prolactin (PRL)
Gonadotrophin-releasing hormone (GnRH)	Stimulates	LH
	Stimulates	FSH
Dopamine	Inhibits	Prolactin
	Inhibits	LH
Corticotrophin-releasing hormone (CRH)	Stimulates	ACTH
Growth hormone-releasing hormone (GHRH)	Stimulates	GH
Growth hormone-inhibiting hormone (somatostatin)	Inhibits	GH
	Inhibits	TSH
	Inhibits	Insulin

Table 6: Hormones Secreted by Pituitary and Their Physiological Effects

Hormones	Organs	Major functions
Anterior pituitary gland		
Growth hormone (GH)	Liver, adipose tissue	Promotes growth (indirectly), control of protein, lipid and carbohydrate metabolism
Thyroid stimulating hormone (TSH)	Thyroid gland hormones	Stimulates secretion of thyroid
Adrenocorticotrophic hormone (ACTH)	Adrenal gland (cortex)	Stimulates secretion of glucocorticoids
Prolactin (PRL)	Mammary gland	Milk production
Luteinising hormone (LH)	Ovary and testis	Control of reproductive function
Follicle stimulating hormone (FSH)	Ovary and testis	Control of reproductive function
Posterior pituitary gland		
Antidiuretic hormone (ADH)	Kidney	Conservation of body water
Oxytocin	Ovary and testis	Stimulates milk ejection and uterine contractions

Table 7: Hormones Secreted by Other Glands and Their Actions

Gland	Hormones	Major functions
Thyroid	Thyroxine (T4) Triiodothyronine (T3)	Increases the rate of chemical reaction and basal metabolic rate
	Calcitonin	Promotes calcium deposition in bone
Adrenal cortex	Cortisol	Glucose homeostasis, anti-inflammatory effects and many others
	Aldosterone	Na^+, K^+ and water homeostasis
	DHEA, Androstenedione	Androgenic action
Adrenal medulla	Epinephrine Norepinephrine	Same effects as sympathetic stimulation
Pancreas	Insulin and glucagon	Carbohydrate metabolism
Parathyroid	Parathyroid hormone (PTH)	Controls serum calcium ion concentration by increasing calcium absorption
Testis	Testosterone	Development of male reproductive system and male secondary sexual characters
Ovaries	Oestrogens Progesterone	Development of female reproductive system, female breasts and female secondary sexual characters
Placenta	Human chorionic gonadotrophin	Promotes growth of corpus luteum
	Human somato-mammotropin	Promotes development of some foetal tissues
Kidney	Renin	Conversion of angiotensinogen to angiotensin
	Erythropoietin	Increases erythrocyte production
Stomach	Gastrin	Stimulates the gastric acid secretion
Small intestine	Secretin	Stimulate pancreatic acinar cells to release bicarbonate
	Cholecystokinin	Stimulate gallbladder contraction
Adipocytes	Leptin	Inhibits appetite
Heart	Atrial natriuretic peptide	Increases sodium excretion by kidneys

CONTROL OF ENDOCRINE ACTIVITY

Hypothalamic anterior pituitary hormones, and those produced by target organs under their influence, are regulated by a classical feedback loops which involve hormonal, neural and direct feedback mechanisms (**Figure 3**). Another category of hormones, such as insulin and PTH, are directly regulated by circulating levels of glucose and calcium.

The concentration of hormone as seen by target cells is determined by three factors:

- Rate of production
- Rate of delivery: dependent of blood flow
- Rate of degradation and elimination

MECHANISMS OF ENDOCRINE DISEASES

Based on the physiological functions, endocrine diseases are classified into three subtypes: hormone excess, hormone deficiency and hormone resistance.

Effects of Hypo- and Hyperfunctioning of Various Endocrine Glands

The various endocrine dysfunctions due to hypo- and hyperfunctioning are depicted in **Table 8**.

LABORATORY DIAGNOSIS OF HORMONAL DISORDERS

The diagnosis of endocrine disorders is based on clinical examination and focused investigations. The basic approach in the diagnosis involves:

- Proving hypo- or hyperfunction of the glands by measurement of serum or urine hormone levels as compared to normal age and sex-matched individuals
- Establishing aetiologic basis by radiological investigations and ancillary tests like FNAC and biopsy in some cases.

The laboratory evaluation is discussed in detail in the chapter on 'Endocrine Disorders: A Clinical Approach', in great detail.

TREATMENT

Treatment of endocrine diseases depends on the functional status of the endocrine glands, degree of disability, age and coexistent morbidities. In general, hypofunctioning glands are treated by replacement of the appropriate hormones in adequate physiological doses with regular follow-up and dose adjustment for stressful conditions. Hyperfunctioning glands need careful evaluation to determine the cause of the excess function. Medical therapy is attempted whenever feasible, using hormone antagonists and receptor blockers. In case of tumours that are not responsive to medical therapy, surgical removal of the glands can achieve cure, however, at the risk of causing iatrogenic hypofunctioning.

Deficiency Disorders

Almost all the hormones are available, either as chemically synthesised entities or as recombinant molecules. Some are oral preparations (T3, T4, steroids) while others are given parenterally (GH, testosterone). Novel systems of delivery are being used like testosterone patches, insulin analogues.

The hormones are usually started in physiological doses and adjusted according to the response. Details of hormone replacement are provided in the relevant chapters discussing individual hormone deficient states.

Hormone Excess States

The treatment of such diseases can be either medical or surgical.

Medical

Medical therapy for hyperfunctioning states includes agents which, either function as antagonists (e.g. somatostatin analogues for GH excess), agonists for endogenous inhibitors (bromocriptine, dopamine analogue for prolactin excess) or enzyme inhibitors (carbimazole and propylthiouracil for hyperthyroidism; metyrapone, ketoconazole for Cushing's syndrome).

Surgical

In addition to medical therapy, hyperthyroid states can also be treated with surgery (thyroidectomy) or radioactive iodine ablation. Primary hyperparathyroidism due to parathyroid adenoma or parathyroid hyperplasia are cured by surgically removing the parathyroid glands. Pituitary micro- and macro-

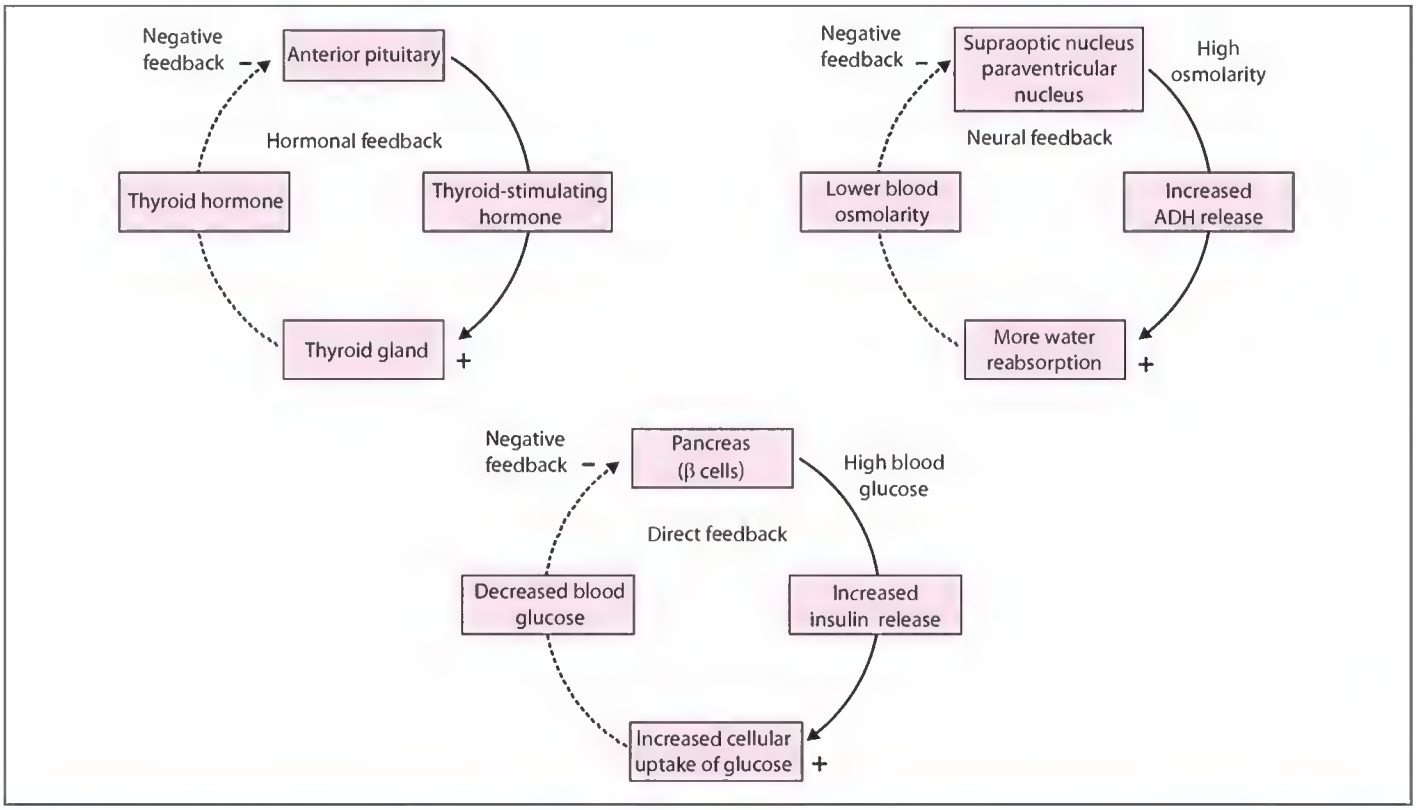

Figure 3: Classic feedback loops for control of hormone secretion.

Table 8: Showing Effects of Hypo- and Hyperfunctioning of Various Endocrine Glands

	Hormones	Hyperfunction	Hypofunction
Anterior pituitary	Growth hormone	Acromegaly and gigantism	Impaired growth and short stature
	Adrenocorticotropic hormone	Cushing's disease	Secondary hypoadrenalism
	Prolactin	Galactorrhoea amenorrhoea syndrome in women; reduced libido and hypogonadal features in men	
	Luteinising hormone Follicle stimulating hormone		Hypogonadotrophic hypogonadism
Posterior pituitary	Anti-diuretic hormone		Diabetes insipidus
Thyroid	Thyroxine (T4) Triiodothyronine (T3)	Hyperthyroidism	Hypothyroidism
Adrenal cortex	Cortisol	Cushing's syndrome	Addison's disease
	Aldosterone	Conn's syndrome	
Adrenal medulla	Epinephrine Norepinephrine	Hypertension (Pheochromocytoma)	
Pancreas	Insulin	Insulinoma	Diabetes mellitus
	Glucagon	Glucagonoma	
Parathyroid	Parathyroid hormone (PTH)	Primary hyperparathyroidism	Hypoparathyroidism: hypocalcaemia
Testis	Testosterone		Hypogonadism
Ovary	Oestrogens Progesterone		Hypogonadism

adenomas can be surgically resected by various surgical approaches in case of compressive symptoms and mass effect or treated with radiation delivered either by conventional means or through a stereotactic approach.

10.2 Endocrine Disorders—A Clinical Approach

MS Seshadri

INTRODUCTION

Endocrinology is a discipline that deals with hormonal disorders. The term 'hormone' traditionally means a chemical signal produced by a discrete gland which reaches distant target organs and tissues through the blood stream and regulates their function. Glands producing hormones constitute the endocrine system. In addition, cells may also produce other chemical signals, which may either exert an effect on the cell which produces them (autocrine) on adjacent cells (paracrine).

Endocrine glands may be a single discrete gland, e.g. adenohypophysis (anterior pituitary), or multiple discrete glands, e.g. parathyroid glands or could even be scattered throughout an organ, e.g. islets of Langerhans in the pancreas. Further, the same endocrine gland may produce more than one hormone, e.g. production of glucocorticoid, mineralocorticoid and adrenal androgens from the adrenal cortex.

There may be different receptors through which a single hormone exerts its effect such as the receptors for epinephrine and the response of the target tissue may depend on the nature of the receptor that it expresses.

CHEMICAL NATURE OF HORMONES

Hormones may be derived from a single amino acid such as thyroxine or serotonin, from cell membrane lipids as in prostaglandins or from cholesterol, e.g. steroid hormones. They can be polypeptides, e.g. parathyroid hormone (PTH) or glycopeptides, e.g. thyroid stimulating hormone (TSH).

FUNCTIONS OF THE ENDOCRINE SYSTEM

The role of this complex system is to maintain the consistency of the internal environment (*milieu interior*) of all the cells in the intact organism. Hormones also mediate growth, differentiation, sexual maturation and reproduction. Together with the nervous system, the endocrine system helps the organism to cope with changes in the external environment also. At different times in the life of the organism, the same hormone may play different roles, e.g. during intrauterine life, insulin promotes growth but in the extrauterine life it is a powerful regulator of plasma glucose.

MECHANISM OF ACTION OF HORMONES

Hormones act on target cells through receptors which are located on the cytoplasmic membrane, e.g. PTH receptor or in the nucleus, e.g. steroid hormone receptors. A hormonal disorder may be due to abnormal production of the hormone, e.g. overproduction of thyroxine by the thyroid gland in hyperthyroidism. Sometimes, the endocrine disorder is due to abnormalities in the signal transduction through the receptor, e.g. complete androgen insensitivity syndrome where a genotypic male with 46 XY (male) karyotype with normal testosterone production presents phenotypically as a female. The biochemical nature of hormonal resistance is defined in some disorders. For example, in pseudohypoparathyroidism, there is a defect in the G protein coupled to PTH receptor which precludes PTH action on target tissues, resulting in hypocalcaemia despite inappropriately normal or elevated PTH levels. Constitutive activation of the hormonal receptor in spite of normal circulating levels of the hormone can lead to endocrine disorders with clinical features of hormonal over-activity. For example, in McCune Albright syndrome focal activation of the G protein coupled to skeletal PTH receptors leads to lytic bone lesions indicative of excessive PTH action on the skeleton, even though circulating PTH levels are not elevated.

SYNTHESIS OF HORMONES

Synthesis of hormones is an orderly and sequential process and involves the action of a series of enzymes on a defined substrate. Polypeptide hormones are initially produced as preprohormones which are cleaved to prohormones which in turn are converted to the hormone by sequential removal of short peptide fragments. If there is a deficiency of any of the enzymes involved in intracellular hormone synthesis, the concerned hormone will not be produced and a precursor may accumulate, giving rise to clinical symptoms, e.g. in congenital adrenal hyperplasia (CAH), a deficiency of the 21 hydroxylase enzyme leads to decreased production of cortisol leading to hypoadrenalism, while adrenal androgens accumulate and produce virilisation of a female infant. A number of hormones exert their cellular effects by stimulating or suppressing intracellular enzymes.

GENES AND HORMONES

The production of hormones, receptors and enzymes are regulated by genes in the endocrine cell or in the target cell. Therefore, it is not surprising that several endocrine disorders are genetically determined. The clinician therefore needs to elicit a detailed family history in patients with endocrine disorders. The genetic abnormality may involve an entire chromosome as in Turner's or Klinefelter's syndrome or may just involve single gene mutations as in some patients with growth hormone deficiency.

INTERACTIONS BETWEEN ENDOCRINE AND IMMUNE SYSTEMS

There is a close interaction between the endocrine system and the immune system. There may be a primary alteration in the immune system that leads to endocrine gland dysfunction, or a primary alteration in endocrine function that leads to altered immune responses. Further, biochemical changes in the extracellular fluid due to primary endocrine disease may lead to decreased ability to tackle infections.

Several endocrine disorders such as primary thyrotoxicosis, autoimmune hypothyroidism and autoimmune adrenal insufficiency (Addison's disease) are clearly immunologically mediated. The altered hormonal mileau in endocrine disorders

may significantly impair immunity, e.g. hypercortisolism in Cushing's disease suppresses humoral and cell-mediated immune responses and leads to opportunistic infections. In endocrine disorders such as diabetes mellitus the alteration in plasma glucose levels as a consequence of the endocrine disease may alter neutrophil function and predispose to recurrent bacterial infections and non-enzymatic glycosylation of collagen may interfere with proper wound healing.

Some patients with systemic autoimmune disorders such as Sjögren's syndrome or systemic lupus erythematosus may have associated autoimmune endocrine disease leading to hypothyroidism or hypoadrenalism.

Most autoimmune endocrine disorders are caused by organ-specific autoimmune responses, e.g. Type 1 diabetes mellitus and autoimmune thyroiditis. The tendency for familial aggregation of endocrine disorders may therefore be due to heritable abnormalities of the immune system. When autoimmunity is the basis for the development of an endocrine disorder more than one endocrine gland may malfunction, e.g. association of autoimmune thyroid disease with adrenal deficiency or hypoparathyroidism. Other non-endocrine tissues may be affected by the autoimmune process in a patient with autoimmune endocrine disease, e.g. association of atrophic gastritis and B12 malabsorption with autoimmune thyroid disease. Therefore, when a patient presents with one endocrine problem, the clinician may have to look for other associated endocrine and other immunologically mediated non-endocrine disorders. A detailed evaluation of other organ systems may be necessary if the patient has additional symptoms. For instance, in a patient with autoimmune thyroiditis with some symptoms of peripheral neuropathy, a detailed neurologic examination may reveal features of subacute combined degeneration of the cord due to B12 deficiency.

TRANSPORT OF HORMONES IN CIRCULATION

Hormones are carried in the circulation usually bound to plasma proteins and the bound fraction constitutes the major portion of the measured hormone level, e.g. thyroxine bound to thyroxine binding proteins constitutes more than 99% of circulating total thyroxine. However, it is only the free fraction, which is not bound to circulating proteins, that is physiologically active. The concentration of the free hormone is so low that accurate measurement may be very difficult, e.g. free T4 or free cortisol. Therefore, a calculated value for the free hormone level such as free thyroxine index or a free testosterone index is often used. There are many disorders where the concentration of the hormone in serum is altered due to alterations in the concentration of the binding protein. For example, during pregnancy hepatic production of thyroxine binding proteins like thyroxine binding globulin (TBG) increases in response to oestrogen, accounting for increase in Total T4 levels seen in pregnancy. In nephrotic syndrome, the serum albumin is very low because of massive proteinuria and this may lead to low levels of measured Total T4, without affecting free hormone levels.

METABOLIC INACTIVATION OF HORMONES

Hormones are degraded at different sites such as the liver and kidney and major dysfunction of these organs may cause abnormal levels of certain hormones. This in turn may lead to clinical symptoms and signs, e.g. in chronic liver disease there are clinical features of hyperoestrogenism, like gynaecomastia and testicular atrophy in men. Similarly, there may be a sharp decline in insulin requirements in patients with diabetes who develop chronic kidney disease, resulting in frequent hypoglycaemic events unless insulin dose is reduced. Some drugs used in treating endocrine disorders are inactivated or excreted by the liver or kidney. Hence, in the presence of renal or hepatic insufficiency, these agents need to be either withdrawn or their doses reduced. For example, metformin must not be used in people with even mild elevations of serum creatinine (>1.5 mg/dL).

RHYTHMIC NATURE OF HORMONE SECRETION

Several circulating hormones exhibit characteristic biological rhythms. ACTH and cortisol show diurnal variation with peak levels in the early morning while oestrogen and progesterone show cyclical variations during different phases of the menstrual cycle over a period of about one month. Altered rhythmicity of hormone production may be the earliest sign of disease and can be used as a diagnostic test, e.g. loss of diurnal variation in serum cortisol levels is an early abnormality in Cushing's syndrome.

CLINICAL FEATURES OF ENDOCRINE DISORDERS

The clinical features in endocrine disorders can be very common such as weight-gain or very unusual such as hypokalaemic periodic paralysis in thyrotoxicosis. Since, hormones circulate to all parts of the body, symptoms and signs may reflect involvement of a range of organ systems. For example, in a patient with thyroid hormone excess, there may be weight loss, palpitations, dyspnoea, fatiguability, increased appetite, diarrhoea and nervousness suggesting involvement of the cardiovascular, respiratory, musculoskeletal, alimentary and nervous systems. Hence, a detailed general physical examination (e.g. height, weight, heart rate, blood pressure) and evaluation of all major organ systems is mandatory for any patient with suspected endocrine disease. In children height should be recorded at each visit and the height velocity in cm/year calculated annually so that early disorders of growth can be identified, evaluated and treated. In adolescents, the extent of pubertal development (Tanner staging) should be recorded accurately.

The unusual nature of symptoms in endocrine diseases may lead to wrong referrals to a number of different specialists including psychiatrists. Symptoms in a patient with pheochromocytoma may be mistaken for a panic attack or a patient with insulinoma and recurrent hypoglycaemia may land up with a neurologist for 'seizure disorder' or with a psychiatrist for a behavioural disorder. Several endocrine disorders such as primary hypothyroidism and Cushing's syndrome may have psychosis or altered behaviour as a major component of the symptom complex. On the other hand drugs used in psychiatric practice often cause endocrine dysfunction, e.g. hyperprolactinaemia, amenorrhoea and galactorrhoea in patients who are on phenothiazines.

Iatrogenic Endocrine Disorders

Drugs used in endocrine practice are often misused and may result in clinical manifestations of endocrine disease.

Glucocorticoid misuse is the most common cause for Cushing's syndrome in clinical practice. Supraphysiological doses of thyroxine are often erroneously prescribed to obese patients and may result in thyrotoxicosis with osteoporosis or atrial fibrillation. Amiodarone induced thyrotoxicosis, anticonvulsant induced osteomalacia, ketoconazole induced adrenal and androgen deficiency and antipsychotic drug-induced hyperprolactinaemia are other common examples of iatrogenic endocrine disease. It is, therefore, mandatory to elicit a detailed drug history in patients presenting with endocrine disorders so as to avoid expensive investigations and unnecessary procedures.

When Should a Physician Suspect an Endocrine Disorder?

The basis for suspecting an underlying endocrine disorder is given in **Table 1**.

Table 1: Basis of Clinical Suspicion of Endocrine Disorder

Suspect an endocrine disorder in the event of
Rapid changes in body-weight
Unpredictable changes in blood pressure
Hypotension on trivial insults
Unexplained hypertensive response to drugs
Inappropriate responses of body temperature
No fever in the presence of an infection
High fever in the absence of an infection
Unusual reactions to drugs
Hypertension during anaesthesia in unrecognised-pheochromocytoma
Failure to recover from anaesthesia in unrecognised-hypothyroidism
Recent changes in skin pigmentation
Hyperpigmentation in adrenal insufficiency and ACTH producing tumours
Hypopigmentation of usually pigmented areas in hypopituitarism
Disorders of growth and sexual maturation
Disorders of sexual differentiation in an infant
Disorders of menstrual function and reproduction
Inappropriate secondary sexual characters
Gynaecomastia in a male
Hirsutism in a female
Inappropriate biochemical changes
Hyponatraemia in the presence of a high urine spot sodium (SIADH)
Kaliuresis despite hypokalaemia (Conn's syndrome)

LABORATORY TESTS AND THEIR INTERPRETATION

Circulating levels of hormones are usually present in minute concentrations. The methods used for assaying hormones follow some general principles. A fixed concentration of a specific antibody against the hormone is incubated with the serum sample for a defined period of time. Subsequently, a fixed quantity of a labelled hormone is added and incubated for a defined time period. Finally, the antibody-bound and unbound fractions of the hormone are separated by a chemical agent or a second antibody. The concentration of the label is measured in the bound and in the free fraction by a detector. The proportion of labelled hormone bound to antibody is inversely proportional to the quantity of the unlabelled hormone present in the clinical sample. This same process is carried out with known concentrations of highly purified hormone and a standard curve is constructed. The reading of the unknown sample can be read off the standard curve. The label can be a radionuclide (radioimmunoassay) or an enzyme (ELISA) or a fluorescent probe or a chemiluminescent probe (chemiluminescence assay).

All assays of hormones should include appropriate quality controls at low, normal and high levels of the analyte in question so that the reproducibility and accuracy of the test from day-to-day and from assay-to-assay is ensured. It is necessary that the clinician knows whether the laboratory is adhering to these standards and it is better to get the tests done by an accredited laboratory [(The national accreditation board for testing and calibration laboratories (NABL) is the agency responsible for accreditation)]. In the event of a laboratory report not consistent with the clinical picture, the clinician should alert the laboratory about a potential error in measurement so that issues can be sorted out. Similarly, the laboratory should alert the clinician if the report is very abnormal, since an early therapeutic response may be mandated. It is this cross-talk between the clinician and laboratory that ensures that the patient gets the maximum benefit out of the test carried out.

The concentrations of hormones in blood are tightly regulated by trophic hormones secreted by the pituitary or by serum levels of chemicals such as glucose or calcium. If T4 levels are low due to a thyroid problem, TSH, which is the corresponding trophic hormone, would be high. On the other hand if T4 is low and TSH also is low, it implies that the gland secreting the trophic hormone, i.e. pituitary is hypofunctioning. Similarly, in a patient with hypercalcaemia, elevated PTH levels imply that the normal

Table 2: Laboratory Tests in Hormonal Disorders

Suspected hypothyroidism: Free T4 and TSH
Suspected hyperthyroidism: Free T4 and TSH
Primary amenorrhoea: FSH and LH
Secondary amenorrhoea: FSH, LH, prolactin and TSH
Suspected metabolic bone disease: Ca, phosphorus, albumin, globulin, alkaline phosphatase, PTH and 25-OH vitamin D if indicated
Tetany: Ca, phosphorous, albumin, creatinine, Na^+, K^+, HCO_3^-, chloride, PTH and 25-OH vitamin D if indicated
Spontaneous hypoglycaemia: Fasting plasma glucose and fasting insulin
Suspected Cushing's syndrome: Screening plasma cortisol at 8 am after 1 mg dexamethasone administered at 11 pm previous night. If cortisol in more than 1.8 µg % do a formal low and high dose Dexamthasone suppression test
Suspected primary hyperaldosteronism: Na, K, HCO_3 and chloride, serum aldosterone and plasma renin activity
Suspected endocrine hypertension: Na^+, K^+, HCO_3^-, chloride, Ca, phosphorous, creatinine, albumin/globulin, alk phosphatase, 24 hours urine metanephrine and normetanephrine, aldosterone and plasma rennin activity
Suspected Sheehan's syndrome/hypopituitarism: FSH, LH, Free T4, TSH, 8 am cortisol
Virilised female: Testosterone and DHEAS
Suspected polycystic ovary syndrome: Plasma glucose fasting and post-prandial, fasting lipid profile, testosterone, prolactin, TSH
Child with ambiguous external genitalia: 17-OH progesterone, Na^+, K^+, HCO_3^-

regulatory process is not in place and that there is unregulated overproduction of PTH. In contrast, if a hypocalcaemic patient has elevated PTH this is expected and would be interpreted as secondary hyperparathyroidism. Therefore, when tests are ordered both trophic and target hormone should be measured together for proper interpretation.

The clinician ordering the test should know details of collection, e.g. PTH samples and ACTH samples which are thermolabile, should be collected in test tubes placed in a beaker of crushed ice and the serum separated using a refrigerated centrifuge. When FSH and LH are checked in menstruating women it is appropriate to collect the sample on the second or third day of the menstrual cycle, i.e. follicular phase enabling appropriate interpretation in the clinical context. A mid-cycle sample on the other hand may have a very high LH value, and unless the clinician is informed the result may be misinterpreted. In women when tests are ordered one should verify the last menstrual date and if pregnancy is suspected or confirmed, be aware that the serum level of several hormones such as total T4, prolactin and cortisol are higher in pregnancy than in the non-pregnant state.

The common set of tests ordered in typical clinical situations is shown in **Table 2**. These will be the initial tests. Further testing may be needed in individual situations.

STIMULATION AND SUPPRESSION TESTS

These are used in ambiguous situations when the basal level of the hormone has yielded a borderline low or high value indicating that the hormonal abnormality is subtle. By and far these tests need to be validated in each institution as the published 'normal' responses vary.

In general, stimulation tests are used in target organ hypofunction and suppression tests in target gland hyperfunction. For example, in a patient with endogenous overproduction of cortisol from an adrenal adenoma, exogenous administration of high doses of a synthetic glucocorticoid like dexamethasone fails to suppress cortisol levels. This is one of the most common suppression tests used in endocrine practice. Conversely, in patients with symptoms suggestive of adrenal insufficiency, the basal serum cortisol levels are not adequate to discriminate a normal from a deficiency state. Serum cortisol levels <20 µg/dL with dynamic testing using intravenous synthetic ACTH 1-24 (Synacthen), are diagnostic of adrenal insufficiency. Individual situations and the appropriate tests will be discussed in each individual chapter in this section.

10.3 Disorders of Hypothalamus and Pineal Gland

Abdul Hamid Zargar, Bashir Ahmad Laway

HYPOTHALAMUS

Hypothalamus is the ultimate brain structure that allows maintenance of homeostasis. This neuroendocrine gland, weighing approximately 4 grams, is situated between thalamus above and pituitary gland below. The key functions of hypothalamus are:

1. Reception of sensory inputs like light, pain and temperature from external environment.
2. Receiving information regarding internal environment like blood pressure, osmolality and glucose.
3. Other inputs like feedback, both positive and negative, from hormones such as glucocorticoids, sex hormones and thyroid hormones.

Functionally, hypothalamus and pituitary act in concert as a unit and pituitary could be considered as an extension of hypothalamus. The unit is supplied by a rich network of portal vessels. Hypothalamic neuronal cells synthesise and release specific stimulatory and inhibitory factors directly into the portal system of vessels. This allows reliable transmission of hypothalamic peptides into the pituitary, without any systemic dilution.

The hypothalamic nuclei along with afferent and efferent nerve fibres connect the hypothalamus to various portions of brain and brainstem. The hypothalamus is divided into four regions from anterior to posterior including preoptic, supraoptic, tuberal and mammary regions and three zones namely, periventricular, medial and lateral.

The hypothalamus is responsible for important body functions including water metabolism, temperature regulation, appetite control, sleep-wake cycle, circadian rhythms and control of sympathetic and parasympathetic functions. The neuro-endocrine control of anterior pituitary is the most important function of hypothalamus.

CLINICAL FEATURES OF HYPOTHALAMIC DISORDERS

Disorders of varied aetiologies affecting hypothalamus may give rise to similar clinical features because of small size of the hypothalamus. Common manifestations are headache, vomiting, visual disturbances, signs of pyramidal and extrapyramidal tract involvement and cerebellar signs. Other manifestations include disturbances of puberty, water metabolism and caloric imbalance.

MANIFESTATIONS OF HYPOTHALAMIC DISORDERS

Disorders of Water Metabolism

Central diabetes insipidus

Destruction of anti-diuretic hormone (ADH) producing magnocellular neurons in supraoptic and paraventricular nuclei or defects in the transport of ADH to posterior pituitary results in central diabetes insipidus. Common causes are idiopathic, Langerhans cell histiocytosis, vascular accidents and neuro-surgical trauma. Patients present with polyuria, polydipsia with dilute urine in presence of increased serum osmolality and good response to administration of ADH.

Syndrome of inappropriate ADH secretion (SIADH)

Manifests with hyponatremia. Clinical features depend upon the severity of hyponatremia. Normal serum sodium is 136 to 145 mEq/L. Mild hyponatremia (plasma sodium 125 to 135 mEq/L) presents with nonspecific symptoms in the form of weakness, lethargy, and headache. Severe hyponatremia (plasma sodium <125 mEq/L) presents with confusion, seizures and coma. Diagnosis of SIADH requires presence of hyponatremia with plasma osmolality <270 mosmol/kg (normal plasma osmolality being 285 to 295 mosmol/kg); urinary osmolality of >100 mOsm/kg with elevated urinary sodium (>40 mEq/L) and presence of normal thyroid and adrenal function without any volume overload state.

Disorders of Appetite

Hypothalamic obesity

Almost one fourth of patients with hypothalamic disorders manifest with obesity. Obesity results from involvement of ventromedial nucleus (satiety centre). Common causes include craniopharyngioma, granulomatous disorders, head trauma and infiltrations. Syndrome also presents with headache, visual disturbances, hypogonadism, diabetes insipidus and increased sleep.

Anorexia nervosa

Common disorder affecting women of less than 25 years. These women have distorted body image, exercise excessively and induce vomiting. There is a functional hypothalamic disturbance and many endocrine abnormalities are associated with it. These include amenorrhoea, low serum thyroxine (T4) and adrenocorticotrophic hormone (ACTH). Growth hormone (GH) and prolactin levels are elevated. The manifestations completely reverse with weight gain.

Abnormalities of Sleep-Wake Cycle and Circadian Rhythm

Suprachiasmatic nuclei are responsible for the maintenance of circadian rhythms resulting in sleep-wake cycle, temperature control and cognitive function. Hypersomnolence with or without obesity occur in around 30% of patients with hypothalamic syndrome. Day time sleepiness and night time hyperactivity is common.

Abnormalities of Emotion and Behaviour

Agitation, destructive behaviour with activation of sympathetic nervous system during the episodes is more common in lesions of ventromedial nucleus. Gelastic or laughing seizures are common in hamartoma of tuber cinereum. Abnormalities in EEG are present during the seizures.

Disordered Control of Pituitary

Precocious puberty

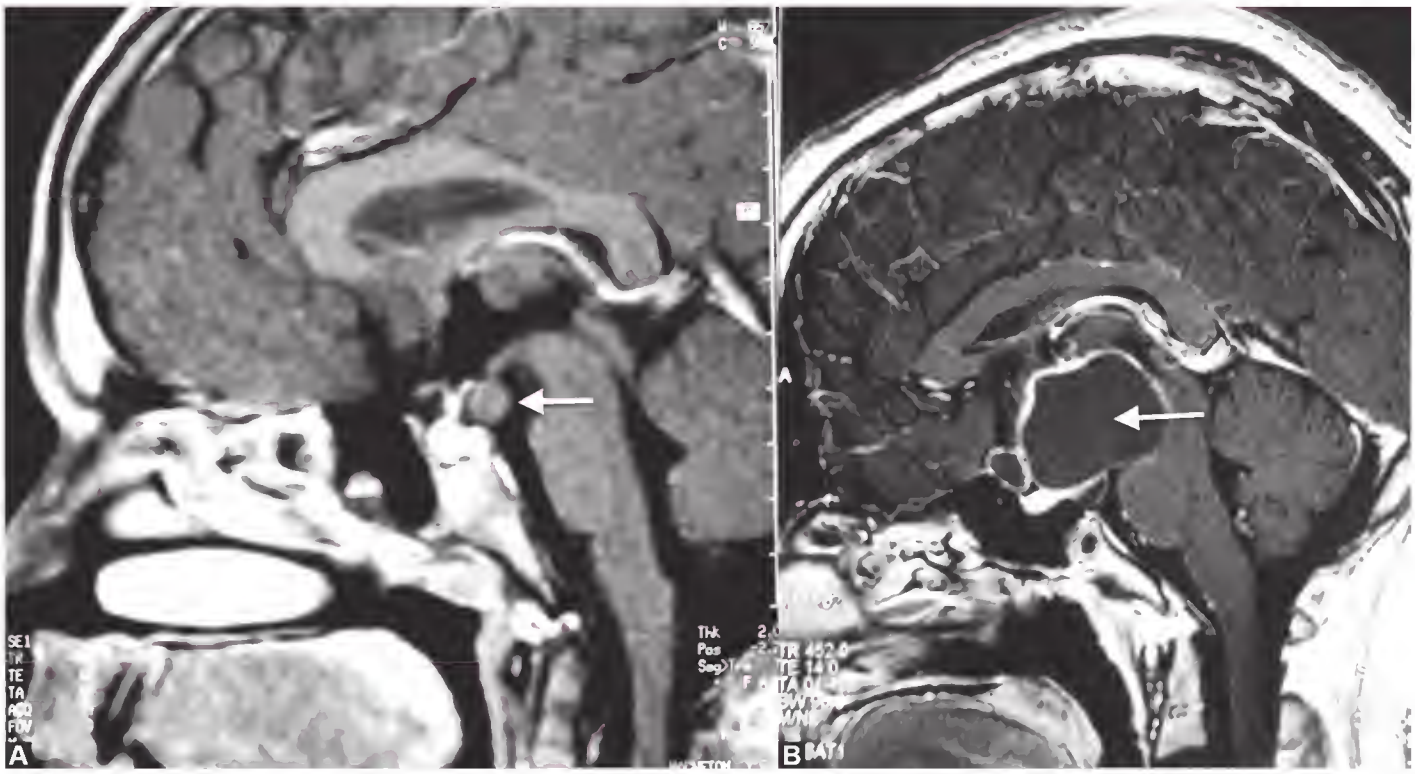
Premature activation of hypothalamo-gonadal axis results in precocious puberty in girls (<8 years of age) and boys (<9 years of age). Activation of the axis in girls is mostly idiopathic, but in boys around 50% have hypothalamic lesion, hamartoma being the most common (**Figures 1A and B**). Precocious puberty in these patients is gonadotrophin releasing hormone (GnRH) dependent confirmed by predominant LH rise after GnRH injection.

Specific Hypothalamic Syndromes

Clinical features of common hypothalamic syndromes are summarised in **Table 1**.

disorder is more common in boys causing undescended testes and hypogonadism. Nerve deafness, colour blindness, cleft palate, exostosis and renal abnormalities may also be associated.

Growth Hormone Deficiency



Many congenital defects involving hypothalamus like septo-optic dysplasia, anencephaly may result in GHD. Affected children have normal height and weight at birth with delay in height and bone age at one year of age associated with increased subcutaneous fat and hypoglycaemia.

Congenital ACTH Deficiency

It can occur in septo-optic dysplasia. Children present with vomiting, hypoglycaemia without pigmentation and electrolyte abnormalities.

Table 1: Clinical Features of Common Hypothalamic Syndromes

System	Prader-Willi	Laurence–Moon-Biedl	Cohen	Carpenter	Alstorm
Facial	Narrow forehead, olive shaped eyes, squint, V shaped mouth, high arched palate	Squint	High nasal bridge, open mouth, short philtrum, dysplastic ears	Flat nasal bridge, acrocephaly, high arched palate	—
Skeletal	Short stature, syndactyly, scoliosis, dislocated hips	Short stature, polydactyly, clinodactyly	Short or tall stature	Polydactyly, syndactyly, genu valgum	Short stature
Neuro-muscular	Decreased IQ, hypotonia	Decreased IQ, retinitis pigmentosa	Mild mental retardation	Mild mental retardation	Normal IQ
Endocrine	Hypogonadism, diabetes mellitus, obesity	Hypogonadism, diabetes insipidus, obesity	Hypogonadism, delayed puberty, obesity	Obesity	Hypogonadism in males, obesity
Others	Hyperphagia	Renal abnormalities	—	—	—

Figures 1A and B: (A) Sagittal view T1-weighted pre-contrast MRI in 6-year old boy with central precocious puberty showing hypothalamic hamartoma (arrow); (B) Sagittal view T1-weighted contrast enhanced MRI in a 20-year boy presented with hypogonadism and delayed puberty showing nodular soft tissue component and cyst wall enhancement suggestive of craniopharyngioma (arrow).

HYPOTHALAMIC HYPOFUNCTION SYNDROMES

Kallmann's Syndrome

KAL gene normally directs migration of GnRH neurons from the olfactory placode to hypothalamus. Defective gene causes agenesis of olfactory bulb (and subsequent hypo/anosmia). The

HYPOTHALAMIC TUMOURS

Craniopharyngioma

It constitutes 3% to 5% of all intracranial neoplasms. These arise from Rathke's pouch, are cystic or partially cystic, and are usually located in suprasellar area. Most cases present in childhood with

features of raised intracranial tension, visual disturbances, short stature, delayed puberty and diabetes insipidus. Most of the adults present with visual symptoms; suprasellar calcification in curvilinear, flocculent or granular pattern may be present on skull X-ray. Computed tomography or MRI is the preferred imaging modality (**Figures 1A and B**). Treatment usually involves surgery and radiotherapy.

Hypothalamic Hamartoma

A rare benign brain tumour located near the hypothalamus. It consists of mass of neurosecretory neurons, fibre bundles and glial cells and secretes LHRH. It presents as true isosexual precocious puberty more so in boys before the age of 3 years, and can be associated with laughing seizures if the size is larger than 10 mm. MRI is the preferred imaging and appears as isodense prepontine mass without any enhancement after giving contrast (**Figures 1A and B**). Mass usually does not increase in size on long-term follow up and does not need surgical intervention. Puberty is LHRH dependent and is treated with LHRH agonists.

PINEAL GLAND

The pineal gland is a small central structure and weighs around 100 to 150 mg in humans. The main cellular component is the pinealocyte and it is richly vascularised. Its predominant innervation is sympathetic, arising from the superior cervical ganglion. In humans it gets calcified after puberty. The main function of this gland is to synthesise melatonin. Most synthetic activity occurs during the dark phase, with a major increase in the activity of serotonin-N-acetyltransferase. Melatonin has been traditionally considered to be derived principally from the pineal gland. However, several investigations have now demonstrated that melatonin synthesis occurs also in the retina of several vertebrate classes, including mammals. As in the pineal gland, melatonin synthesis in the retina is elevated at night and reduced during the day.

Physiology of Pineal Gland

Shortly after birth very little melatonin is detectable in body fluids. The melatonin rhythm appears around 6 to 8 weeks of life. The plasma concentration of melatonin increases rapidly thereafter and reaches a life-time peak on an average at 3 to 5 years age. Subsequently steady decline occurs reaching mean adult concentrations in mid to late teens with a major decline prior to puberty. Melatonin is synthesised and secreted during the dark phase of the day. The duration of secretion of melatonin correlates with duration of darkness (night). Even a brief exposure to light of sufficient intensity at night rapidly suppresses melatonin production. It is reasonable to assume that the pineal gland conveys information concerning light-dark cycles for the organisation of seasonal and circadian rhythms in humans. Circadian rhythm disturbance is associated with shift work, jet lag, blindness, insomnia and old age.

Pathology of Pineal Gland

Psychiatry

Abnormalities of circadian function have been postulated in depression and mania. There is evidence to suggest a decrease in the amplitude of melatonin in depression and increase in mania. Most pharmacological anti-depressant treatment stimulates melatonin secretion, acting through increased availability of the precursors (tryptophan and serotonin), or by direct action on serotonin and catecholamine receptors.

Pineal tumours

Pineal tumours are rare and constitute less than 1% of intracranial space-occupying lesions. These tumours originate from three different cell lines: parenchymal cells (pineoblastomas and pineocytomas); germ cells (teratomas, germinomas and mixed germ cell tumours); and supporting stroma (gliomas). The most common symptoms are secondary to hydrocephalus (headache, vomiting and drowsiness) together with visual disturbances, diabetes insipidus and reproductive abnormalities. Germinomas and teratomas occur predominantly in males. There is no consistent information on overproduction or underproduction of melatonin with specific types of tumour.

Clinical Uses of Melatonin

The established role of melatonin in humans is that of phase shifting and resetting of circadian rhythms and melatonin has been used to treat jet lag and disorders of circadian-based sleep disorders. Melatonin has also been shown to regulate sleep in humans. It also has been shown to have a hypnotic effect. It also is believed to be effective in seasonal affective disorders. Scientific evidence in favour of melatonin in sleep disorders is not strong, but the drug is safe if given for less than three months. It is available as an over-the-counter drug.

10.4 Disorders of Anterior Pituitary

RV Jayakumar

The pituitary gland consists of the anterior pituitary (adenohypophysis), posterior pituitary (neurohypophysis) and the intermediate lobe. It is located inside the sella turcica, a depression in the sphenoid bone in the base of the skull. It is related superiorly to the optic chiasma, hypothalamus and the third ventricle from which, it is separated by the diaphragma sellae, antero-inferiorly to the sphenoid sinus and laterally to the cavernous sinuses on either side. Histologically, anterior pituitary has five different hormone secreting cells. The somatotrophs (secrete growth hormone, GH), lactotrophs (secrete prolactin, PRL), thyrotrophs (secrete thyroid stimulating hormone, TSH), corticotrophs (secrete adrenocorticotropic hormone, ACTH) and gonadotrophs (secrete follicle stimulating hormone, FSH; and luteinising hormone, LH). The release of anterior pituitary hormones is under control of hypothalamic releasing hormones, which have either stimulatory or inhibitory action (**Table 1**). These hypothalamic hormones are carried to adenohypophysis through the portal venous plexus located on the median eminence. The release of hypothalamic hormones is modulated partly by neuronal and chemical inputs and partly by input from higher centres.

Table 1: Hypothalamic Control of Anterior Pituitary Hormones

Hypothalamic factor	Action	Anterior pituitary hormone
Growth hormone releasing hormone (GHRH)	Stimulatory	Growth hormone
Growth hormone releasing inhibiting hormone (GHRIH)/somatotrophin release inhibitory factor (SRIF)	Inhibitory	Growth hormone
Thyrotrophin releasing hormone (TRH)	Stimulatory	Thyroid stimulating hormone (TSH), Prolactin
Gonadotrophin releasing hormone (GnRH)	Stimulatory	Luteinising hormone (LH) Follicle stimulating hormone (FSH)
Prolactin inhibiting factor/dopamine	Inhibitory	Prolactin
Corticotrophin releasing hormone (CRH)	Stimulatory	Adrenocorticotropic hormone (ACTH)
Vasopressin	Stimulatory	ACTH

Anterior pituitary develops from the ectoderm of Rathke's pouch, an upward invagination from the roof of the embryonic stomodaeum. Many pituitary transcription factors have now been identified which temporally regulate the development of anterior pituitary cell lineages. The main factors include LHX 3, HESX 1, Prop 1 and Pit 1. Deficiency of these transcription factors can lead to congenital, isolated or combined, pituitary hormone deficiencies.

ADRENOCORTICOTROPHIC HORMONE (ACTH)

This is a 39 amino acid polypeptide derived from a precursor molecule proopiomelanocortin (POMC). The secretion of POMC is stimulated by CRH, arginine, vasopressin and stress. It is inhibited by glucocorticoids. ACTH stimulates synthesis and secretion of glucocorticoids and androgens from the adrenal cortex. The release of ACTH has a diurnal rhythm, with the highest levels recorded at around 4 am and lowest in the evening. Plasma cortisol release also responds to this rhythm accordingly. In addition to pituitary secretion, ACTH can be produced ectopically from other sources, e.g. small cell carcinoma of lung, medullary carcinoma of thyroid and carcinoid tumours.

Increased production of ACTH from a pituitary adenoma results in Cushing's disease and is the commonest cause of Cushing's syndrome (detailed in the chapter on Adrenal). Such adenomas are usually microadenomas (<10 mm) and are treated by surgical removal. Those not responding to surgery may require radiotherapy. Medical treatment with cabergoline and somatostatin analogues are sometimes beneficial for ACTH secreting pituitary adenomas

Defective production of ACTH results in secondary adrenal insufficiency with predominantly glucocorticoid deficiency in the face of normal mineralocorticoid production, because the latter is under the dominant control of the renin angiotensin system. So classic features of Addison's disease like salt wasting, hyperkalaemia and hyperpigmentation are absent. Treatment involves replacement with glucocorticoids.

THYROID STIMULATING HORMONE (TSH)

This is a glycoprotein hormone having an alpha and a beta subunit similar to other glycoprotein hormones such as FSH, LH and hCG. While the alpha subunit is common for all these hormones, the beta subunit is responsible for specific biological activity. TSH regulates thyroid hormone and release by the thyroid gland. Plasma level of thyroid hormone and TRH regulate the TSH release. It is so finely adjusted that even a slight decrease in circulating thyroid hormone increases pituitary TSH release; hence measurement of plasma TSH is the single most sensitive test to assess primary hypothyroidism.

The tumours of anterior pituitary involving TSH producing cell are extremely rare. They present with hyperthyroidism by chronically stimulating the thyroid gland (central hyperthyroidism). Serum T4 levels are high while TSH levels are inappropriately normal or marginally elevated. The characteristic feature of TSH secreting adenoma is the elevation of alpha subunit in blood. Deficiency of TSH is usually part of a plurihormonal deficiency secondary to neoplasia or vascular conditions.

GONADOTROPHINS

The gonadotrophic hormones, FSH and LH are secreted from the anterior pituitary under the stimulation of pulsatile secretion of GnRH. In males, LH acts on Leydig cells to increase synthesis and

secretion of testosterone, while in females LH activates production of oestrogens, androgens and progesterone from interstitial cells of ovary. Gametogenesis in both sexes is controlled by FSH. Both LH and FSH are under stimulatory control of hypothalamic GnRH (LHRH). In pre-pubertal period, FSH response to LHRH is greater than LH while with onset of puberty, LH response exceeds that of FSH. A decrease in testosterone in males and oestrogens in females increases LH secretion whereas damage to germ cells increase the FSH, contributed by loss of inhibin production from Sertoli cells in males. Functioning gonadotrophic adenomas producing LH and FSH are rare. In adults they usually present with features of a non-functioning pituitary mass lesion.

Patients with isolated gonadotrophin deficiency usually have hypothalamic pathology coming under the group of Kallmann's syndrome with anosmia. Isolated LH deficiency in men is a rare syndrome (fertile eunuch syndrome), in which patients lack secondary sexual characters but have normal sized testes with arrested spermatogenesis.

GROWTH HORMONE

Human growth hormone is a linear polypeptide with 191 amino acids. A significant proportion of it in the serum is bound with GH binding protein. The main biological effect of GH is promotion of linear growth in postnatal life until completion of puberty. In addition, GH, both directly and through release of IGF-1 (Insulin growth factor-1) from the liver, has anabolic effects on protein, lipid and carbohydrate metabolism. The release of GH occurs in a pulsatile fashion. Hypothalamic GHRH stimulates whereas GHIH/SRIF inhibits its release from the pituitary (**Table 2**). Circulating GH, IGF-1 and glucocorticoids also decrease its secretion. GH deficiency in children results in short stature, while that in adults has been correlated to general asthenia.

Table 2: Factors Affecting GH Release

Augment GH release	Suppress GH release
Stages III and IV NREM sleep	REM sleep
Exercise	Obesity
Stress	Emotional deprivation
GHRH	Glucocorticoids
Insulin-hypoglycaemia	Somatostatin
Arginine	Hyperglycaemia
L-Dopa	IGF-1
Clonidine	Hypothyroidism
Oestrogen	Cyproheptadine
Glucagon	

Gigantism and Acromegaly

Excess production of GH prior to closure of skeletal epiphysis leads to gigantism while in adults it causes acromegaly. In nearly 98% of such patients, excess GH release is from a pituitary somatotroph adenoma. In exceptional cases, it may be secondary to excess release of GHRH from a hypothalamic tumour or due to ectopic secretion of GHRH from a bronchial carcinoid, pancreatic islet cell tumour or phaeochromocytoma.

Clinical Features

Patients with gigantism have abnormally tall stature (**Table 3**). In acromegaly (**Figures 1 and 2**), there is acral (hand and feet)

Table 3: Causes of Tall Stature

Gigantism
Marfan's syndrome
Hyperthyroidism in childhood
Homocystinuria
Cerebral gigantism
Sexual precocity

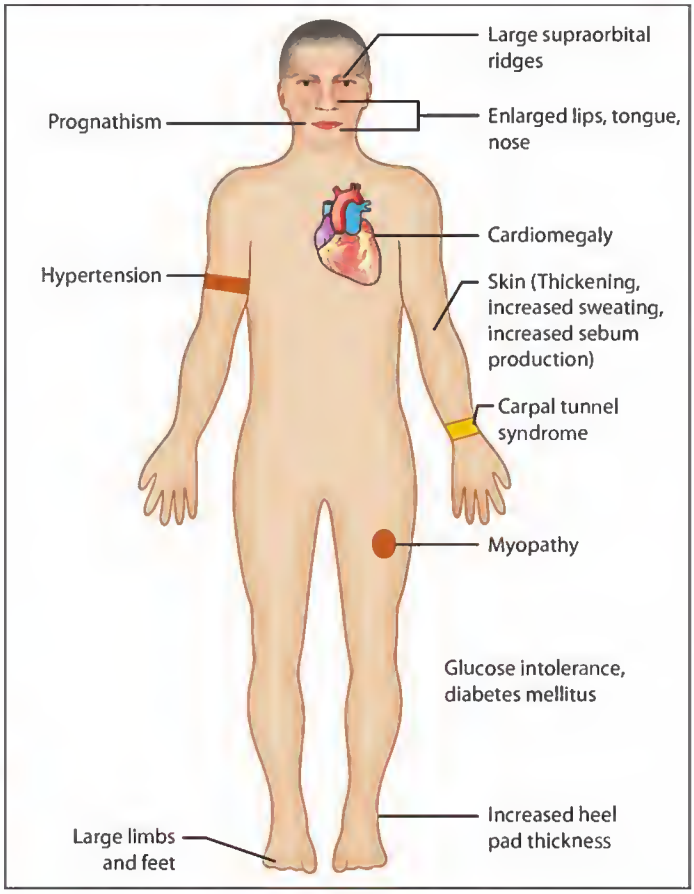

Figure 1: Clinical features of acromegaly.

Figure 2: Broad hands in acromegaly.

and soft tissue enlargement leading to facial disfigurement (bulbous nose, prominent supra-orbital ridge, prognathism, thick lips, malocclusion and splaying of teeth causing difficulty in biting food and macroglossia). There may be cutaneous gyratus on the scalp and thick heel pad.

Other cutaneous manifestations include thick skin, prominent palmar creases, forehead furrows, increase in skin tags, acanthosis nigricans, hirsutism, acne, increased sweating and malodourous sebum secretion. Patients may notice increase in size of ring, shoes and hat. Enlargement of visceral organs like liver, spleen, heart and thyroid are common, but this may not always be clinically apparent. Enlargement of larynx and paranasal sinuses lead to thick sonorous voice. Cardiovascular diseases like cardiomyopathy, hypertension and congestive heart failure are the major cause for excess mortality in these patients. Respiratory disturbances including central and obstructive sleep apnoea are common. Synovial oedema often leads to entrapment neuropathies like carpal/tarsal tunnel syndrome. Arthralgia, degenerative arthritis and hyperextensibility of joints are common and are directly related to the severity and duration of GH excess. An excess cancer risk, putatively mediated through IGF-1 excess, has been suggested, but the issue is far from settled. In view of this, close follow-up including surveillance for colonic polyps is indicated in patients with acromegaly. Rarely, some patients may have galactorrhoea with or without associated hyperprolactinaemia. Enlarging pituitary macroadenoma may cause bitemporal headache, visual field defect (bitemporal hemianopia) and signs of raised intracranial tension. In 15% to 25% of patients there may be impaired glucose tolerance or frank diabetes mellitus.

Diagnosis

The diagnosis of acromegaly can be made on the basis of the characteristic clinical appearance. However, as the changes may be subtle and slowly progressive, diagnosis is often delayed for more than 10 years from onset of the disease and serial photographs provide a good evidence for clinical diagnosis.

For GH secretory status, failure of GH suppression after an oral glucose load is considered diagnostic. In normal subjects, GH levels after glucose load fall to <1 ng/mL, whereas in acromegaly, GH levels remain unsuppressed. Serum IGF-1 levels are also elevated and can be used in the diagnosis, but more importantly in the follow-up of acromegaly. Nearly 30% of patients may have associated hyperprolactinaemia, while secretion of other pituitary hormones such as gonadotrophins, TSH and ACTH may be decreased.

MRI, with gadolinium enhancement, is the gold standard for detecting a pituitary somatotroph adenoma (**Figure 3**); imaging of chest and abdomen for ectopic production of GHRH or GH is rarely required. Radiological studies of skull reveals thickness of calvarium, enlarged air sinuses and mastoid air cells, sellar enlargement (deep and wide sella, occasionally having double floor) and nuchal ligament calcification. X-ray hand shows tufting of terminal phalanx with soft tissue swelling whereas X-ray foot reveals heel paid thickness (>20 mm). X-ray spine may show scoliosis with calcification of spinal ligament. Rarely acromegaly occurs as part of familial syndromes like MEN 1 (parathyroid adenoma and pancreatic tumours) or Carney's complex or McCune Albright syndrome.

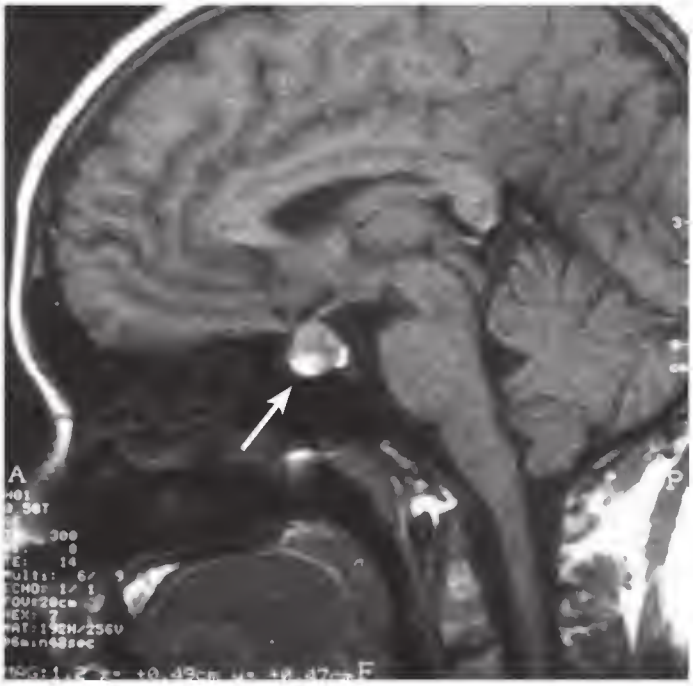

Figure 3: MRI scan showing pituitary GH secreting microadenoma.

Prognosis

The mortality in acromegaly is about four times greater than in general population. The high mortality is due to cardiovascular, cerebrovascular, pulmonary and neoplastic disorders. The post treatment GH level is the significant determinant of mortality in patients with acromegaly.

Treatment

Treatment of acromegaly should aim to normalise GH and IGF-1 levels, remove tumour mass effect and preserve normal pituitary function. The general consensus about the criteria for cure is to achieve a mean growth hormone level of less than 2.5 ng/mL and a glucose suppressed GH <1 ng/mL, with a normal IGF-1 which is associated with survival rates equal to those of general population. Trans-sphenoidal surgery, pharmacological therapy and various forms of radiation therapy are used to treat GH secreting adenomas.

Surgery

Trans-sphenoidal surgery for the pituitary adenoma is the accepted first line therapy in patients with a somatotroph adenoma. Surgery alleviates acromegalic symptoms, removes the tumour mass, relieves optic tract pressure effects and regularises GH level in about 70% of patients. The most important determinant of a successful surgical outcome is the experience of the surgeon. Better results are obtained in microadenomas (90%) while less than 50% of macroadenomas respond to surgery alone.

Radiotherapy

Pituitary irradiation is a mode of therapy for pituitary adenomas but the slow biochemical response rate of 20% cure in 10 years time, qualifies it as a follow-up therapy after inadequate surgical removal rather than as a primary form of treatment. External

radiotherapy aims to give 4500-5000 rads to the pituitary gland, Proton beam therapy, giving heavy particle pituitary radiation, achieves higher cure rates. Stereotactic ablation of GH secreting adenoma by gamma knife radiosurgery or linear accelerator are newer forms of treatment for acromegaly. However, these are available only in few centres and the initial long-term results are favourable.

Treatment

Somatostatin analogues constitute the main medical modality of treatment for acromegaly. They mainly bind to somatostatin receptor subtypes 2 and 5 (SSTR2 and 5) expressed on somatotrophs and inhibit secretion of GH 45 times more potently than endogenous somatostatin. Previously, octreotide a synthetic analogue of somatostatin used to be given as subcutaneous injection in doses of 50 to 200 mcg, eight hourly to normalise GH; GH is normalised in more than 70% of patients by this drug. Presently, several long acting preparations of somatostatin analogues are available for treatment and their long-term efficacy is also well established. The commonly used drugs are octreotide LAR and lanreotide. A monthly injection of 20 mg octreotide LAR or a fortnightly injection of 30 mg Lanreotide will effect persistent suppression of GH in more than 60% to 70% of acromegalic patients. These agents are relatively safe, side effects being transient gastrointestinal symptoms and increased incidence of gall stones. Recently, the new somatostatin analogue SOM 230 (Pasreotide) which acts on more types of somatostatin receptors has been found to be useful in tumours unresponsive to the conventional somatostatins. Because of their cost, in the Indian scenario, these somatostatin analogues are used while waiting for the radiotherapy to be effective or after insufficient surgical removal of pituitary adenoma, even though primary medical treatment with these agents are becoming common in the West. Dopamine agonists like bromocriptine have been used for several years to reduce GH levels. However, GH normalisation occurred in less than 15% patients on a dose of 10 to 30 mg per day in divided doses. Cabergoline, a long acting dopamine agonist, is also used at a dose of 0.5 mg daily but the long-term efficacy is the same as that of bromocriptine.

Another form of medical treatment of acromegaly is the use of growth hormone receptor antagonist called pegvisomant which antagonises the action of GH on GH receptor and decrease the IGF-1 levels. This agent has no effect on tumour size, and may even be associated with an increase in size.

PROLACTIN

Prolactin is a single chain 198 amino acid polypeptide, which is essential for production of milk from the mammary gland in lactation and pregnancy. It is mainly under the inhibitory control of PIF, which is dopamine. The major stimulus for prolactin secretion is suckling, but its level can go up with stress, sleep and hypoglycaemia. Administration of oestrogens, phenothiazines and TRH increases its serum levels. Excess circulating prolactin in females results in amenorrhoea-galactorrhoea syndrome, while in men it manifests as loss of libido and sexual dysfunction. Its deficiency is not symptomatic in males and non-lactating women, whereas in post-partum period and in lactating women its deficiency produces absence of lactation.

Hyperprolactinaemia and Prolactinomas

Persistent elevation of serum prolactin level in the absence of pregnancy and lactation indicates hypothalamo-pituitary dysfunction. The elevation of prolactin may be physiological, pathological or secondary to drug therapy (**Table 4**).

The hyperprolactinaemic syndrome is commoner in women, which may be explained by their exposure to oestrogen. Prolactinomas are a frequent cause of organic hyperprolactinaemia, and they form about 40% to 50% of all pituitary adenomas. About 65% to 70% of prolactinomas are microadenomas (<10 mm in size) which are frequently present in females whereas macroadenomas (>10 mm in size) are seen with equal frequency in both the sexes.

Table 4: Causes of Hyperprolactinaemia

Physiological	Pathological
Sleep, stress, pregnancy and nursing	Hypothalamo-pituitary tumours, inflammatory and granulomatous diseases
Pharmacological	Pituitary stalk lesions prolactinomas
Dopamine receptor blockers, phenothiazines, haloperidol, metoclopramide, domperidone	Plurihormonal adenomas empty sella
Dopamine synthesis inhibitor methyl dopa	Primary hypothyroidism Polycystic ovarian syndrome
Catecholamine depletors, reserpine	Chronic kidney disease Liver cirrhosis Idiopathic
Ranitidine,cimetidine, fluoxetine, amitriptyline, oestrogens	

Clinical Manifestations

The frequent clinical presentations of hyperprolactinaemia in women are amenorrhoea, galactorrhoea and infertility. The alteration of menstrual cycle may vary from oligomenorrhoea to amenorrhoea, and rarely no menstrual dysfunction may be seen. Galactorrhoea, occurs in about 60% to 80% of hyperprolactinaemic women and may be the only finding in a patient presenting with infertility. Seborrhoea and moderate hirsutism may be present due to increased adrenal androgen production. In men with hyperprolactinaemia, the common presenting complaints are progressive loss of libido and sexual potency. Galactorrhoea or gynaecomastia are present in 15% to 25% of patients. Fluid retention with increase in body weight is seen in both sexes. Headache is present in patients with both micro- and macroadenomas and has no correlation with the size of adenoma. Defects in visual fields and hypopituitarism can occur in macroadenomas.

Diagnosis

Diagnosis of hyperprolactinaemia is confirmed by measuring basal levels of prolactin from multiple pooled samples. Sometimes, a high prolactin level may be revealed only by doing the test in dilution (Hook effect) and conversely prolactin levels may be falsely elevated by the presence of biologically inactive prolactin called macroprolactin. Thyroid function tests should be done in all cases of hyperprolactinaemia as primary hypothyroidism can cause elevation of PRL, mediated by the high TRH levels. In all cases of macroprolactinomas other

pituitary hormones should be carefully evaluated to assess accompanying deficits. A prolactin of >100 ng/mL in a non-pregnant woman is generally due to a pituitary adenoma. Imaging of the hypothalmo-pituitary area is very important in such situations, with contrast enhanced dynamic MRI being the preferred method. Using high resolution scans, microadenomas as small as 2 to 3 mm can be detected.

Treatment

The aim of treating hyperprolactinaemia is to normalise prolactin level, relieve symptoms and shrink the tumour. In this regard, the efficacy of dopaminergic drugs is well established and it is accepted as the first-line therapy with prolactinomas. Other treatment modalities available are pituitary surgery and radiation. Pituitary surgery is indicated mainly for those who are intolerant and resistant to dopamine-agonists, and for those macroprolactinomas that do not shrink adequately with medical therapy.

The most extensively used dopamine agonists are ergot derivatives bromocriptine and cabergoline. These drugs should be started in low doses (e.g. 1.25 mg at night for bromocriptine and 0.5 mg cabergoline once a week) and slowly increased in step-wise manner. The usual dose of bromocriptine is 2.5 mg to 20 mg per day in two or more divided doses. It causes reduction of prolactin level to normal in 60% to 100% cases. Clinical symptoms are relieved in 1 to 3 months, and tumour shrinkage occurs in 70% to 90% cases. Cabergoline is a long acting ergot derivative and at a dose of 0.5 mg to 1 mg, prolactin levels are suppressed for 7 to 14 days; hence weekly dose is sufficient. Once prolactin levels are normalised and sexual functions have improved and tumour has reduced in size, the dose of dopamine agonists can be reduced and a supervised trial off therapy can be given especially in microprolactinomas.

The common adverse effects of dopamine agonists are nausea and postural hypotension which can be circumvented by starting the drug at a smaller dose given at night after meals. It can also exacerbate underlying psychosis. Other rare but serious side effects are hepatic dysfunction, CSF rhinorrhoea, cardiac arrhythmias and valvular stenosis. During pregnancy, prolactinomas can enlarge and cause visual impairment. This is more common in macro- than microprolactinomas. Hence, dopamine agonists are discontinued when a lady with microprolactinoma conceives, and they are closely monitored for headache and signs of visual field defects. Macro-prolactinomas may need treatment during pregnancy. Bromocriptine has been the most widely used dopamine agonist in pregnancy with no reported adverse effects on the mother and baby; cabergoline also appears safe in pregnancy even though experience with its use in pregnancy is limited.

PITUITARY INSUFFICIENCY (HYPOPITUITARISM)

This is a clinical condition characterised by deficiency of one or more of the pituitary hormones. While selective deficiency of one or two hormones is either congenital or idiopathic, multiple hormone deficiencies usually result from tumours or destructive lesions. Causes of hypopituitarism are varied (**Table 5**). Common causes include non-hormone secreting pituitary tumours, pituitary surgery and cranial iradiation.

Table 5: Aetiology of Hypopituitarism

Pituitary and para-pituitary tumours; craniopharyngioma and chromophobe adenoma
Radiotherapy
Surgery
Trauma: Skull fracture and perinatal
Vascular: Apoplexy, Sheehan's syndrome, post-snake bite, sickle cell disease
Infiltration: Sarcoidosis, histiocytosis, haemochromatosis
Lymphocytic hypophysitis
Infection: Basal meningitis and encephalitis
Congenital and genetic disorders: Pit 1, Prop1, HESX 1, LHX 3 mutations
idiopathic

Clinical Features

Clinical features of hypopituitarism depend on the type (single or plurihormonal) and extent of hormone deficiency, speed of onset and local pressure effects of the pituitary lesion. The clinical features of pituitary mass lesions include bi-temporal headache, visual field defect (bi-temporal hemianopia), features of raised intracranial pressure, rarely cranial nerve palsies, CSF rhinorrhoea (when the mass erodes the sellar floor), temporal lobe epilepsy and hypothalamic features. In slowly progressive pituitary lesions like that following radiation or vascular insult, e.g. Sheehan's syndrome or post-snake bite hypopituitarism, a characteristic pattern is present. Secretion of growth hormone fails first, followed by gonadotropins, TSH and lastly, ACTH. Prolactin deficiency is rare, except in Sheehan's syndrome. Generally, hyperprolactinaemia is the rule. This may be due to release of lactotrophs from the tonic inhibition of dopamine or due to secretion from a prolactinoma. Diabetes insipidus is not a feature of anterior pituitary disease; its presence denotes hypothalamic or stalk lesion. The clinical features of individual hormone deficiencies are given in **Table 6**.

Table 6: Clinical Features of Hormone Deficiency

Hormone	Age group	Manifestations
Growth hormone	In children	Short stature
	In adults	Abnormal body composition, reduced sense of well being and performance, low bone mass
Gonadotropins	In males	Poor libido, impotence, reduced facial hair, atrophic testes, infertility
	In females	Amenorrhoea, infertility, breast atrophy
TSH	In children	Growth retardation, dry skin, constipation
	In adults	Myxoedema, slow relaxation of deep tendon reflexes
ACTH		Weakness, tiredness, postural hypotension and giddiness, pallor and hypoglycaemia
Prolactin		Lactation failure

For diagnosis of pituitary failure, clinical examination is important. In children, documentation of height, weight and pubertal status are necessary. Blood pressure should be checked

for postural drop and visual fields documented by perimetry. It is a good guide to suspect pituitary deficiency in the following situations: post-partum failure of lactation, hyperinvolution of uterus, and involution of breast; sparse pubic and axillary hair, in patients with unexplained amenorrhoea, features of ACTH or TSH deficiency and raised intracranial pressure; women with unexplained anaemia and asthenia; males with decreased libido and sexual potency.

Diagnosis

The diagnosis of hypopituitarism is based on endocrine tests ranging from measuring basal levels of all hormones, to stimulatory tests of individual hormones. Insulin tolerance test is the gold standard to assess the pituitary GH and ACTH reserve. LHRH and TRH tests are done to assess the reserve of gonadotropins and TSH, respectively. MRI of the hypothalamo-pituitary area should be done to look for structural lesions. Congenital mutations in pituitary transcription factors can be associated with small anterior pituitary, absent stalk and an ectopic posterior pituitary bright spot.

Treatment

The treatment of hypopituitarism includes therapies directed at the underlying disease process and hormone replacement therapy (**Table 7**) which should aim at improving symptoms, while avoiding over-treatment and should mimic the normal hormonal milieu as far as possible. Replacement is usually given with the target hormones rather than pituitary hormones.

Table 7: Endocrine Replacement Therapy for Hypopituitarism

Hormone deficiency	Replacement	Dose
Growth hormone	Growth hormone	0.25 to 0.7 mg/d S/C
Gonadotrophin	Women	
	Oestradiol valerate	1 to 2 mg/d
	Conjugated oestrogens/	0.625 to 1.2 mg/day
	Ethinyl oestradiol	20 to 30 mcg/day
	Progesterone	Cyclical therapy
	Men	
	Testosterone enanthate or propionate	250 mg every 3 weeks IM
TSH	L-thyroxine	50 to 200 µg/d oral
ACTH	Hydrocortisone	15 to 20 mg/d oral
Prolactin	None	None

In combined deficiency of TSH and ACTH, steroid replacement should always precede thyroid replacement. In patients on steroid replacement therapy the importance of increasing the dose of steroid during stress should be emphasised. Acute adrenal crisis will require parenteral steroids. Replacement of growth hormone in AGHD (adult growth hormone deficiency) is known to improve lean body mass and bone mass and improve cardiovascular risk. In hypogonadal patients desirous of fertility, treatment with gonadotropins (recombinant HCG and FSH) are indicated. There is now evidence that hypopituitarism is associated with excessive mortality as compared to normal population. It is possible that with proper hormone replacement therapy, this mortality can be reduced. Lastly, as hypopituitarism requires complex drug regimens, every effort should be made to prevent its occurrence by avoiding unnecessary and extensive radiation or surgical therapy.

NELSON'S SYNDROME

This entity results from an aggressive ACTH producing adenoma in a patient who has undergone bilateral adrenalectomy for Cushing's syndrome. These patients present with headache, visual field defects and external ophthalmoplegia, all suggestive of pituitary mass lesion. The high circulating ACTH levels produce hyperpigmentation due to its MSH-like action. This condition represents enhancement of tumour growth, by removal of negative feedback of high cortisol secretion from adrenal gland. This is shown to be preventable by external pituitary irradiation in some patients. Once established, transsphenoidal decompression and radiotherapy are the modalities of treatment. In order to identify Nelson's syndrome early, periodic pituitary imaging is recommended in all patients who have undergone bilateral adrenalectomy for Cushing's syndrome.

PITUITARY APOPLEXY

This is a life-threatening clinical situation arising from acute infarction of the pituitary gland. A haemorrhagic infarction usually arises in the presence of pituitary tumour, while ischaemic infarction can occur in normal gland following obstetric haemorrhage or anticoagulant therapy. This usually causes anterior pituitary hypofunction, which can be permanent or transient. The degree of hypopituitarism depends on the extent of pituitary destruction. Clinically, pituitary apoplexy presents with severe headache, sudden change of sensorium, ophthalmoplegia, visual loss and prostration. Once suspected, it should be treated immediately with glucocorticoid supplementation and other supportive measures to reduce pressure effects. Deterioration in sensorium and visual impairment are indications for surgical decompression.

CRANIOPHARYNGIOMAS

These tumours, which are often cystic, arise from the Rathke's pouch remnants. They constitute 3% to 5% of intracranial tumours and majority are diagnosed when children present with growth failure or sexual infantilism. There may be associated diabetes insipidus. The treatment of choice is surgery followed by radiation.

EMPTY SELLA SYNDROME

This is a clinical condition similar to a pituitary tumour, and occurs when a defect in the diaphragma sellae results in subarachnoid space herniation into the sellar space. Pressure on the bony walls of the sella causes subsequent remodeling, sellar enlargement and flattening of the pituitary gland. Though the exact pathogenesis remains unclear, raised intracranial pressure in a subject with a diaphragmatic defect is thought to predispose to the empty sella syndrome. This is frequently detected when a patient with obesity and headache is investigated by pituitary imaging (**Figure 4**). Though clinically uncommon, this is seen in 20% of women at autopsy. It can cause diagnostic difficulty when it mimics the radiological appearance of a pituitary tumour. Treatment is

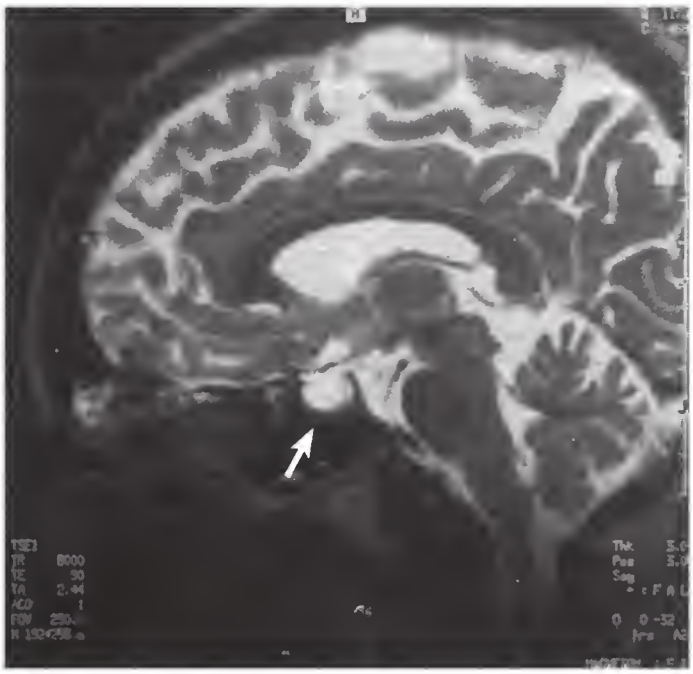

Figure 4: Sagittal view MRI showing empty sella (white arrow).

symptomatic for primary empty sella, and those with a secondary cause should receive appropriate therapy of the underlying disease process.

LYMPHOCYTIC HYPOPHYSITIS

This occurs usually in the post-partum period and patients present with headache, visual disturbance, hyperprolactinaemia, diabetes insipidus or hypopituitarism. It is thought to be autoimmune in origin and it is difficult to differentiate it from pituitary adenoma. Patients may have antipituitary antibodies and other organ and non-organ specific autoantibodies. Treatment is with steroids and surgery is usually not necessary except for a tissue diagnosis. It may remit spontaneously also.

10.5 Disorders of Posterior Pituitary

GR Sridhar

The posterior pituitary develops from neural ectoderm of the forebrain and secretes the hormones vasopressin and oxytocin. Vasopressin or anti-diuretic hormone (ADH) is produced by hypothalamic supraoptic nucleus and *oxytocin* by paraventricular nucleus. They traverse with neurophysins to posterior pituitary, from where they directly enter systemic circulation. ADH regulates water balance in the kidney. It is released in late sleep to prevent dehydration and enuresis. Oxytocin primarily affects uterine contraction and post-partum milk ejection, although it could influence cognition.

DISORDERS OF POSTERIOR PITUITARY

ADH deficiency (impaired production or end organ resistance) leads to diabetes insipidus. Inappropriate secretion causes SIADH (syndrome of inappropriate ADH).

DIABETES INSIPIDUS (DI)

Epidemiology and Clinical Features

Diabetes insipidus is uncommon (3:100,000 general population) but, when it occurs, must be identified and promptly corrected. It presents as polyuria (>3 litres of urine daily of dilute urine), leading to thirst that may disturb sleep. It can occur at any age and in both sexes. Its occurrence in adults depends on the aetiology; it often occurs as a result of pathological insults to the hypothalamic-pituitary axis. In children, organic central DI should be suspected in children presenting after the age of five years, and with features of anterior pituitary insufficiency, such as growth retardation.

Urine specific gravity (SG) is <1.010 and serum sodium exceeds 145 mEq/L. Polyuria may be less severe when ADH deficiency is partial or when other endocrine diseases coexist, such as hypothyroidism or Addison's disease.

Aetiology

DI may result from deficient ADH production from the hypothalamus-pituitary (central DI) or from renal end-organ resistance to ADH action (nephrogenic DI) (**Table 1**).

Hereditary DI results from mutations of genes: arginine vasopressin gene, arginine vasopressin receptor gene, and vasopressin sensitive water channel gene.

Clinical Features

Polyuria, depends on the degree of ADH deficiency. Daily urine volume may vary from a few litres to nearly 18 litres. Nocturia is invariable, unlike in primary polydipsia.

If water is denied, hypertonia leads to irritability, fever, mental dullness, prostration and death. If DI is due to primary pituitary lesion, neurological abnormalities coexist. Children may present with poor feeding, failure to thrive and irritability.

Post pituitary-surgery DI is often transient. When permanent, persistent polyuria begins about 10 to 14 days postoperatively.

Table 1: Causes of Diabetes Insipidus (DI)

- **Central DI**
  - Tumours of hypothalamo-pituitary region
    - Craniopharyngioma
    - Suprasellar extension of pituitary tumours
    - Germinoma

    - Metastasis
  - Infiltrative lesions
    - Sarcoidosis
    - Histiocytosis X
    - Tuberculosis
    - Leukaemias
  - Pituitary or hypothalamic surgery
  - Severe head injury (stalk section)
  - Ruptured cerebral aneurysm
  - Idiopathic
  - Familial
- **Nephrogenic DI**
  - Congenital or familial
  - Acquired
    - Chronic renal diseases
    - Acute tubular necrosis
    - Primary aldosteronism
    - Chronic hypercalcaemia
    - Drug-induced (lithium, demeclocycline)

Modalities of Diagnosis

Firstly polyuria (>3 L/d) should be demonstrated by measuring 24 hours fluid intake and urine output. In diabetes insipidus hypertonicity occurs if water loss cannot be corrected by fluid ingestion. In the presence of polyuria, hypertonicity and the absence of other causes of polyuria, the diagnosis of diabetes insipidus can be made. In the face of unambiguous features, water deprivation may not be performed. Further investigations may be needed to differentiate DI from primary polydipsia, identify partial forms of DI and to evaluate for the cause of DI.

Water deprivation test

This test, done under supervision, is started early in daytime; the earlier the better. The subject is weighed, 97% baseline weight calculated and noted prominently, for termination if this is reached during the test. In those who are already on replacement with desmopressin, it must be stopped 24 hours earlier, while steroids (for other indications, e.g. hypopituitarism are not stopped).

Fluid is withheld until one of the following occurs: orthostatic hypotension and postural tachycardia appear, $\geq$ 5% of the initial body weight has been lost, or the urinary concentration does not increase >0.001 SG or >30 mOsm/L. Serum osmolality is determined and 5 units of aqueous vasopressin injected SC. Urine for SG or osmolality measurement is collected 60 min after the injection before allowing fluids to be ingested.

A normal response produces maximum urine osmolality after dehydration (often >1.020 SG or >700 mOsm/L), exceeding the plasma osmolality; osmolality does not increase more than an additional 5% after injection of vasopressin.

Interpretation

A plasma osmolality of more than 288 mOsmol/kg before vasopressin injection denotes sufficient dehydration. In a normal person, vasopressin results in <9% rise of urine osmolality, in contrast to central DI, where the rise is more than 9%. Nephrogenic DI shows little change in urine osmolality with dehydration and little further increase with vasopressin. Psychogenic polydipsia requires prolonged fluid deprivation before plasma osmolality reaches 288 mOsm/kg; though vasopressin results in less than 9% increase.

Differential Diagnosis

In primary polydipsia, rather than nocturia, modest daytime polyuria occurs; acquired nephrogenic DI has less polyuria compared to primary nephrogenic DI or central DI. Hypernatraemia with normal serum creatinine and low urine sodium with polyuria suggests water diuresis (e.g. DI) than osmotic diuresis. On MRI a 'bright spot' is shown by normal posterior pituitary; it is absent in central DI, although some 'normal individuals', i.e. without diabetes insipidus could also have absent bright spot. Coexistence of DI with pituitary mass suggests the mass is likely malignant or infiltrative.

Management, Course and Prognosis

Central DI is treated by desmopressin, a long acting vasopressin analogue. Ambulatory replacement is started with intranasal administration (5 to 10 µg) at bedtime, and the dose titrated by control of nocturia. Oral desmopressin preparations are available; although there is no single fixed dose, it can be started at one oral tablet of DDAVP (0.1 mg) per 8 hours. The antidiuretic dose-equivalence ratio for intranasal to oral desmopressin is 1:18.

An intact thirst mechanism is an important defense against complications. When unconscious (e.g. postoperative period, following head injury), 1 µg of DDAVP is injected; although some if residual vasopressin exists, potentiators such as chlorpropamide (100 to 500 mg/d), clofibrate (500 mg 6 hourly) or carbamazepine (400 to 600 mg/d) are used. Carbamazepine and vasopressin are best not used together.

Annual follow-up is necessary. DI should not be considered idiopathic till four years later.

Nephrogenic DI is treated with thiazide diuretics (hydrochlorothiazide 25 to 50 mg/d) and low salt intake. Thiazide diuretics impair sodium chloride co-transporter in renal distal convoluted tubule. Increased renal sodium excretion causes antidiuretic effect. Rarely, indomethacin or high dose vasopressin may be needed.

Rarely when diabetes mellitus and diabetes insipidus coexist, the latter can be suspected by the low specific gravity in an individual with diabetes mellitus.

SYNDROME OF INAPPROPRIATE ADH SECRETION (SIADH)

In SIADH, hyponatraemia occurs due to excess water relative to solute. There is no oedema. Causes are listed in **Table 2**. Clinical features are due to hyponatraemia: anorexia, nausea, vomiting, cramps, weakness and coma. SIADH is diagnosed by hypotonic hyponatraemia, urine osmolality >100 to 150 mmol/kg, without extracellular depletion. Systemic conditions such as dysfunction of thyroid, adrenal, heart, liver and kidney, head injury, malignancy or lung infection should be excluded.

Table 2: Causes of SIADH

Pulmonary disorders
Pneumonia
Tuberculosis
Lung abscess
Pneumothorax
Positive pressure ventilation
Bronchogenic carcinoma
CNS disorders
Encephalitis, meningitis, brain abscess
Vascular injury
Trauma
Guillain-Barré syndrome
Brain tumours
Endocrine disorders
Myxoedema
Adrenal insufficiency
Anterior pituitary insufficiency
Ectopic ADH production
Drugs
Stimulation of ADH release (clofibrate, vincristine, cyclophosphamide)
Enhancement of ADH action (chlorpromazine)
Unknown (morphine, carbimazine)

It is treated by correcting the cause and depends on the severity: restriction of free water by 500 to 1000 ml/d may only be needed. Demeclocycline (600 to 1200 mg/d) is needed uncommonly.

OXYTOCIN

The other posterior pituitary hormone, oxytocin, has two actions: it contracts uterine myometrium, and stimulates breast milk ejection. It also affects social and emotional bonding. There is no clinical condition of excess oxytocin.

RECENT ADVANCES

Vasopressin is also used in treatment of cardiac arrest and in vasodilatory shock. Newly developed vasopressin antagonists are useful in treating hyponatraemia of heart failure. Oxytocin use may improve communication in autism. Potential roles for oxytocin are being studied as a regulator of bone mass.

10.6 Disorders of Thyroid Glands

Nikhil Tandon, Gunjan Garg

STRUCTURAL EMBRYOLOGY

Thyroid tissue is present in all vertebrates, and is first recognised in humans about 1 month after conception. The primordium begins as thickening of epithelium in the pharyngeal floor. This forms a diverticulum which later is displaced caudad assuming a bi-lobate shape. It remains attached to pharyngeal floor by the thyroglossal duct, the lower portion of which differentiates into pyramidal lobe of the gland. Rest of the thyroglossal duct undergoes dissolution and fragmentation by about second month of conception, leaving behind a small depression at the junction of the middle and posterior thirds of the tongue (foramen caecum). Persistence of this duct can form thyroglossal cyst. About 10% of the thyroid, the parafollicular or C cells, develops from the ultimobranchial bodies originating from 4th and 5th pharyngeal pouches. A number of proteins are known to be crucial for normal thyroid gland development. These include the thyroid-specific transcription factor PAX8, as well as thyroid transcription factors 1 and 2 (TTF1 and 2).

FUNCTIONAL ONTOGENY

Thyroid follicular cells acquire capacity to form thyroglobulin (Tg) by 29th day of gestation, while the ability to concentrate iodine and initiation of hormonogenesis occurs by the 11th week of gestation. Thyroxine-binding globulin (TBG) is detectable in serum by 10th gestational week and increases subsequently, enabling a progressive increase in circulating thyroid hormone levels to term.

ANATOMY AND HISTOLOGY

The thyroid is one of the largest of endocrine organs, weighing about 15 to 20 gm in adults, with each lobe being approximately 4 cm (height) × 2 cm (width) × 2 to 2.5 cm (thickness). The two lobes are connected by the isthmus, which is approximately 2 cm in height and width, and 0.5 cm in thickness. The gland is supplied by the superior and inferior thyroid arteries. The gland is formed of follicles, which are filled with colloid. From the apex of follicular cells, numerous microvilli extend into colloid. It is at or near this surface of the cell that iodination, exocytosis and the initial phase of hormone secretion occur. Colloid contains Tg molecules in which thyroid hormones are present. The lining cells of the follicle are cuboidal in the inactive phase and columnar in the active phase. About 20 to 40 follicles are grouped to form a lobule, which is demarcated by connective tissue septa and supplied by a single artery. The parafollicular cells (C cells) secrete calcitonin, which participates in calcium metabolism.

SYNTHESIS AND SECRETION OF THYROID HORMONES

The thyroid secretes two iodine containing hormones, tetraiodothyronine (T_4) and triiodothyronine (T_3). Active uptake of iodine by the follicular cell, against a concentration gradient, is mediated by the NaI symporter (NIS), which is expressed at the basolateral margin of the cell. NIS enables the entry of one iodine atom against the downhill transport of two Na atoms. The NIS also transports TcO_4^-, ClO_4^-, and SCN^-, which has allowed these agents to be used for thyroid scanning and blocking iodine uptake. The NIS is also present in non-thyroidal tissues e.g. breast, salivary gland. Another protein involved in iodine transport is pendrin, which is a product of the PDS gene. Mutation in NIS and PDS genes are associated with congenital hypothyroidism.

After uptake, iodine is oxidised by the enzyme thyroid peroxidase (TPO), followed by iodination of tyrosine molecules in Tg, a process called organification. TPO is now recognised to be the major component of what was previously called thyroid microsomal antigen. Monoiodotyrosine (MIT) and diiodotyrosine (DIT) are then coupled in varying proportion to form T_3 and T_4, a reaction also catalysed by TPO. There are 3 to 4 T_4 molecules on each molecule of Tg, while only 20% of Tg molecules contain T_3. Tg is then processed in lysosomes to release T_4 and T_3 in circulation, while the uncoupled MIT and DIT are deiodinated by dehalogenase thereby recycling iodine. The thyroid gland contains enough stored hormone to maintain a euthyroid state for at least 6 to 8 weeks.

REGULATION OF THYROID HORMONE SECRETION

Thyroid stimulating hormone or thyrotrophin (TSH), released from the anterior pituitary, stimulates all steps in the formation and release of thyroid hormones, and the conversion of T_4 to T_3. TSH itself is under the positive regulation of the hypothalamic tripeptide, thyrotropin releasing hormone (TRH). Somatostatin, glucocorticoids, cytokines such as IL-1 and TNF-α, phenytoin and dopamine suppress TSH secretion. In turn, TSH and TRH secretion is inhibited by T_4, forming a negative feedback loop that keeps free T_4 levels within a narrow range.

While T_4 is solely secreted directly by the thyroid, about 80% of T_3, which is the active hormone, is generated by 5' monodeiodination of T_4. T_4 to T_3 conversion is impaired by fasting, systemic illness or acute trauma, oral contrast agents and variety of medications (e.g. propylthiouracil (PTU), propranolol, amiodarone, glucocorticoids).

THYROID HORMONE TRANSPORT AND ACTION

Thyroid hormone exists in circulation in both free and bound form. About 75% to 80% of thyroid hormone is bound to thyroxine binding globulin (TBG). Other proteins to which thyroid hormone is bound are transthyretin (TTR), and albumin. Only the free-fraction enters cells and produces biological effect by binding to a nuclear DNA bound thyroid hormone receptor (TR), for which T_3 has a 15-fold higher binding affinity than T4. There are two TR genes, TRα and TRβ. The coded protein has three major functional domains, one to bind ligand, one to bind DNA, and the other for transcriptional activation.

Resistance to thyroid hormones (RTHs) occurs because of mutation in TRβ gene. Patients with RTH may have features of

hypothyroidism if resistance is severe and generalised, while in some instances they may have features of hyperthyroidism if resistance is predominantly in the hypothalamic-pituitary axis and not in peripheral tissues. Treatment is difficult and is directed towards suppression of TSH using thyroid hormone analogues such as TRIAC (3, 5, 3' triiodo-thyroacetic acid).

CLINICAL EVALUATION

History and physical examination should be tailored to evaluate for presence of a thyroidal enlargement: size, shape, symmetry, nodularity, consistency, associated lymphadenopathy, fixity, retrosternal extension, and auscultation for a bruit; presence of the features of hypothyroidism or hyperthyroidism. In case of Graves' disease, associated features of thyroid associated ophthalmopathy and infiltrative dermopathy must also be sought.

During clinical examination the exact dimensions of the thyroid gland can be documented, while in epidemiological studies goitre can be graded as follows:

Grade 0: No visual or palpable goitre.

Grade 1: A goitre that is palpable, but not visible when the neck is in the normal position. Thyroid nodules in a thyroid which is otherwise not enlarged are included in grade 1.

Grade 2: A swelling in the neck that is clearly visible when the neck is in normal position and is consistent with an enlarged thyroid when the neck is palpated.

Goitre is said to be present when each lateral lobe has a volume greater than the terminal phalanx of the thumb of the subject being examined.

IODINE DEFICIENCY DISORDERS (IDDs)

Iodine is the key trace element required for thyroid hormonogenesis. The recommended dietary allowance (RDA) for iodine in a non-pregnant adult is 150 mcg/day, while that in a pregnant female is 200 mcg/day. Iodine content in food and water depends critically on the iodine content of the soil. Soil iodine content is increased by plants that concentrate iodine, colloids that absorb iodine and by an acid pH, while it is decreased by repeated flooding and by an alkaline pH. Sea food and sea weed are rich sources of dietary iodine.

Iodide in the plasma is taken up via active transport into the thyroid follicular cells, a process which becomes more efficient in the iodine deficiency state. Iodine deficiency results in enlargement of the thyroid to enhance the ability of the glands to trap iodine. The term endemic goitre is used to describe goitre seen in a population with iodine deficiency. An area is defined to be endemic if more than 5% of children, between 6 to 12 years of age, are found to have goitre. The stages of goitre formation include an initial diffuse parenchymatous goitre, followed by diffuse colloid goitre, hyperplastic nodular goitre, nodular parenchymatous goitre and nodular colloid goitre. The first two stages are most likely to disappear after making region iodine replete, while later stages are unlikely to involute.

Other manifestations of iodine deficiency depend on the severity and age at exposure. Endemic cretinism is a state of severe congenital hypothyroidism occurring in an endemic area. Two clinical types are recognised: neurological cretinism characterised by mental retardation, abnormal speech and hearing, diplegia, and strabismus; myxoedematous type, characterised by prominent features of hypothyroidism, mental retardation and short stature. Learning disability has been described even in euthyroid children living in endemic areas. Exposure to iodine deficiency during pregnancy is also associated with abortions, stillbirths, increased foetal anomalies and perinatal mortality.

Magnitude of the Problem in India

Results of sample surveys conducted in 325 districts covering all the States/Union Territories revealed that 263 districts are endemic, where the prevalence of iodine deficiency disorders is more than 10%. It is estimated that more than 71 million persons are sufferring from goitre and other iodine deficiency disorders.

To address this public health problem, the Government of India, has implemented the National Iodine Deficiency Disorders Control Programme (NIDDCP) formerly known as National Goiter Control Programme (NGCP). This is a 100% centrally assisted programme with a focus on the provision of iodised salt, IDD survey/resurvey, laboratory monitoring of iodised salt and urinary iodine excretion, health education and publicity. Government of India has banned the sale of non iodated salt in the entire country for direct human consumption under Prevention of Food Adulteration Act (1954), with effect from 17th May, 2006.

For effective implementation of the programme at the State level, the Ministry of Health is providing financial assistance to all the States/UTs for establishment of an IDD Control Cell, and IDD Monitoring Laboratory, in addition to assistance for conducting surveys and health education and publicity for consumption of iodated salt by the population.

HYPERTHYROIDISM

Thyrotoxicosis is the hypermetabolic condition associated with elevated levels of free thyroxine (FT_4) and/or free triiodothyronine (FT_3). Hyperthyroidism includes diseases that are a subset of thyrotoxicosis, that are caused by excess synthesis and secretion of thyroid hormone by the thyroid.

The common causes of thyrotoxicosis are shown in **Table 1**. It is important to remember that all causes of hyperthyroidism, except iodine-induced hyperthyroidism, are associated with an increased radioactive iodine uptake (RAIU). Thyrotoxicosis without hyperthyroidism is not associated with an increased RAIU.

Table 1: Common Causes of Thyrotoxicosis

Conditions causing hyperthyroidism
Graves' disease
Toxic multinodular goitre
Toxic adenoma
Iodide-induced hyperthyroidism
Trophoblastic tumour
Increased TSH secretion: thyrotrophinoma
Conditions causing thyrotoxicosis not associated with hyperthyroidism*
Thyrotoxicosis factitia
Subacute thyroiditis
Post-partum thyroiditis
Chronic thyroiditis with transient toxicosis
Ectopic thyroid tissue (struma ovarii, functioning metastasis of Ca thyroid)

** These conditions are associated with decreased radioactive iodine uptake.*

Clinical Features

The common symptoms and signs of thyrotoxicosis can be explained on the basis of an increased metabolic rate and sympathetic activity (**Table 2**). The latter are observed despite no change in circulating levels of catecholamines and could result from a heightened sensitivity at the receptor level. The symptom profile depends on the severity and duration of thyrotoxicosis and the age of the patient. Patients commonly complain of weight loss despite an increased appetite, irritability, palpitation, tremors, increased sweating, hyperdefaecation, weakness and fatiguability.

Table 2: Common Symptoms and Signs of Thyrotoxicosis

System	Symptoms	Signs
CVS	Palpitation, dyspnoea	Tachycardia, atrial fibrillation, cardiac failure, wide pulse pressure
CNS	Restlessness, irritability, tremors, insomnia	Tremors, proximal muscle weakness, periodic paralysis
GIT	Increased appetite, hyperdefaecation	Exaggerated bowel sounds, pernicious anaemia
Eye	Foreign body sensation, prominence of eyes*, diplopia*, diminished vision*	Stare, lid lag, globe lag, proptosis*, extraocular muscle involvement*, exposure keratitis*, lagophthalmos*
Reproductive system	Short menstrual cycles, loss of libido	Gynaecomastia
Thyroid	Neck swelling	Goitre, bruit
General	Weight loss, weakness, heat intolerance, hyperpigmentation pruritus	Weight loss, warm and moist skin, onycholysis, palmar erythema

**Reported only in infiltrative ophthalmopathy in Graves' disease (and not routinely, in other causes of thyrotoxicosis).*

On examination, the common signs are: goitre, tachycardia, rhythm disturbances like atrial fibrillation, widened pulse pressure, warm and moist skin, bruit over thyroid, and eye signs. Hair and nails may be soft and friable. Eye signs common to all thyrotoxic states include: lid retraction (retraction of the upper eyelid with a rim of sclera visible between lid and limbus); lid lag, globe lag, and fine tremors of lightly closed eyelids. A typical thyrotoxic face is depicted in **Figure 1**. Proximal muscle wasting disproportionate to the weight loss, thyrotoxic myopathy, can be disabling. Untreated thyrotoxicosis can lead to osteoporosis. Menstrual disturbance, commonly hypo- or oligomenorrhoea or even amenorrhoea, and loss of libido, erectile dysfunction and gynaecomastia have been described.

Older patients may present with 'apathetic thyrotoxicosis' where typical adrenergic features are lacking and they may present instead with depression or apathy, weight loss, atrial fibrillation, worsening angina pectoris or congestive heart failure.

Diagnosis

Approach to the diagnosis of a patient with clinical suspicion of thyrotoxicosis is shown in **Figure 2**. Elevated serum total and FT_4 and suppressed TSH are seen in patients with thyrotoxicosis. Some patients may have normal T_4 and an isolated elevation of T_3, a state called T_3 toxicosis. As mentioned above, increased RAIU

Figure 1: Thyrotoxic facies.

is seen in all patients with hyperthyroidism except those with iodide-induced hyperthyroidism. On a thyroid scan in a hyperthyroid patient, uniform tracer distribution suggests Graves' disease, patchy distribution suggests toxic MNG and unifocal activity corresponding to a nodule, with suppression of the rest of the thyroid gland, suggests a toxic adenoma.

GRAVES' DISEASE

This is the most common cause of hyperthyroidism in iodine replete parts of the world and is characterised by the triad of diffuse toxic goitre, infiltrative ophthalmopathy and infiltrative dermopathy. It is a part of the spectrum of autoimmune thyroid disease which also includes Hashimoto's thyroiditis and atrophic thyroiditis. Peak presentation occurs in the 3rd and 4th decades, while the disease is rare in the first decade and in the elderly. While data from the Western world suggests a female: male ratio of 7-10:1, most reports from India describe only a 2- to 3-fold excess of female disease. The immunopathogenesis of Graves' disease involves the formation of autoantibodies which stimulate the TSH-receptor and can activate adenylate cyclase as TSH agonists. Evidence for genetic susceptibility to Graves' disease is provided by a high concordance rate in monozygotic twins and is possibly mediated through the HLA and CTLA-4 locus. It is currently believed that immune response directed against an antigen common to the thyroid and orbital tissue or skin can be responsible for ophthalmopathy and dermopathy respectively. Precipitation of autoimmunity may be caused by infection and stress, though this has never been unequivocally proven.

Clinical Features Specific to Graves' Disease

In addition to those common to all causes of thyrotoxicosis, certain clinical features are observed exclusively in Graves' disease due to its autoimmune aetiology.

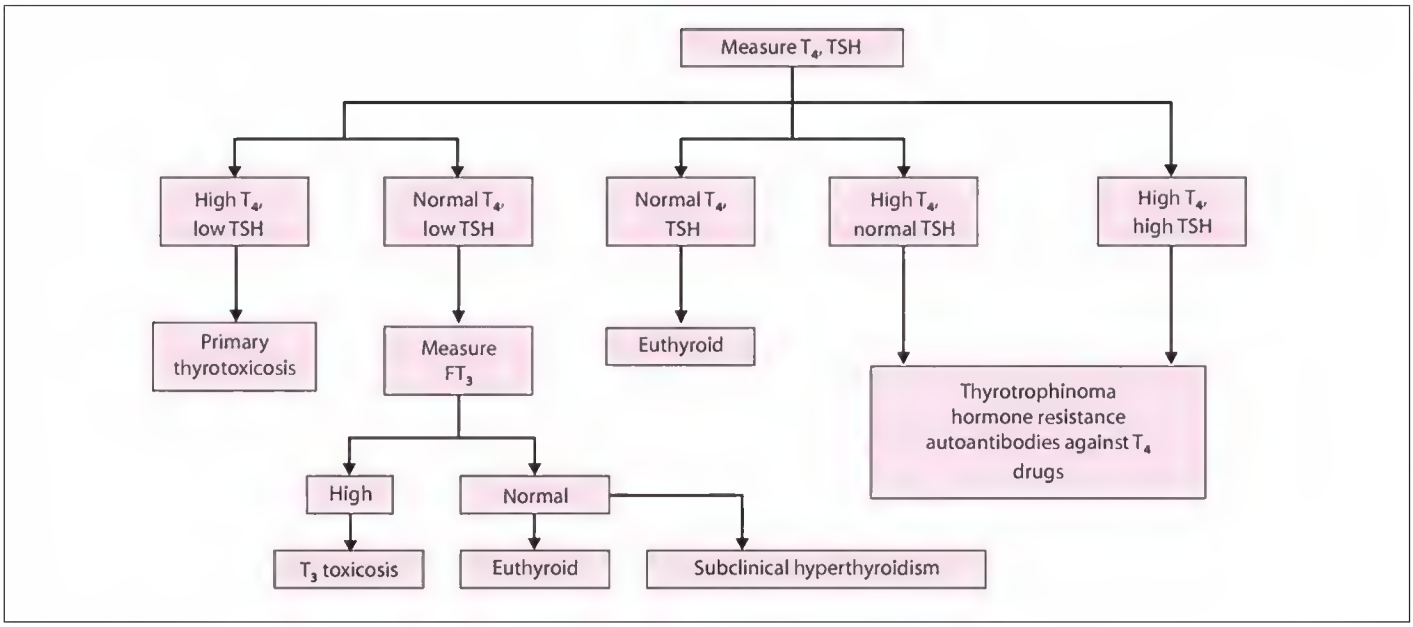

Figure 2: Approach to a patient with clinical features suggestive of thyrotoxicosis.

Coeliac disease and gastric achlorhydria may coexist with Graves' disease. Up to 3% patients may have pernicious anaemia. Myasthenia gravis may occur in approximately 1% of patients with Graves' disease, while 3% to 5% of patients with myasthenia may have Graves' disease.

Infiltrative ophthalmopathy

Extraocular and orbital adipose tissue are inflamed and swollen by the accumulation of glycosaminoglycans (GAGs) secreted by fibroblasts under influence of cytokines. Smoking is considered an important risk factor for development of ophthalmopathy in Graves' disease. Early symptoms include foreign body sensation, conjunctival congestion and periorbital swelling. Exophthalmos, which can be asymmetric, may prevent eyelid closure during sleep, a condition called lagophthalmos. Diplopia due to extraocular muscle involvement, corneal ulceration due to exposure keratitis and loss of vision are extreme manifestations. The American Thyroid Association has classified thyroid-associated ophthalmopathy (**Table 3**), which can be remembered by the mnemonic NOSPECS based on the first letter of each category.

Table 3: The NOSPECS Classification of Thyroid Associated Ophthalmopathy

Class	Description
N	No eye symptoms or signs
O	Only signs, no symptoms (upper eye lid retraction, stare, lid lag, proptosis <22 mm)
S	Soft tissue involvement (signs and symptoms)
P	Proptosis >22 mm
E	Extraocular muscle involvement
C	Corneal involvement
S	Sight loss (optic nerve involvement)

An overall activity score (0 to 7) is helpful in the follow-up of such patients and can be determined by assigning 1 point each for the presence of spontaneous retrobulbar pain, pain on eye movement, eyelid erythema, conjunctival injection, chemosis, swelling of the caruncle, or eyelid oedema or fullness.

Infiltrative dermopathy

This occurs in 5% to 10% of white patients with Graves' disease and is invariably accompanied by severe ophthalmopathy. It is rarely reported in Indian patients with Graves' disease. Lesions are non-pitting, indurated areas of skin on legs commonly on shins (pretibial myxoedema), but can occur at other sites, often as nodular lesions (**Figure 3**). Clubbing has been reported in long standing disease and is called thyroid acropachy. The hypermetabolic state leads to axial bone destruction, presumably secondary to enhanced osteoclast activity.

Figure 3: Severe dermopathy.

Laboratory investigations in Graves' disease

Like all causes of thyrotoxicosis, Graves' disease is associated with elevated T_4 and T_3 and suppressed TSH. Elevation of T_3 is proportionately to a greater extent than T_4. TPO antibodies are present in 80% patients. Thyroid scan will show a diffusely enlarged gland with uniformly increased radiotracer uptake. By definition, TSH-receptor autoantibody should be present in all patients, though they are not recommended for routine clinical use. CT or MRI of the orbits usually reveal thickening of extra-ocular muscles with sparing of tendons.

Treatment

Three main therapeutic modalities are available for the management of Graves' disease: medical therapy with antithyroid drugs; radioactive iodine ablation; and surgery.

Medical therapy

Thionamides (methimazole, carbimazole and propylthiouracil) are the preferred agents used for medical therapy. All these agents inhibit thyroid hormone synthesis, with the organification step being most sensitive to their action. In addition, propylthiouracil (PTU) also inhibits extrathyroidal conversion of T_4 to T_3. Carbimazole is entirely converted to methimazole (half-life is 6 hours), which is the active agent. The usual dose for carbimazole is 30 to 45 mg/day, initially given in three divided doses. Once euthyroid state is achieved, the dose can be gradually reduced to a maintenance dose of approximately 10 mg, which can be given as a single daily dose. PTU, due to a shorter duration of action (half-life is 1.5 hours), is given as a dose of 50 to 100 mg at 8 hourly intervals. If T_4 levels do not fall after 4 to 8 weeks, the dose should be increased. Later dose is adjusted to maintain T4 levels in normal range. There is no consensus about the duration of treatment which is usually given for 12 to 18 months. In addition to the titration regimen described above, an alternate regimen is the block-replacement regimen, which is currently not preferred because of a concern of increase in side effects.

The likelihood of long-term remission with a full course of antithyroidal agents is about 50%. Once a patient relapses, there is no advantage in repeating another full course of medical therapy because the chance of a relapse is nearly 100% in this situation.

Minor side effects including cutaneous reactions, arthralgia, and gastrointestinal adverse events, occur in approximately 5% of patients and tend to be mild or transient. Agranulocytosis is the most feared adverse effect requiring drug withdrawal. Recently, serious hepatic adverse effects including acute liver failure have been reported with propylthiouracil in children.

Current guidelines recommend that methimazole be used as the first line therapy in treatment of patients with hyperthyroidism and that the use of propylthiouracil should be reserved for individuals in the first trimester of pregnancy, patients with life-threatening thyrotoxicosis or thyroid storm and patients who have experienced adverse effects of methimazole (except agranulocytosis).

Other agents occasionally used to treat hyperthyroidism include lithium, which decreases thyroid hormones release. Dexamethasone, in a dose of 2 mg 6 hourly, inhibits secretion of hormone, T_3 neogenesis and has immunosuppressive effects. It has been used in patients with severe thyrotoxicosis or thyroid storm. Inorganic iodine (as in Lugol's solution or SSKI) acutely reduces the synthesis and release of T_4 and T_3, and also reduces the vascularity of thyroid gland. Iodine is used to prepare patient rapidly for surgery or as an adjunctive measure in patient with thyroid storm. Typical doses are Lugol's solution 3 to 5 drops tid and SSKI one drop tid. Iodine containing medications like sodium ipodate and iopanoic acid have also been used in those with side effects to thionamides.

Symptomatic therapy with beta-adrenergic antagonists is used to relieve symptoms like palpitations, tremors and anxiety. Propranolol (20 to 40 mg qid) or atenolol (25 to 50 mg OD) are the preferred agents.

Radioactive iodine ablation

Pregnancy should be excluded immediately before RAI therapy is planned in potentially fertile women. Thionamide therapy should be stopped at least 3 to 7 days prior to RAI therapy. In recent years, the trend is favouring a simple fixed dose regimen. Most patients with Graves' disease are treated with 5 to 10 mCi. These doses are effective in 90% to 95% of patients. Even with small doses of radioiodine, permanent hypothyroidism will occur in about 40% patients within 10 years. Pregnancy should be deferred for at least 6 months after I^{131} ablation. In patients with moderate to severe Graves' ophthalmopathy, RAI therapy may worsen the eye disease and thus shall be avoided. If RAI therapy is used in such patients, they should stop smoking and receive a course of oral corticosteroids immediately after the radioiodine treatment.

Surgery

Surgery is usually preferred in patients with very large goitre causing compressive symptoms or patients with significant eye involvement, or in those having severe adverse reaction to antithyroid drugs. Surgery is also indicated if there are suspicious or proven malignant nodules. Patients should be euthyroid before surgery to decrease the risk of arrhythmias during induction of anaesthesia and risk of post-operative thyroid storm. The surgical procedure of choice is bilateral subtotal thyroidectomy taking care to avoid potential complications, hypoparathyroidism and recurrent laryngeal nerve injury and bleeding into the operative site.

OTHER CAUSES OF THYROTOXICOSIS

Two other important causes, in addition to Graves' disease, are toxic MNG and toxic adenoma.

Toxic Multinodular Goitre (MNG)

Toxic MNG is usually reported in a person with a long-standing MNG, in which one or more nodules become functionally autonomous. It usually occurs in older individuals, 4th-5th decade, and in addition to the usual features of thyrotoxicosis may also have obstructive symptoms due to a large goitre. Further, cardiovascular manifestations may be prominent because of the older age of patients. Patients with mild toxic MNG are also at risk for developing iodine-induced thyrotoxicosis (Jod-Basedow effect) after exposure to intravenous contrast or treatment with amiodarone.

Radioisotope scans show a combination of hyper- and hypofunctioning areas. Medical therapy should be used to attain euthyroidism following which either radioiodine ablation (25 to 30 mCi) or surgery should be performed as definitive therapy.

Toxic Adenoma

The disorder is usually caused by a benign single adenoma that is palpable as a solitary nodule and hence is sometimes referred to as *hyperfunctioning solitary nodule* or *toxic nodule*. The basic pathogenesis of a large fraction of these tumours, is one of several somatic point mutations in the TSHR gene, commonly in the third transmembrane loop. This condition occurs in a younger age group than does toxic multinodular goitre, typically in patients in their 30s or 40s.

Patients develop features of thyrotoxicosis only when the adenoma achieves a diameter of 2.5-3 cm. Radioisotope scan shows a hyperfunctioning 'hot' nodule, with suppression of the remainder of the gland. Radioiodine ablation of the adenoma is the treatment of choice, since usually the remaining thyroid tissue does not take up radioiodine. Larger adenomas may require surgery.

Figure 4 provides the approach to making an aetiological diagnosis in a patient with thyrotoxicosis.

Thyroid Storm (Thyrotoxic Crisis)

Thyroid storm is a life-threatening condition, with features of severe thyrotoxicosis, including fever (38.5°C), tachycardia out of proportion to the fever, confusion, agitation, nausea and vomiting, hypertension, congestive cardiac failure, increased transaminases, with biochemical evidence of thyrotoxicosis.

It is unusual for untreated hyperthyroidism to present as thyroid storm, as there are usually precipitating events such as surgery, sepsis, burns injury, cardiovascular accident, parturition, status epilepticus, I^{131} treatment.

The treatment principles are to decrease the production and release of thyroid hormones, to block the effects of circulating T_4 and T_3, to deal with the underlying precipitants, and to provide general support.

Large doses of antithyroid drug (PTU 300 to 400 mg every 4 hourly) are given by mouth, by nasogastric tube, or if necessary, per rectum. PTU is preferred to methimazole due to its additional effect of inhibiting the peripheral conversion of T4 to T_3. SSKI (5 drops every 6 hours), ipodate (500 mg twice daily) or Lugol's solution (3 to 5 drops tid) acutely retard the release of hormone from the thyroid gland.

If patients are allergic to iodine, lithium carbonate (300 mg every 6 hours, with twice daily lithium levels checked until a therapeutic dose of 1 mmol/l is attained) can be used instead. Intravenous steroid will also block the conversion of T_4 to T_3 and so dexamethasone 4 mg four times daily intravenous (or hydrocortisone 100 mg four times daily) is recommended. If there are no contraindications to beta-blockers, then the choice is propranolol 80 mg three times daily (orally or via nasogastric tube), or 1mg/min intravenously. If beta-blockers are contra-indicated, the possible alternatives would include calcium channel blockers or digoxin.

Supportive measures include correction of dehydration and hypernatraemia, if present, and administration of glucose. Salicylates should be avoided and hyperpyrexia should be managed with paracetamol, cold sponging, fans or ice packs.

SUBCLINICAL HYPERTHYROIDISM

Subclinical hyperthyroidism is a condition of chronically suppressed serum TSH levels and normal levels of circulating free thyroid hormone. Subclinical hyperthyroidism may accelerate bone loss in postmenopausal women and is associated with a higher incidence of atrial arrhythmia including atrial fibrillation in elderly patients. It can occur either because of excessive supplementation with thyroxine or because of evolving thyrotoxic state. Treatment by titrating thyroxine therapy should be done to ensure that serum TSH remains in the mid-normal range. In endogenous causes of subclinical hyperthyroidism, therapy should be planned if a resultant tissue effect is evident, such as a low bone mineral density or arrhythmias. In other situations, patients can be followed up to assess disease evolution before committing to any definitive therapy.

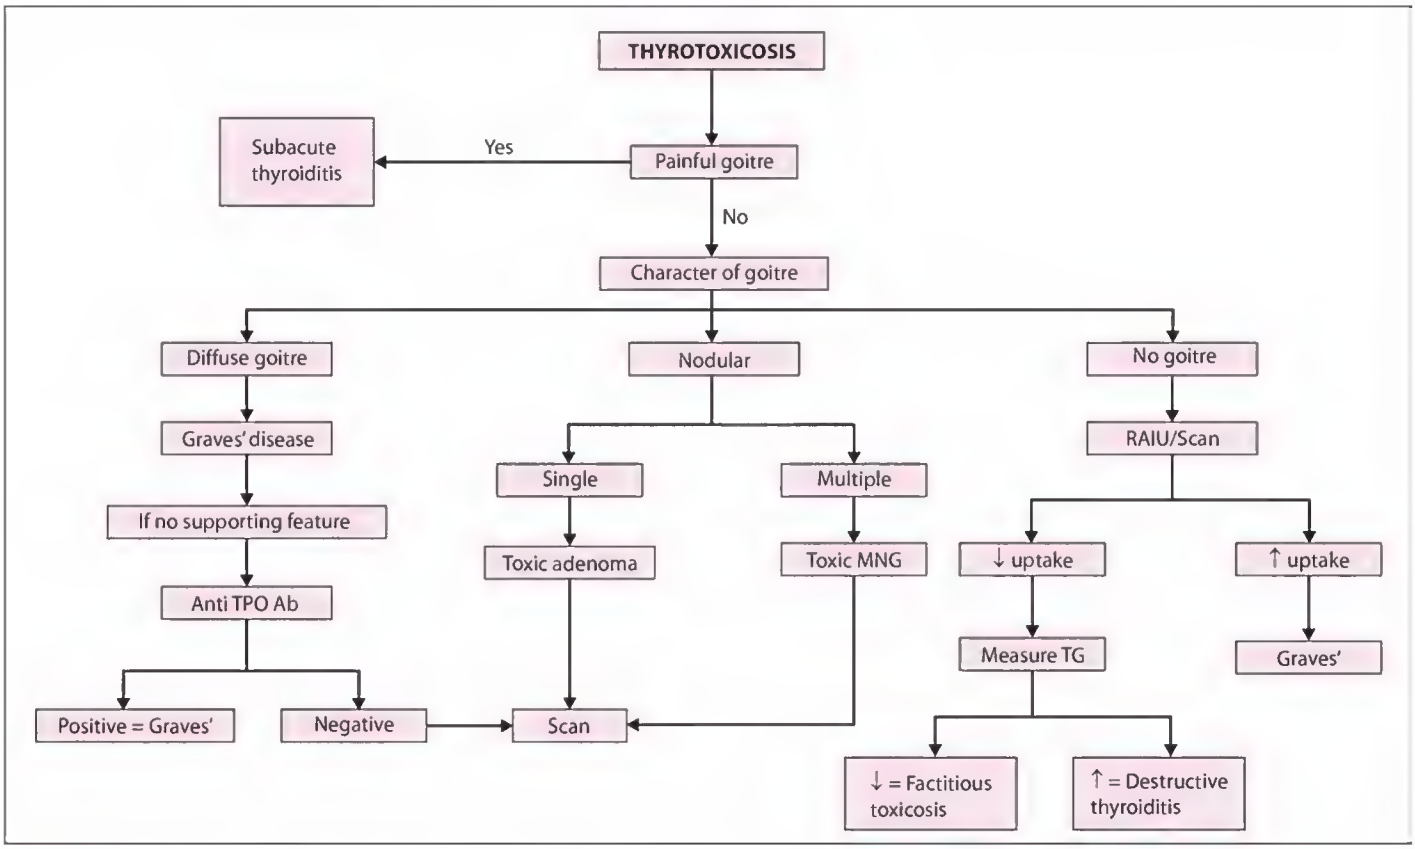

Figure 4 : Approach to establish aetiology in a patient with thyrotoxicosis.

HYPERTHYROIDISM IN PREGNANCY

If a subnormal serum TSH concentration is detected during gestation, hyperthyroidism must be distinguished from both normal physiology during pregnancy and hyperemesis gravidarum, which may also be associated with suppressed TSH with or without elevated serum FT_4 levels. Differentiation of Graves' disease from gestational thyrotoxicosis is supported by evidence of autoimmunity, a goitre, and presence of TSH receptor antibodies.

Rise in TBG levels during pregnancy, results in increase in total T4 levels. Therefore either free T_4 levels should be measured or one can use the normal (non-pregnant) range for the serum total T_4 concentration multiplied by 1.5.

Medical therapy with antithyroid drugs (ATDs) is advocated at the lowest possible dose to ensure a euthyroid state with FT_4 near the upper limit of normal. As methimazole may be associated with congenital anomalies propylthiouracil should be used as a first-line drug, especially during first-trimester organogenesis. TSH receptor-stimulating antibodies freely cross the placenta and can stimulate the foetal thyroid. These antibodies should be measured before pregnancy or by the end of the second trimester in mothers with current Graves' disease, or with a history of Graves' disease.

In women with elevated TRAb or in women treated with ATD, foetal heart rate monitoring, and assessment of foetal thyroid size by ultrasound should be performed to assess foetal thyroid status. Surgery is best avoided, but if it becomes essential it should be performed in the second trimester. Neither radioactive iodine ablation nor iodine/iodine-containing agents should be considered for therapy in pregnancy.

HYPOTHYROIDISM

Reduced production of thyroid hormone is the central feature of the clinical state termed *hypothyroidism*.

Primary hypothyroidism is due to disease of thyroid itself. It accounts for approximately 99% of cases, with < 1% being due to TSH deficiency known as central or secondary hypothyroidism. Primary hypothyroidism can be further subclassified depending on whether it is associated with goitre or an atrophic gland, and each of these entities can either be congenital or acquired in aetiology (**Table 4**).

Clinical Features

In adult hypothyroidism, clinical features can largely be explained by the reduced metabolic rate and deposition of glycosaminoglycans (GAG) in different body compartments. Symptoms of hypothyroidism develop gradually. The term myxoedema refers to the boggy appearance of the skin and subcutaneous tissues in the patients in a severe hypothyroid state. Peripheral manifestations of hypothyroidism are less manifest in patients with secondary hypothyroidism.

Skin is pale and cool, and reduction in sweat and sebaceous secretion causes dryness and coarseness. Capillary fragility causes easy bruisability. Scalp and body hair become dry and brittle and tend to fall. GAG deposition in the pharynx and larynx contributes to hoarseness of voice.

Cardiovascular involvement includes decreased cardiac output, narrowing of pulse pressure and increased systemic vascular resistance causing diastolic hypertension and decrease in exercise tolerance. Pericardial effusion may occur in severe primary hypothyroidism, while a small heart size is common in central hypothyroidism. ECG changes include sinus bradycardia and low voltage complexes with ST-T wave abnormalities. Cold intolerance occurs due to diminished blood supply and vasoconstriction. Pleural effusion and obstructive sleep apnoea may occur as well.

Table 4: Causes of Hypothyroidism

Primary hypothyroidism with goitre

Acquired
- Hashimoto's thyroiditis
- Iodine deficiency disorders
- Goitrogen exposure
- Antithyroid drug treatment

Congenital
- Iodide transport or utilisation defect
- Defects in thyroid hormonogenesis

Primary hypothyroidism with atrophic gland

Acquired
- Atrophic thyroiditis
- Post-ablative hypothyroidism (radioiodine therapy, surgery)

Congenital
- Thyroid agenesis
- Thyroid dysplasia

Transient primary hypothyroidism

After thyroiditis: silent, subacute or post-partum thyroiditis

Central hypothyroidism

Acquired
- Pituitary or hypothalamic disease, e.g. tumour, haemorrhage, granulomatous disease, hypophysitis

Congenital
- TSH deficiency or TSH receptor defects

Resistance to thyroid hormone action
- Generalised resistance to thyroid hormone action

Modest weight gain despite reduced appetite and constipation, due to reduced gut peristalsis, are common complaints. Myxoedema megacolon and myxoedema ileus are uncommon. Neuromuscular manifestation include slowed physical and mental functions, lethargy, somnolence, agitation ('myxoedema madness') or depression, deafness, carpal tunnel syndrome and 'hung-up' reflexes may also be present.

In adult women, hypothyroidism may be associated with diminished libido, failure of ovulation, polymenorrhoea, menorrhagia, and reduced fertility. In men, hypothyroidism may cause reduced libido, impotence and oligospermia. These disturbances in the reproductive system are often associated with hyperprolactinaemia (since prolactin is also under the control of TRH) and rarely can also be associated with pituitary enlargement due to thyrotroph hyperplasia. Energy metabolism is reduced leading to a decrease in appetite, cold intolerance, reduced protein synthesis and lipid accumulation (elevated TG and LDL-cholesterol).

A child with congenital hypothyroidism is sluggish and may present with prolonged physiological jaundice, meconium ileus, umbilical hernia, feeding difficulty, dry scaly skin and a large tongue. Unless diagnosed and treated early, irreversible neurological impairment can occur. Severe hypothyroidism in infancy is called cretinism.

During infancy, in addition to constipation, hoarse cry, and somnolence, there is delay in eruption of deciduous teeth and reaching physical and mental milestones. Persistence of untreated hypothyroidism will cause impaired linear growth, resulting in dwarfism and delay in closure of fontanelles. X-ray pelvis will reveal dysgenesis of femoral capital epiphysis, which is pathognomonic for hypothyroidism in infancy and childhood.

Clinical features of hypothyroidism beginning in childhood, juvenile hypothyroidism, are a combination of those seen in infantile and adult hypothyroidism. Retarded linear growth, delayed sexual maturation and poor intellectual performance are important.

Diagnosis

Plasma TSH is the best initial diagnostic test, and a normal value excludes primary hypothyroidism. Low T_4 with elevated TSH confirms the diagnosis of primary hypothyroidism, while normal T_4 with isolated elevation of TSH leads to the diagnosis of subclinical hypothyroidism. Individuals with subclinical hypothyroidism who have elevated anti-TPO antibodies are more likely to progress to overt hypothyroidism than antibody negative individuals.

Central hypothyroidism is characterised by a low T_4 and an inappropriately normal TSH. Evaluation for other pituitary hormone deficiency is recommended to confirm the diagnosis and guide therapy. Imaging to look for pituitary-hypothalamic disease using MRI should also be performed.

In severe non-thyroidal illness also, total plasma T_4 and T_3 are low. These may revert to within normal range in 3 to 6 months after recovery from illness.

ACQUIRED CAUSES OF PRIMARY HYPOTHYROIDISM

Hashimoto's Thyroiditis/Chronic Lymphocytic Thyroiditis

It is the most common cause of goitrous hypothyroidism in iodine sufficient parts of the world. It is more common in women. It is characterised by intrathyroidal lymphocytic infiltration with germinal centre formation, follicular damage or destruction and fibrosis. Goitre develops gradually, and is firm in consistency. Presence of anti-TPO antibodies and thyroglobulin autoantibodies favours the diagnosis. History of autoimmune endocrinopathies and other autoimmune diseases like rheumatoid arthritis should be ascertained in the individual and first degree relatives. Immunogenetic predisposition, exposure to excess iodine, therapy with interferon and pregnancy or post-partum state are known risk factors for Hashimoto's thyroiditis.

Iodine Deficiency Disorders

(Already Discussed)

Primary Idiopathic Hypothyroidism

Several authors use the term autoimmune thyroiditis to include the goitrous (Hashimoto's thyroiditis) and non-goitrous variants (primary idiopathic hypothyroidism/atrophic thyroiditis). The lack of goitre in atrophic thyroiditis is attributed to antibodies that block the action of TSH. Clinical manifestations are the same as for Hashimoto's thyroiditis except for the absence of goitre.

Post-ablative Hypothyroidism

Hypothyroidism after thyroidectomy depends on the extent of the surgery. The incidence is 100% after total/near total thyroidectomy for cancer but can also occur with less complete forms of thyroidectomy depending on the amount of tissue left behind. Hypothyroidism after destruction of thyroid tissue with radioiodine is common and is the one established disadvantage of this form of treatment for hyperthyroidism in adults. Its frequency is determined, in large part, by the dose of radioiodine. The incidence of post-radioiodine hypothyroidism increases with time. Even when doses are calculated to render a patient euthyroid, approximately 10% of patients are hypothyroid at the end of the first year and a further 2% to 3% become hypothyroid every year, over the next decade.

Drugs

Lithium and amiodarone are commonly used drugs which are associated with hypothyroidism.

CONGENITAL CAUSES OF PRIMARY HYPOTHYROIDISM

In addition to thyroid agenesis or dysplasia, iodide transport defects (NIS or pendrin mutations) and defects in thyroid hormone genesis can cause goitrous primary hypothyroidism. Pendred's syndrome is characterised by sensorineural hearing loss.

Therapy

Since primary hypothyroidism inevitably requires life long replacement therapy, it is advisable to reconfirm the diagnosis by repeating thyroid function tests, if the clinical features are equivocal, before starting therapy.

Adults

Levothyroxine is the drug of choice and most adult patients require a daily dose of 75 to 150 µg (1.7 µg/kg/day). The initial dose depends on the degree of hypothyroidism, age and general health status of the patient. Therapy in young healthy subjects can be initiated with the full dose. In elderly patients, average replacement dose is slightly lower and treatment should be started with a small initial dose. The recommended starting dose in the elderly is 25 µg/day, which is then increased by 12.5 to 25 µg at monthly intervals. In pregnancy, thyroxine requirement increases by 25 to 50%. If any patient is requiring a dose >150 µg/day, compliance should be assessed. The dose should be given as a single dose, on an empty stomach, in the morning. Absorption of thyroxine is hampered by iron preparations and antacids containing aluminium and these preparations should not be given at the same time as thyroxine. Aim of treatment is to keep TSH in the mid-normal range. Keeping in mind the time required by the pituitary-thyroid axis to reset, TSH should be measured no sooner than 6 to 8 weeks after initiating therapy or making a dose change. Once an individual becomes euthyroid on a stable dose of thyroxine, an annual TSH is adequate for monitoring. Over treatment, as indicated by suppressed TSH levels, should be avoided due to risk of osteoporosis and atrial fibrillation.

Subclinical hypothyroidism may be treated if any of the following are present: goitre, high titres of anti-TPO antibodies or pregnancy. In the absence of these findings, patients may be kept under follow-up, with repeat thyroid function tests at 6 monthly intervals to look for progression to overt hypothyroidism.

Infants and children

A dose of approximately 50 µg/day, is advocated in congenital hypothyroidism with the aim of maintaining T_4 levels at about

10 µg/dL. The pituitary feedback mechanism matures at 2 years of age, and the target of therapy then can be normal TSH level.

Secondary hypothyroidism: Since corticotroph failure may co-exist, glucocorticoid replacement must be initiated before starting T_4 therapy. Monitoring is with serum T_4 levels.

Myxoedema Coma

Myxoedema coma is the ultimate stage of severe long-standing untreated hypothyroidism, most often in elderly subjects and frequently in cold winter months.

Myxoedema coma can be the first presentation of new hypothyroidism, often precipitated by infection, stroke, myocardial infarction, sedative drugs or exposure to cold. Treatment is initiated on the basis of clinical suspicion, especially in non-responsive patients with a history of hypothyroidism, although blood should be taken for thyroid function tests and cortisol first. Initially, the precipitating illness needs to be identified and treated and general supportive treatments instituted. Functional adrenal insufficiency should also be treated with intravenous hydrocortisone.

The important clinical features are altered sensorium (or coma), subnormal temperature, bradycardia, manifestations of severe myxoedema and hypotension. The core temperature must be checked using a low reading thermometer, as the mortality of this condition is related to the severity of the hypothermia.

If intravenous thyroxine is available, a single dose of 500 µg T_4 can replete the hormone pool and can be followed by 100 µg IV daily. Alternatively, 500 µg thyroxine can be administered through a nasogastric tube, followed by 100 to 200 µg/day. Glucocorticoid replacement with IV hydrocortisone (5 to 10 mg/hour) should also be given. No hypotonic fluids should be given. Respiratory support using ventilator may be required. No external heating should be done because it may cause cutaneous vasodilatation and increase the strain on the heart. Despite aggressive intensive care, a high mortality rate of up to 50% is reported.

THYROIDITIS

The term thyroiditis indicates inflammation of the thyroid gland. Causes of thyroiditis include chronic autoimmune (Hashimoto's) thyroiditis, subacute thyroiditis, postpartum thyroiditis, Riedel's thyroiditis, amiodarone-induced thyroiditis (all of the above conditions are painless) and also acute infectious thyroiditis, radiation thyroiditis and traumatic (e.g. surgery, palpation, FNAB), thyroiditis (all of which are painful).

Subacute Thyroiditis (de Quervain's Thyroiditis, Viral Thyroiditis, Granulomatous Giant Cell Thyroiditis)

It is most likely viral in origin. It commonly presents with neck pain, which may radiate to ear or mandible. Hoarseness, dysphagia and signs of thyrotoxicosis may be present. Patients may also complain systemic features like lassitude and weakness. Thyroid gland is very tender and firm. The characteristic feature on histopathological examination is a well developed follicular lesion that comprises of a central core of colloid, surrounded by multinucleate giant cells. On evaluation, ESR is usually high and RAIU is suppressed to extremely low levels (0 to 5%). Serum TSH is suppressed and serum T_4 and T_3 levels are high. This condition is nearly always self-limiting, but can pass through a transient hypothyroid phase before reverting to euthyroidism. Using propranolol 10 to 20 mg, orally 3 to 4 times daily, controls symptoms of thyrotoxicosis. NSAIDs can be used for pain relief, though severe cases may require glucocorticoid therapy.

Postpartum Thyroiditis

Postpartum thyroiditis is the occurrence of thyrotoxicosis, hypothyroidism, and/or thyrotoxicosis followed by hypothyroidism in the first postpartum year in women without overt thyroid disease before pregnancy.

It occurs in 8% to 10% of women in postpartum period and up to 30% of those who were anti-TPO antibody positive in pregnancy. The thyroid gland does not show fibrosis as in Hashimoto's thyroiditis or giant cell infiltration as in subacute thyroiditis. The condition is painless. These patients are very likely to experience a recurrence following a subsequent pregnancy. Course of this disease in majority is self-limiting. The clinical manifestations can include an initial thyrotoxic phase (3 to 6 months after delivery) followed by a hypothyroid phase lasting for a few months before returning to euthyroid state.

Symptomatic treatment with beta-blockers is needed in the toxic phase and thyroxine replacement in the hypothyroid phase. Reassessment of thyroid function tests should be performed after stopping thyroxine therapy, one year after delivery to check for return to the euthyroid state.

Women with a history of postpartum thyroiditis have increased risk of developing permanent primary hypothyroidism in the 5- to 10-year period following the episode of postpartum thyroiditis. An annual TSH level should be performed in these women.

Since hypothyroidism is a potentially reversible cause of depression, women with postpartum depression should be screened for hypothyroidism, even though there is limited evidence supporting an association between postpartum depression and postpartum thyroiditis.

Riedel's Thyroiditis

This rare cause of thyroiditis is characterised by fibrosis of the thyroid and adjacent structures and occurs primarily in middle aged women. Patients usually present with a stony hard, immobile goitre resulting in pressure symptoms due to compression of trachea, oesophagus and recurrent laryngeal nerve. The presence of eosinophils on fine needle aspiration specimens has been demonstrated histologically, suggesting a unique autoimmune response to fibrous tissue.

One-third of the patients have hypothyroidism. When symptoms of obstruction are present, surgical removal of gland is indicated.

Glucocorticoids have been used for treatment because they reduce inflammation. Tamoxifen, 20 mg twice daily, has been successful in some patients. The proposed mechanism of action is the induction of transforming growth factor beta (a potent inhibitor of fibroblast proliferation).

Non-Toxic Goitre

Simple, non-toxic or euthyroid goitre represents any thyroid gland enlargement that is not associated with either hyperthyroidism or hypothyroidism and which does not occur

due to inflammation or neoplasia. The diagnosis of euthyroid gland is based on palpation and imaging of thyroid gland or on evaluation of thyroid functions. Thyroid enlargement may be diffuse or multinodular or there may be a solitary nodule. Each nodule contains a collection of thyroid follicles. Larger nodules may develop a fibrous capsule by compressing surrounding parenchyma.

Most affected patients do not exhibit clinical symptoms and signs of thyroid dysfunction and usually seek medical attention for thyroid enlargement. Large goitre may cause symptoms of dysphagia, dysphonia, or hoarseness by compressing local structures like oesophagus, trachea, or the recurrent laryngeal nerve.

Suspicion of malignancy is higher if the nodule occurs in the very young or elderly, shows rapid progression in size, is hard in consistency, has restricted mobility, associated lymphadenopathy or hoarseness.

The incidence of multinodular goitre (MNG) is more common in women and increases with age. Most patients are asymptomatic and do not require any therapy. Intervention is required if hyperthyroidism results (toxic MNG) or an enlarging MNG causes pressure symptoms. Surgery is the best option for these situations. A dominant nodule in a MNG has the same biological behaviour and chance of harbouring a malignancy as a solitary thyroid nodule.

Investigations

Fine needle aspiration cytology

Fine needle aspiration cytology (FNAC) is the investigation of choice in nodular goitre. In case of an inconclusive aspiration, a repeat FNAC should be performed. If even that is inconclusive, an ultrasound-guided FNAC increases the likelihood of reaching a diagnosis. Multiple sites should be aspirated to improve the diagnostic yield. A satisfactory specimen contains at least five or six groups of 10 to 15 well-preserved cells.

Thyroid function tests

A suppressed TSH, with or without elevated T_4 is suggestive of an autonomously functioning nodule/s.

Radionuclide scan

A pertechnetate scan is often used to make a functional diagnosis of a nodular goitre. Nodule showing no uptake of radioactivity is called a 'cold' nodule, while that with an uptake similar to the rest of the thyroid is called a 'warm' nodule. Nodules which take up increased amount of radioactivity along with suppressed uptake in the rest of the gland are called 'hot' nodules. Initially it was considered that only 'cold' nodules harboured malignancy. However, current evidence suggests that all types of functional nodules can contain malignancy.

Ultrasound

This is a useful modality to differentiate solid from cystic nodules. A purely cystic nodule is unlikely to contain a neoplasm. However, most nodules have both a solid and a cystic component. Ultrasound can be used to guide the FNAC from the solid component of such nodules.

Management of a solitary thyroid nodule (Figure 5)

'Hot' nodules with a suppressed TSH should be treated with radioiodine ablation or with surgery if they are large in size. Other emerging treatment alternatives are percutaneous ethanol and laser treatment.

If FNAC is suggestive of a malignancy or is suspicious, patient should be managed surgically with appropriate follow-up. If the

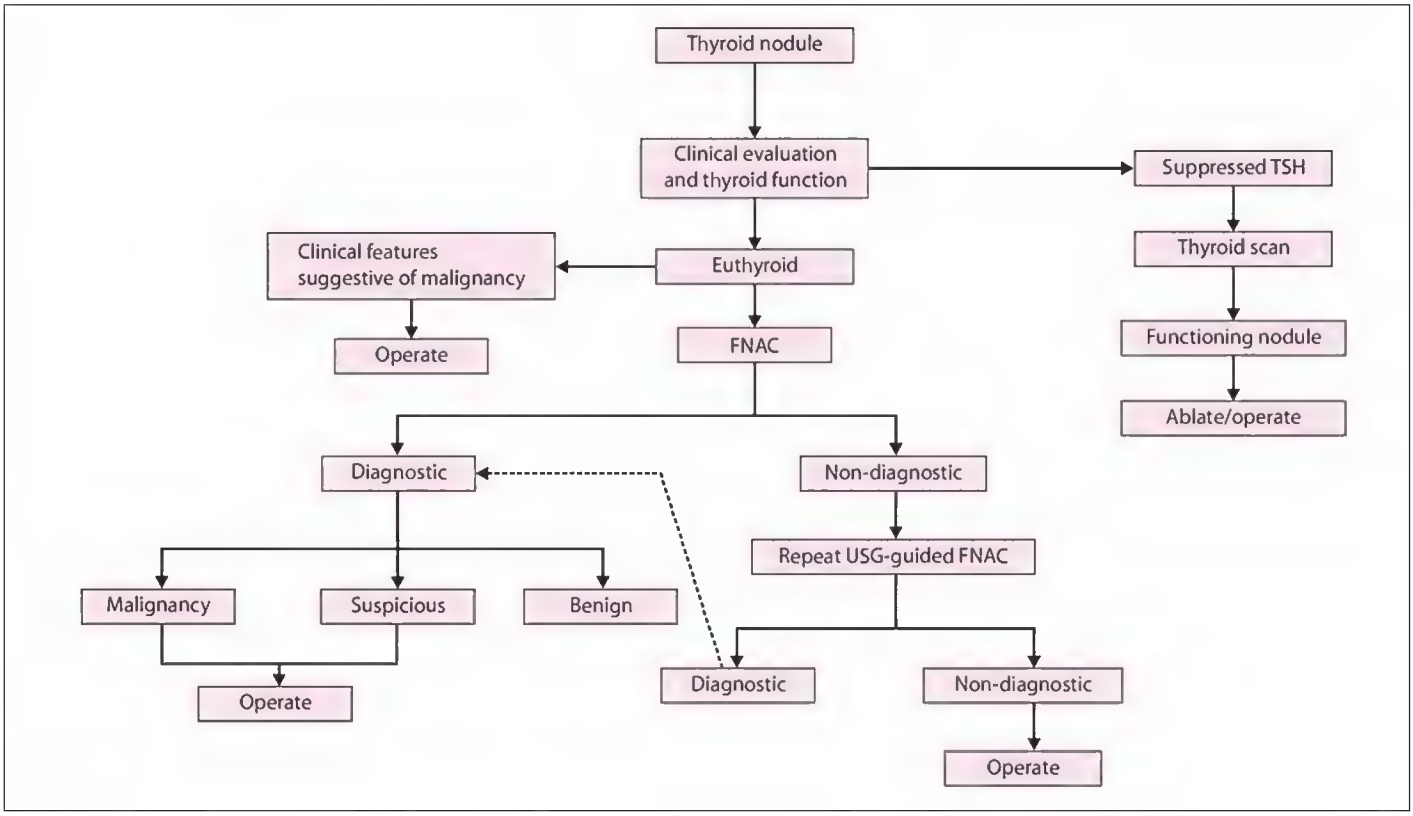

Figure 5: Approach to a patient with a solitary thyroid nodule.

FNAC suggests a benign disease, the patient can be followed up without any intervention. Suppressive regimens with levothyroxine have been tried with non-significant trend towards 50% reduction in nodule size. The disadvantage with this approach is the likelihood of causing subclinical thyrotoxicosis and its attendant complications.

Table 5: Classification of Thyroid Neoplasia

Primary epithelial tumours
- Tumours of follicular cells
  - Benign tumours: Follicular adenoma
  - Malignant tumours: Papillary carcinoma, follicular carcinoma, poorly differentiated cancer, undifferentiated cancer (anaplastic cancer)
- Tumours of C cells
  - Medullary thyroid cancer
- Mixed tumours
  - Mixed medullary–follicular cancer

Non-epithelial tumours
- Lymphomas
- Others

If FNAC is non-diagnostic, even after an ultrasound-guided aspirate, surgery is the preferred option.

Thyroid Neoplasia

Thyroid tumours are the most common endocrine neoplasm. Most of these are benign hyperplastic (or colloid) nodules or benign follicular adenomas but approximately 5% to 10% of these are carcinomas. The likelihood of malignancy is high if the lesion occurs in the young (<20 years) or elderly (>70 years), male, history of external neck radiation in childhood/adolescence, recent onset of compressive features and a family history of thyroid cancer. FNAC is the investigation of choice, as described in the section above. A classification of thyroid neoplasia is provided in **Table 5**.

10.7 Disorders of Parathyroid Glands

Ambrish Mithal, Beena Bansal

There are four parathyroid glands located posteromedial to the thyroid gland. The upper two glands develop from the fourth branchial arch, while the lower two develop from the third branchial arch, but migrate caudally with the thymus. Anomalies in migration may result in glands in ectopic positions, like the mediastinum.

There are two types of cells in parathyroid glands—chief cells, which secrete parathormone (PTH) and oxyphil cells, which are considered non-secretory.

PARATHORMONE

PTH is a single chain polypeptide with 84 amino acids. The principal role of PTH is tight regulation of extracellular calcium levels.

Parathyroid glands have calcium sensing receptors (CaSRs) on the cell membrane and vitamin D receptors in the nucleus. The parathyroid gland is exquisitely sensitive to calcium—it is said that that the chief cell can virtually 'sniff' calcium!

Point mutations associated with loss of function cause a syndrome, familial hypocalciuric hypercalcaemia (FHH). On the other hand, gain-of-function mutations cause autosomal dominant hypocalcaemia hypercalciuria (ADHH).

Low calcium and low vitamin D will stimulate PTH synthesis, secretion and also increase number of chief cells. Prolonged hypocalcaemia and hypovitaminosis D can therefore lead to secondary hyperparathyroidism and enlarged parathyroid glands.

PTH ACTIONS

PTH acts through cell surface receptors PTH1R and PTH2R. PTH1R is the classic PTH receptor expressed in bone and kidney.

Bone

(a) PTH releases calcium from bone and increases remodelling.
   i. It acts directly on the osteoblasts through its receptors. The action on osteoclasts is indirect (through cytokine release from osteoblasts which then stimulate osteoclasts).
   ii. Continuous exposure to PTH (as in hyper-parathyroidism) increases osteoclast mediated bone resorption leading to osteoporosis. On the other hand, intermittent exposure to PTH increases net bone formation and therefore synthetic PTH (1-34) called teriparatide is given for treating osteoporosis.

Kidneys

(a) PTH increases calcium reabsorption in renal tubules and increases phosphorus excretion.

(b) It stimulates 1-α hydroxylase which converts 25(OH) vitamin D to active $1,25(OH)_2$ vitamin D, which in turn stimulates calcium absorption from the gut.

PRIMARY HYPERPARATHYROIDISM

This is a disorder characterised by increased PTH secretion by the gland. The causes are outlined in **Table 1**.

Table 1: Causes of Primary Hyperparathyroidism

Adenomas
- Solitary
- Multiple
  - Isolated
  - Part of hereditary syndromes
    - MEN-1
    - MEN-2A
    - Hyperparathyroidism-jaw tumour syndrome (HPT-JT)

Chief cell hyperplasia

Clinical Features

The effects of primary hyperparathyroidism are mainly seen on bone and kidneys. *Typically, in India, the disease very much resembles the description by Fuller Albright in 1930s—a disease of 'bones, stones and groans'. This is thought to be related to the widespread vitamin D deficiency in Indians. Some form of bone involvement is seen in 80% to 100% of cases in India.* Patients present with bone pains, skeletal deformities and pathologic fractures. The distinctive bone manifestation othef primary hyperparathyroidism seen in 50% to 90% of Indian patients is brown tumours (on radiograph) or osteitis fibrosa cystica (histologically). Clinically palpable bony swellings may be present. On histopathology, the pathognomonic features are increase in giant multinucleated osteoclasts in scalloped areas on the bone surface (Howship's lacunae) and a replacement of the normal cellular and marrow elements by fibrous tissue. Other radiological findings include subperiosteal resorption of phalanges and salt and pepper appearance of the skull.

Kidney involvement, due to deposition of calcium in renal parenchyma (nephrocalcinosis) is seen in 5% to 10% cases and recurrent nephrolithiasis in 10% to 40% of Indian patients.

Proximal muscle weakness and atrophy of muscles may be so striking as to suggest a primary neuromuscular disorder.

The patient who suffers a combination of severe bone disease and profound myopathy can be rendered immobile and has been referred to as a 'parathyroid cripple'.

Neuropsychiatric manifestations, mild gastrointestinal symptoms, pancreatitis, chondrocalcinosis, pseudogout, pancreatitis and hypertension are associated with primary hyperparathyroidism.

Rarely, the patient may present in hypercalcaemic crisis. The symptoms are general malaise, anorexia, polyuria, thirst, vomiting, constipation, abdominal pain, depression, confusion, progressing to stupor and coma.

In the West (North America and Europe), the majority of patients with hyperparathyroidism are asymptomatic and diagnosed during routine biochemical screening. Such cases are now increasingly seen in India as well.

Diagnosis

In a patient with hypercalcaemia, the diagnosis is established by demonstrating elevated PTH levels. With the exception of lithium, thiazide use and familial hypocalciuric hypercalcaemia (FHH), virtually all other causes of hypercalcaemia are associated with suppressed PTH (**Table 2**).

Table 2: Differential Diagnosis of Hypercalcaemia

High PTH
- Primary hyperparathyroidism
- Lithium therapy
- Familial hypocalciuric hypercalcaemia

Hypercalcaemia of malignancy
- Local osteolytic hypercalcaemia
  - Multiple myeloma
  - Breast cancer
- Humoral hypercalcaemia of malignancy

High vitamin D levels
- Vitamin D intoxication
- Increased $1,25(OH)_2D$: sarcoidosis and other granulomatous diseases
- Idiopathic hypercalcaemia of infancy

High bone turnover
- Hyperthyroidism
- Immobilisation
- Thiazides
- Vitamin A intoxication

Renal failure
- Severe secondary hyperparathyroidism
- Aluminium intoxication
- Milk-alkali syndrome

Management

Management of hypercalcaemic crisis

If a patient presents with hypercalcaemic crisis, immediate management of hypercalcaemia followed by definitive treatment of hyperparathyroidism is needed.

1. *Hydration, increased salt intake, mild and forced diuresis:*

   Many hypercalcaemic patients are dehydrated because of vomiting, and/or hypercalcaemia induced polyuria. The first principle of treatment is to restore normal hydration. Calcium levels start decreasing within hours.

   Under life-threatening circumstances, up to 6 litres of isotonic saline plus frusemide in doses up to 100 mg every 1 to 2 hours may be required. Careful monitoring of central venous pressure and serum electrolytes should be done.

2. *Bisphosphonates:*

   IV pamidronate 30 to 90 mg or zolendronate 4 to 8 mg reduces calcium levels over 24 to 48 hours. Flu like reactions are common. Rarely, these drugs can precipitate renal dysfunction, so proper hydration is essential.

Management of symptomatic primary hyperparathyroidism

Parathyroidectomy is the treatment of choice in all symptomatic cases after preoperative localisation by ^{99m}Tc-sestamibi scintigraphy or ultrasonography.

Postoperative management: Serum calcium declines within 24 hours after successful surgery. Acute postoperative hypocalcaemia is seen if:

- Severe bone disease is present preoperatively
- The patient is vitamin D deficient
- There is associated hypomagnesaemia
- There is injury to all the parathyroid glands or their blood supply during surgery.

Parenteral calcium replacement is indicated if:

- There are signs of hypocalcaemia; or
- Serum calcium is less than 8 mg/dL

An infusion of 0.5 to 2 mg/kg/h of 1 mg/mL solution of calcium gluconate in dextrose (not saline) usually suffices to relieve symptoms.

Magnesium deficiency impairs the secretion of PTH, so hypomagnesemia should be corrected whenever detected.

Management of asymptomatic primary hyperparathyroidism

The National Institutes of Health (NIH) sponsored Third Workshop in 2009 recommends surgery only if significant hypercalcaemia, renal dysfunction or osteoporosis is present (**Table 3**). It is also recommended in young individuals and in whom medical surveillance would be difficult. All other cases should be appropriately monitored (**Table 4**).

Table 3: Guidelines for Parathyroid Surgery in Asymptomatic Primary Hyperparathyroidism (PHPT)

- Serum calcium 1 mg/dL above upper limit of normal
- Creatinine clearance <60 mL/min
- Bone mineral density T-score < -2.5 at any site and/or a previous fragility fracture
- Age <50 years
- Patients in whom medical surveillance is neither desired nor possible

Table 4: Asymptomatic Primary Hyperparathyroidism Patients Who Do Not Undergo Parathyroid Surgery

Asymptomatic patients should be monitored regularly:
- Serum calcium biannually
- Serum creatinine annually
- Bone density every 1 to 2 years (lumbar spine, hip, forearm)

Bisphosphonates can be given to individuals with PHPT for whom skeletal protection is the primary reason for intervention whereas the calcimimetic cinacalcet can be used to lower serum calcium and PTH levels during long-term therapy in PHPT.

HYPOPARATHYROIDISM

Hereditary or acquired hypoparathyroidism presents with chronic hypocalcaemia. The differential diagnosis of
